Abstract

Background: Suicide prevention is currently a national health priority in Canada. Emergency departments (EDs) are critical settings for suicide prevention, and in our local psychiatric ED at the Centre for Addiction and Mental Health, we plan to embed an app-based tool called the Hope app to support suicide safety planning intervention. The app is free and available on app stores, and usability tests have been completed. As a next step to embed this new tool into the routine clinical workflow, research is needed to assess determinants of and design strategies for implementation with the end goal of routinization.

Objective: The purpose of this 2-phased research is to implement the app in the routine clinical workflow in our local psychiatric ED. The specific objectives are as follows: (1) understanding ED clinicians' perceptions and experience of implementing the app in routine practice and identifying barriers to and facilitators of implementation (phase 1) and (2) using findings and outputs from phase 1 and collaborating with service users, families, and ED clinicians to co-design implementation strategies for the app (phase 2).

Methods: We will use an integrated knowledge translation approach throughout this project. In phase 1, we will conduct interviews with ED clinicians to identify implementation determinants using a behavior change framework. In phase 2, a co-design team comprising clinicians, ED service users, and families will design implementation strategies that align with the determinants identified in phase 1.

Results: This protocol presents detailed information about the entire structure of the 2-phased research project. Ethics approval for conducting the qualitative descriptive study (phase 1) has been obtained, and the recruitment and data collection processes will be completed no later than December 2023. Ethics approval for phase 2 is underway.

Conclusions: Involving multiple knowledge user groups early in the research and decision-making process is crucial for successful implementation. Although co-designing is commonly practiced during innovation development, there is often a misconception that the responsibility for implementing what has been designed falls on others. This research aims to fill this methodological gap in the health informatics literature. By the end of this project, we will have developed theory-informed implementation strategies to support Centre for Addiction and Mental Health ED clinicians in adopting the Hope app to complete safety planning intervention. These strategies, guided by a behavior change framework, will target clinicians' behavior change and seamlessly integrate the app into the routine clinical workflow. In addition, this research project will provide recommendations

XSL•FO

on how to involve multiple knowledge user groups and offer insights into how the methodology used can be adapted to other areas within the health informatics literature.

Introduction

Background

Suicide is currently the second leading cause of death among youth in Canada [1]. Emergency departments (EDs) are critical settings for suicide prevention for many reasons [2]. First, individuals, both adult and pediatric patients, requiring mental health services visit EDs more frequently than those who do not [3-5]. Second, EDs frequently provide care to individuals who attempt suicide and are often the first point of contact for individuals who experience suicidal crises [2,6,7]. Third, when looking at service use patterns for people who died by suicide, many of them were already in contact with health services, including EDs [8-10]. For example, a Canadian study published in 2014 examined 8851 suicide deaths in Quebec and found that one-third of these individuals had visited an ED within the month before death [9]. Finally, some individuals living with suicide-related thoughts and behaviors seek help in the ED as a last resort [11,12]. Although this indicates a promising fact that individuals are continuing to seek help, suicide risk may not always be obvious, recognized, or addressed [13-18]. As such, there is a critical need for research to bridge the evidence-to-practice gap in suicide prevention practices within ED settings, and EDs present a critical window of opportunity for identifying and providing care to patients at risk of suicide.

Currently, safety planning intervention (SPI) [19] is one of the best available practices for suicide prevention [20,21]. There is an evidence base (ie, systematic reviews) to support the effectiveness of SPI in reducing suicidal behaviors [20,21]. For example, SPI has been shown to decrease suicidal behaviors by up to 45% [22]. SPI is a collaborative process between clinicians and patients for developing a plan regarding coping strategies, emergency contacts, and restriction of lethal means [19]. SPI is traditionally delivered pen-on-paper, which limits portability. Patients report trouble locating or losing the paper safety plan [23,24], which can be a dire challenge during crises as SPI cannot generate its intended benefit given that it is not available *at hand*. Studies have shown that mobile phones as an intervention modality are acceptable, feasible, and useful for mental health patients [25-27], including those managing suicide-related thoughts and behaviors [28,29]. Moreover, the use of apps and various forms of information and communications technologies (ICTs) has the potential to enhance suicide prevention efforts through the elimination of geographical limitations while also increasing the accessibility and availability of evidence-based interventions [30].

At the Centre for Addiction and Mental Health (CAMH) in Canada, a research team collaborated with clinicians and patient partners and developed an app-based tool for SPI called the Hope app by CAMH [31]. In 2019, at the Innovation Expo held at CAMH, the Hope app was introduced as an innovative solution [32,33]. The idea for the app was presented by an individual with lived experience who had cared for a family member who had attempted suicide [32,33]. The Hope app has several strengths, with its primary advantage being its accessibility “at hand” for individuals living with suicide-related thoughts and behaviors. The idea of having a suicide prevention tool readily available was the main reason behind its recognition at the Innovation Expo [32,33]. In addition, the app provides other valuable resources, including the ability to email the safety plan. It is well documented in the literature that friends and families play a significant role in helping individuals who are seeking assistance when dealing with suicidal thoughts and behaviors [34-39]. As suicide-related symptoms worsen and suicidal thoughts and behaviors become more frequent, friends, families, or other trusted individuals can offer emotional support and encourage professional help if necessary [34-39]. The Hope app’s feature of sending a safety plan is a valuable tool for patients to inform their close social network.

The Hope app is free on app stores and is compatible with Android and Apple phones. A usability test of the app was completed at the CAMH, and a total of 54 REDCap (Research Electronic Data Capture; Vanderbilt University) surveys were administered [40]. Among the respondents, 57% found wellness activity content in the app, such as grounding techniques, to be the most frequently used, and 67% reported that the app increased their knowledge of safety planning [40]. Second, a total of 10 usability participants were recruited, and the research team administered the System Usability Scale, a validated 10-item questionnaire [41]. This yielded an overall usability score of 88.2 out of 100, with higher scores indicating better usability [40]. To better understand users’ perspectives, 18 interviews were conducted [40]. It was found that the app was helpful in prompting self-reflection, which made the safety planning process easy [40]. For instance, the paper-based safety plan used at the CAMH requires patients to provide their own answers for coping strategies, whereas in the app, users are presented with potential strategies and can choose relevant ones or add text if the provided options do not align with their needs. In addition, interview participants reported that the app is a useful tool to accompany mental health appointments [40]. Finally, user feedback was obtained from a public avenue at the Apple App Store “Ratings and Reviews” section [42]. As a next step, theory-informed research is needed to develop

XSL•FO
RenderX

implementation strategies to ensure the successful delivery of the Hope app to patients who are at risk of suicide.

Implementation in health services research is about promoting the systematic uptake of evidence-based practices into routine care [43-45]. The systematic uptake of evidence-based practices is dependent on the behaviors of individuals who are involved in health services, including clinicians [46,47]. Although changing behavior is challenging, it is most effectively achieved when behavior change strategies are informed by evidence-based principles and theories of behavior change [48-50]. New innovations or ICTs such as the Hope app do not implement themselves. Implementation requires "organizational effort directed toward diffusing [ICTs] within a user community," with the end goal of routinization [51]. Implementation efforts may include training, making changes in the clinical settings and workflow, providing technical support, or clarifying professional responsibility related to an innovation, all of which are determinants of behavior change influencing one's knowledge, motivation, and opportunity [52]. The organizational decision to adopt the Hope app was based on existing evidence of SPI effectiveness and the organization's priority goal for suicide prevention. As mentioned previously, there are existing systematic reviews supporting the effectiveness of SPI in reducing suicide behaviors [20,21]. Although ICT-based interventions for suicide prevention are still in their early stages, they show promise. For instance, a meta-analysis of these interventions demonstrated a small but significant efficacy in reducing suicide ideation [53]. However, one could argue that, owing to the limited clinical integration of apps [54], the current literature lacks evidence to support the effectiveness of SPI *when* it is delivered via an app (ie, changing the mode of delivery) [55]. This question of concern falls beyond the scope of our study and is an area for future investigation. Nonetheless, the findings from our study can inform the feasibility of conducting a larger experimental design to assess the effectiveness of the Hope app and facilitate its initial integration into routine clinical practice.

EDs are a critical setting for suicide prevention [56], which makes them a priority setting for the implementation of the Hope app. Implementation occurs after organizations make decisions to adopt a new innovation [51], and the end goal of implementation—routinization—involves changing clinicians' behavior [49]. Given the organizational-level decision at the CAMH to adopt the Hope app, this proposed research will concentrate on the subsequent stages of implementation; these stages include adaptation, acceptance, and routinization [51], primarily focusing on changing clinicians' behavior. Adaptation is about developing and revising departmental procedures, such as making changes to the workflow or training staff for new ICTs [51]. Acceptance is about promoting staff's commitments to using new ICTs, and finally, routinization means integrating new ICTs into a normal workflow [51].

Problem and Rationale for This Study

To date, research on mental health apps lacks rigorous implementation and a theoretical basis [54]. In addition, a recent call was made for research to consider the complex contexts in which apps are being implemented to tailor implementation efforts [57]. Without a careful investigation of the context, implementation strategies have often been mismatched with existing barriers in a given context [58,59]. As a prior work for this study, Shin et al [52] conducted a scoping review of ICTs (eg, apps) for suicide prevention that have been implemented in clinical settings and identified that barriers and facilitators collectively influence clinicians' capability, opportunity, and motivation to implement innovations. Therefore, implementation strategies must be tailored and multifaceted to simultaneously target these determinants of behavior change to maximize implementation [60]. However, most of the reported implementation strategies focus on improving knowledge and building skills (ie, capability) without addressing clinicians' motivation and opportunity [52]. The fact that implementation strategies are often developed nonsystematically and do not match contextual implementation determinants is a consistently reported gap in the literature [61].

Another concern with implementing a new innovation of this type is that not everyone owns or has access to a smartphone and unlimited internet or data or has digital literacy skills [62]. Inequities in accessing and using ICTs, as well as the associated outcomes of using ICTs, constitute a phenomenon called the digital divide [63]. There are three levels to the digital divide: (1) access to ICTs and necessary connections, (2) literacy to use these ICTs, and (3) capacity to convert the use of ICTs into outcomes [64]. The digital divide is rooted in social factors such as education, income, age, and place of residence [63,65,66]. To prevent digital divide amplification and avoid unintended harm, implementation strategies must be developed with digital equity considerations in mind [67]. This research is not sufficient to address the structural factors that perpetuate the digital divide but will consider its second and third levels. For example, we will adopt a set of recommendations made by Shaw et al [67] to promote digital health equity in the context of implementing ICTs in health care, such as supporting patients with low digital literacy, collaborating with service users, and providing alternatives (eg, traditional paper format of SPI and emailing electronic copies of safety plans). In addition, the interview guide and co-design session goals in this study include prompts related to digital equity.

Research Objectives

To implement the Hope app with digital equity considerations, this proposed research aims to leverage the integrated knowledge translation (IKT) approaches as well as implementation science frameworks to develop tailored implementation strategies in a psychiatric ED at the CAMH. This project has two main objectives with two corresponding phases, as follows:

1. Understand clinicians' perceptions and experiences of implementing the Hope app in routine practice in the psychiatric ED and identify barriers to and facilitators of implementation (phase 1)
2. Use the findings and outputs from phase 1 and engage with knowledge users to co-design implementation strategies for the Hope app (phase 2).

XSL•FO
RenderX

Methods

Theoretical Frameworks

There is evidence strongly suggesting that theory-informed strategies are more likely to be effective in changing behavior [48-50]. A combined use of theories, models, and frameworks is appropriate to meet the needs of researchers [68]. In this study, several frameworks will be used to address the research objectives.

One way to solve complex problems is to work with knowledge users [69] who will be delivering or receiving the Hope app. Knowledge users are people who will be using research findings to inform their decision on practice, policies, and programs, as well as people who will be affected by research findings and making informed decisions based on them [70]. As such, knowledge users include but are not limited to health care professionals, service users, and health care managers [70]. Collaborative research approaches such as IKT are perceived to be the best ways to produce relevant research outputs to address health care issues and generate a greater impact on practice [71,72]. Although co-designing is common for innovation development, people often think that implementing what has been designed is the responsibility of others [73]. This is not true; researchers can co-design changes in the workflow to support implementation [74].

IKT approaches will be used throughout this proposed research. Specifically, a medical head of the CAMH ED and a CAMH nursing chief clinical informatics officer are coauthors of this paper and members of the steering committee who will oversee the current project throughout phases 1 and 2, ensuring that the research objectives and outputs are relevant to the implementation setting. Securing leadership support for this project is an important facilitator for maintaining commitment to coproduction, as indicated in the IKT literature [71,75]. Patient partners (ie, ED service users) are also a critical knowledge user group, but they will not be part of the steering committee. However, we consulted the CAMH Lived Experience Advisory Group in February 2023. Feedback was received and has been incorporated into this protocol. Such feedback includes co-design team formulation, consensus-achieving activities, and strategies to mitigate dropout. In addition, patient partners and families or caregivers will be closely involved as co-designers in phase 2.

The Knowledge-to-Action (KTA) cycle [76] is a process model that outlines the steps and activities required to integrate a new innovation into practice [48]. We are using KTA to guide the overall research. Specifically, the research objectives have been guided by the KTA action phases leading to effective implementation. Not all stages of KTA will be addressed in this research, and this flexibility of KTA application is one strength that can fit researchers' needs. The objectives of this research will address the following 3 steps of KTA: adapt the identified knowledge or research to the local context; assess barriers to using the knowledge; and select, tailor, and implement interventions to promote the use of knowledge. A previous study addressed steps 1 and 2 of KTA, in which we used a scoping review methodology to explore the breadth of existing evidence on ICT-based interventions for suicide prevention and collated identified implementation characteristics [52]. This step was necessary to make sense of all the relevant knowledge and identify gaps that require new research. Phase 1 in this project will then address steps 3 and 4 using a qualitative design to investigate barriers and facilitators specific to our implementation setting. Phase 2 will then address step 5 selecting and tailoring implementation strategies using a co-design approach to address barriers and leverage the identified facilitators.

KTA outlines steps to translate knowledge into practice, but it does not inform how we can achieve these steps. Therefore, we will use the Behavior Change Wheel (BCW) [77] and the Theoretical Domains Framework (TDF) [78] to further guide this research. The BCW and TDF are comprehensive and evidence-based behavior change frameworks. The BCW was developed from a synthesis of 19 behavior change frameworks. The BCW comprises multiple components, and at its core, it presents the Capability, Opportunity, and Motivation–Behavior (COM-B) model, which is an implementation theory that explains the relationships between internal and external influences of behavior change [46,77]. The TDF is often used as a supplement as it provides a granular breakdown of the COM-B [79]. The BCW can assist with barrier and facilitator assessment and inform the design of implementation strategies [46,77]. The BCW also offers step-by-step guidance on making theory-informed choices of strategies that link to the determinants of behavior change based on the barrier and facilitator analysis [46,77].

There are several related tools that augment the use of the BCW. The Affordability, Practicability, Effectiveness, Acceptability, Safety, and Equity (APEASE) selection criteria are a tool to support decision-making [46,77]. As the BCW provides a wide range of options, it may not be feasible to leverage all possible intervention options. This is when the APEASE criteria can be used to rank options and carefully select the top choices based on the knowledge users' assessment of options considering all domains of APEASE. Next, the behavior change technique (BCT) Taxonomy version 1 provides a granular level of the 9 intervention types [80]. BCTs are the smallest unit and the "active ingredients" of an intervention that generate behavior change [80]. The development of the taxonomy was an international consensus project, and it provides a common language between researchers and allows for clear communication and replication of interventions [80]. Finally, the Theory and Technique Tool provides information on linkages between mechanisms of action (ie, how behavior can be changed) and specific BCTs [81]. It is based on the synthesis of evidence for the links, expert consensus, and triangulation of these 2 sources of findings [82]. This tool provides links between 74 BCTs and 24 mechanisms of action (ie, COM-B) to change behavior [81].

Lynch et al [83] suggest using the BCW and TDF when researchers investigate individual experiences as a preparation for implementation. This is because clinicians' behavior is a determinant of implementing new ICTs, and therefore, it is vital to conduct a thorough behavioral analysis, such as barriers to and facilitators of performing the desired activity. In this study,

XSL•FO
RenderX

our desired behavior change for the clinical team is to deliver the SPI using the Hope app on patients' own devices. The BCW and TDF have been used in a wide range of disciplines such as health promotion [84-87] and health informatics [88-90] to characterize barriers to and facilitators of implementation. For example, in the field of health informatics, the BCW and TDF have been used to inform implementation strategies to facilitate the completion of electronic discharge summaries [90].

Study Setting

This study will take place in the CAMH Gerald Sheff and Shanitha Kachan ED located in an urban academic tertiary care center in Ontario that provides care to approximately 1200 adult patients each month [91]. The CAMH ED is Ontario's only stand-alone psychiatric ED that provides emergency assessment and treatment exclusively focused on adults (aged ≥16 y) with mental health and substance use issues. Approximately 150 staff members (both full time and part time) are employed in this ED. On a daily basis, the ED is staffed by a total of 16 to 20 nurses, program assistants, psychiatrists, residents, and social workers.

Intervention: Hope App

The Hope app by CAMH is a free smartphone app that provides suicide prevention information, resources, and tools to support individuals who are experiencing suicide-related thoughts and behaviors. This app is evidence-based, meaning that it adheres to the best practices available for safety planning [20,21], and was developed in collaboration between service users and clinicians. The collaborative approach to developing the Hope app is a strength, and it has been well documented in the literature that research outputs (eg, interventions) generated through partnerships are more useful and relevant to end users [92]. A core component of the Hope app is a "Safety Plan" (ie, SPI) that includes five items for completion: (1) warning signs, (2) reasons for living, (3) coping strategies, (4) support network, and (5) environmental safety. Multimedia Appendix 1 provides screenshots of the app and its content.

In addition to the SPI, the app includes a direct 9-1-1 line, mental health resources (eg, link to community resources), and wellness activities (eg, journaling and relaxed breathing). This app does not track the user's location and cannot store or access personal data such as names, addresses, and phone numbers. Only when users want to can they share their safety plan with their clinicians or social network via email. The Hope app allows users to send an email copy of the safety plan using the default email app, and users can edit the subject or body of the email before sending it.

Phase 1

In phase 1, we will conduct a qualitative descriptive study [93] to understand clinicians' experiences and perspectives of implementing the Hope app in routine practice in the psychiatric ED and identify barriers to and facilitators of implementation (objective 1).

Sampling and Recruitment

We will use purposeful sampling strategies to recruit a heterogeneous sample to obtain broad insights and information-rich data [94]. All CAMH ED clinicians (ie, physicians, nurses, social workers, and program assistants), including trainees such as residents, will be invited for an interview regardless of their age, gender, and years of experience. The composition of the sample will be purposeful to maintain sufficient representation from each clinician group (ie, at least 2 members/discipline). Nurses make up the majority clinician group in the CAMH ED, so the sample may have a large proportion of nurses. Since the launch of the Hope app without systematic effort for integration, some staff members have been voluntarily using the app, whereas others continue to use the paper-based safety plan or a mixture of both. All clinicians will be invited whether they use the app or not. Both perspectives (ie, users and nonusers) will be valuable to gain insights into adopting the Hope app in routine practice. A specific number of participants will not be predetermined, but instead, data collection and analysis will occur concurrently such that recruitment will stop after data saturation (ie, information redundancy) [95]. Qualitative descriptive studies tend to have an average sample size ranging from 20 to 35 [96]. However, based on a systematic review of empirical tests assessing the number of interviews needed for data saturation, 9 to 17 interviews are sufficient for achieving data saturation [97]. As such, it is possible to reach saturation with <20 interviews. In short, phase 1 aims to recruit a minimum of 20 interview participants, but it could potentially be <20 if data saturation is achieved. Snowball sampling may be used as a secondary method if faced with recruitment challenges using posters and emails.

Data Collection

A semistructured 1:1 interview guide was informed by the COM-B and TDF (Multimedia Appendix 2). The guidelines provided by Atkins et al [79] and Michie et al [77] on applying the COM-B and TDF in research processes and example interview questions to assess each domain of the COM-B and TDF were reviewed. In addition, published examples by other researchers on how to phrase questions to assess all the domains in the COM-B or TDF were reviewed [98-100]. Through this review, adaptations were made to our interview guide to better fit our research context. In addition, a few prompts were added related to digital equity concerns. For example, clinicians will be asked whether they have encountered any challenges while using the app with individuals who have low digital literacy and faced difficulties in providing technical support to these individuals and their thoughts on the potential drawbacks of using either the paper or app format of SPI. In particular, the provision of technical support to patients in the ED aligns with the recommendation by Shaw et al [67] to integrate supportive intermediaries. However, this needs to be explored in the CAMH ED for its feasibility and for redefining professional responsibilities as the role of providing technical support may or may not be perceived as a clinical responsibility of the ED team. Open-ended questions in the interview guide are mapped according to the COM-B and TDF domains, and they are designed to identify what clinicians need, what they are capable of, and what their motivation is for using the Hope app in their normal clinical workflow. In addition, the sustainability potential of the Hope app within the CAMH ED and scalability beyond

XSL•FO
RenderX

the CAMH ED will be explored. The interview guide will be pilot-tested with the internal research team to minimize any ambiguity in wordings. All interviews will be 45 to 60 minutes in length, via web-based video call, telephone, or in person, at a suitable time for the clinicians. Recognizing that accessing interviews with clinicians is challenging, we will need to be flexible with the interview format, setting, and timing and strive for conversation-like interviews, which are less formal in structure. For instance, interviews may be initiated on-site at the CAMH ED, and the remainder of the questions may be completed off-site. Questions that can be asked on-site (eg, questions 2, 3, 9, and 17 in Multimedia Appendix 2) will aim to highlight "in the moment experience" [101] in the ED context as it relates to SPI with the Hope app. All interviews will be audio recorded and transcribed verbatim and have identifying information removed to maintain privacy. We will also collect participant characteristics (eg, age, sex, gender, discipline, and years in practice) at the end of each interview via a web survey using REDCap [102]. Demographic and interview data will not be linked.

Data Analysis

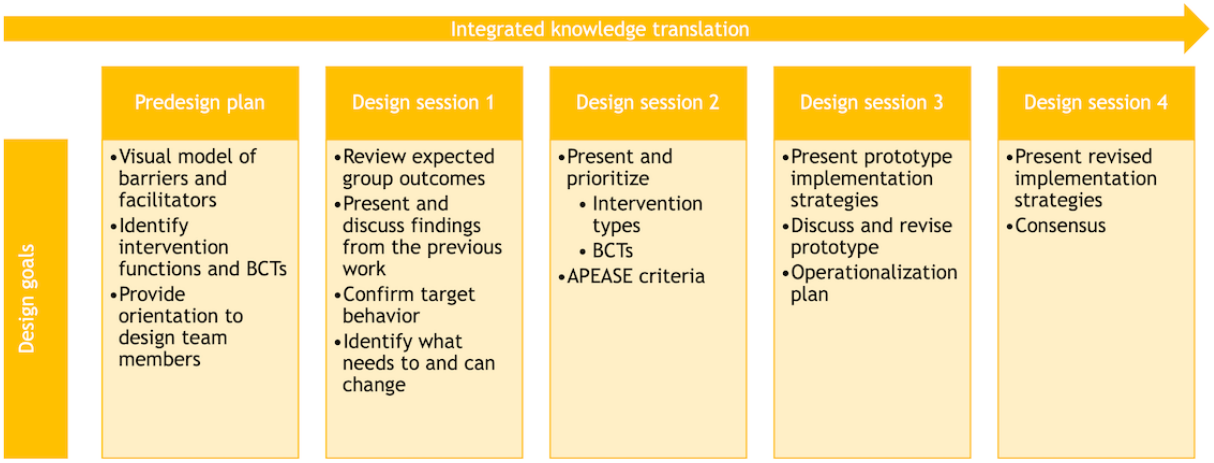
Participant demographic characteristics will be tabulated (ie, descriptive statistics) and narratively described. Interview transcripts will be analyzed using directed content analysis [103] for barriers and facilitators using the COM-B and TDF as a codebook along with operational definitions for all domains. First, 2 reviewers will read the transcripts to categorize relevant statements into the COM-B domains and subcategories of the 14 TDF domains. These categorized segments, known as coding stripes, will be compared between the 2 reviewers for consistency. Once all transcripts are initially coded into COM-B and TDF domains, we will generate specific belief statements in relation to the 14 TDF domains. The belief statements, or initial themes, are a group of similar responses that suggest a potential influence on the target behavior [79]. These belief statements will then be further refined into themes and aligned with the COM-B domains. The final themes organized into COM-B domains will represent the barriers and facilitators perceived to influence clinicians' behavior when delivering the SPI using the app downloaded on the patients' own devices in the ED.

As advised by Atkins et al [79], it is important to emphasize that, although the TDF domains are intentionally designed as broad groupings of potential factors influencing behavior, the primary goal is to examine these domains in greater depth. Some statements from the transcripts may overlap across multiple domains, illustrating the intricate nature of human behavior [79]. The main domains of behavioral influences have been identified a priori, but there may be new behavioral factors unique to the CAMH ED and the Hope app. Therefore, new codes and categories may emerge during the categorization step [103]. At least 2 researchers will first trial the codebook with 1 or 2 transcripts to ensure consistency in the coding strategy. We then will independently code all transcripts. The research team will meet regularly to resolve any interpretation discrepancies through discussion or with a third person. During these regular meetings, we will also look for repetition in participants' responses to determine whether data saturation has been reached. We will use the NVivo software (Lumivero) [104] for data management and analysis. A summary of the findings will be presented via web meetings or email communications to participants for member checking [105] to determine whether they feel that the identified themes are accurate. Outputs from phase 1 will include a list of implementation barriers and facilitators mapped to the COM-B.

Strengths and Limitations

Barriers and facilitators do not linearly affect clinicians' behavior and subsequent implementation. The clinical context as well as human behavior are complex; it is not individual factors that facilitate the implementation of a new innovation but the dynamic interaction between them [106,107]. Nonetheless, the COM-B accounts for interactions between both internal (ie, capability and motivation) and external (ie, opportunity) factors that influence behavior change. Data analysis using the COM-B and TDF as guiding theoretical frameworks will help explain the relationship between factors that influence clinicians' behavior leading to delivering the Hope-app. Therefore, the application of the COM-B and TDF will not downgrade the complexity of human behavior but, rather, will help us organize the data in a way that makes them accessible to work with and facilitates the understanding of complexity.

Phase 1 is limited to clinicians' perspectives, but other ongoing studies at CAMH focusing on patients' perspectives on SPI can be leveraged. Furthermore, we will involve patients (ie, ED service users) in the subsequent phase 2 to co-design implementation strategies with clinicians to integrate the Hope app in the CAMH ED. Patients' insights will be sought during phase 2, and there will be opportunities to identify convergence with and divergence from clinicians' perspectives.



Phase 2

Overview

In phase 2, we will use a co-design approach to develop implementation strategies based on the outputs from phase 1. Specifically, we will select BCTs (ie, active ingredients of implementation strategies) that can mitigate barriers and enhance facilitators. The development of implementation strategies is envisioned in at least 4 co-design sessions, with specific design goals guided by semistructured, open-ended questions, and the findings from each session will feed into the next. All 4 co-design sessions will follow the steps (Figure 1) based on the BCW guide for intervention design and recommendations for co-design [108,109].

XSL•FO
RenderX

Figure 1. Proposed co-design process informed by the Behavior Change Wheel. APEASE: Affordability, Practicability, Effectiveness, Acceptability, Safety, and Equity; BCT: behavior change technique.

Sampling and Recruitment

A co-design team will consist of ED service users (ie, patients), families, and ED clinicians. The representation of clinicians on a team will include at least one nurse and one psychiatrist currently working in the CAMH ED. The composition of the co-design team will be purposely chosen to maintain sufficient representation from each knowledge user group and ensure adequate peer support for patients and families in each co-design session. At least 6 members (ie, 2 service users, 2 family members, and 2 clinicians) but no more than 10 will form a co-design team. The team will ideally stay the same throughout phase 2, facilitating rapport building. However, time and availability of participants may lead to challenges in recruitment and retention, so snowball sampling may be used as a secondary method.

Design Procedures

Overview

All co-design sessions will last approximately 1.5 to 2 hours, either on the web or in person depending on participants' preferences and convenience. To minimize attrition, we will provide a tailored orientation to prepare all participants before each design session for effective collaboration. During this preparation, we will ensure that participants' level of knowledge of the Hope app and the purpose of phase 2 are the same, ensuring that everyone is on the same page. Participants will not enter each design session blindly; instead, they will have a clear idea and expectations for each design session. This strategy was informed by the CAMH Lived Experience Advisory Group meeting in February 2023. Email progress updates will be used to communicate with participants (ie, members of the co-design team) between sessions. We will also inform participants about how we have incorporated their feedback into the implementation strategies. All participants will have access to web-based or telephone support between meetings to address any questions or concerns. The following sections detail the goals of each co-design session.

Predesign Plan

When designing an implementation strategy, it is important to consider the full range of available intervention options [77]. The BCW links the COM-B to the full range of 9 "intervention functions" (ie, strategy types) that can change behavior [77]. Using the BCW, we will identify a full range of strategies that match to the determinants of behavior change based on phase 1 outputs. In addition, we will prepare a list of BCTs that match to the selected strategies.

Co-Design Session 1

There will be an opportunity to get to know the team members. Then, the findings from phase 1 (ie, the list of barriers and facilitators mapped to the COM-B) will be presented with visual aids. As a team, we will confirm the target behavior and then identify which barriers are modifiable and which facilitators can be leveraged. Activities will be used to generate insights into what change is needed to integrate the Hope app into the normal workflow. Ideas will be sought regarding *when* (ie, timing within discharge), *who* (eg, psychiatrists, nurses, or both), and *how* clinicians should deliver the Hope app.

Co-Design Session 2

A summary of the findings from session 1 will be shared with the design team before the meeting. During the design session, prematched strategies and possible content or contents of the implementation strategies (eg, BCTs) will be presented. We will come up with lay language alternatives to BCTs to enable better understanding. The design team's views on the relevance and importance of BCTs will then be asked. Activities using both voting and discussion will focus on prioritizing the content and modes of delivery. The design team will then be asked to identify and discuss potential challenges regarding feasibility associated with the selected content or contents and mode or modes. The discussion will be guided by the BCW APEASE criteria, with a strong emphasis on the *equity* domain of APEASE.

Co-Design Session 3

The prototype of the implementation strategies will be developed based on the findings from session 2. This will be presented

XSL•FO
RenderX

before the meeting and during the co-design session for review following the reporting criteria by Proctor et al [110] for describing implementation strategies. We will also provide a visual representation of how strategies intend to work, linking anticipated behavioral outcomes with mechanisms of action (ie, underlying theoretical assumptions and BCTs that will target the barriers). We will then discuss the operationalization of the strategies and their usability.

Co-Design Session 4

During the last session, we will present the revised implementation strategies along with the operation plan. We will present a visual storyboard, from triage to discharge, and illustrate how a patient is expected to receive the SPI via the Hope app. Specifically, we will highlight how, when, and by whom the Hope app will be delivered. The design team will have the opportunity to provide additional feedback.

Data Collection

All design sessions will be audio recorded, transcribed verbatim, and deidentified. There is great flexibility in the ways in which people approach co-design [111]. We will use a range of activities (eg, think-aloud and voting) to engage participants and provide them with interactive ways to develop and share ideas. We will have a mock-up trial with the internal research team and receive feedback from the ED medical head before finalizing the activities. Other data may include participants' sticky notes of ideas or web-based comments. A cofacilitator will take notes and capture details of the design process (eg, decisional conflicts and group dynamics). In addition, at the end of each design session, we will collect data to evaluate and monitor the experience and engagement of participants. The evaluation questions will consist of Likert scales adapted from the Public and Patient Engagement Evaluation Tool [112]. The questions will ask participants to rate their experience and self-perceived engagement.

Data Analysis

The analysis of transcripts and notes will be pragmatic, focusing on the specific design goals outlined in Figure 1. At least 2 researchers will use NVivo [104] to independently analyze transcripts using directed content analysis [103] to categorize design considerations using the BCW as a codebook. Design session notes made by a cofacilitator will supplement data analysis to provide contextual information. We will meet regularly to resolve any coding discrepancies through discussion. In addition, we plan to do a recap of the previous design session at the start of each design session for member-checking purposes [105]. We will review the evaluation data between each design session to monitor and assess whether any changes are required to improve engagement. We will report engagement evaluation data using descriptive statistics. Outputs from phase 2 include discrete implementation strategies that not only match the determinants of implementation from phase 1 but are also reflective of inputs from several knowledge user groups.

Anticipated Challenges and Mitigation Strategies

There may be concerns about placing service users, family members, and clinicians in the same group as service users may feel uncomfortable speaking up. However, previous research has shown that forming a heterogeneous co-design team with patients and clinicians can be done well [113-116]. Furthermore, the CAMH Lived Experience Advisory Group supported this as an effective approach for reaching a consensus. The principal investigator of this work (HDS) also has previous co-design experience as a clinician participant in a mixed group with youth and parents [113]. To provide a trusting and safe space for all participants to share their ideas and speak respectfully to each other, the project lead (HDS) and cofacilitator will put great effort into practicing transparent dialogue and power sharing, developing a common language and avoiding medical jargon, and fostering mutual respect and making it clear to knowledge user groups that their different expertise is equally valued [117]. The Lived Experience Advisory Group also highlighted the importance of providing orientation to the co-design team members, ensuring that everyone is on the same page and has a clear understanding of the research agenda. Research team members of phase 2 will also practice humility and self-reflexivity, which are facilitators for conducting collaborative research [118]. Finally, we will be collecting progress outcomes on engagement to identify whether modifications are needed for subsequent co-design sessions.

Trustworthiness

There are four criteria for ensuring the trustworthiness of qualitative studies (phase 1-2): (1) credibility, (2) confirmability, (3) dependability, and (4) transferability. Credibility will be achieved by representing research findings drawn from the participants' original data and accurate interpretations of the participants' original views [119]. We will select and show representative quotations from the interviews when reporting the findings. Member checking will further ensure credibility. Confirmability is about ensuring that findings are the result of the experiences and ideas of the participants rather than the characteristics and preferences of the investigator [119]. Therefore, data analysis will involve ≥2 researchers. To demonstrate dependability, all processes and rationales within the study will be recorded and reported in detail [120]. Such documentation will include operational detail regarding sampling, data collection, process logs, memos, and reflexive notes. We will strive for detailed reporting using the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [121] for phase 1 and the GRIPP (Guidance for Reporting Involvement of Patients and the Public) reporting checklist [122] for the co-design phase 2. Any deviations from the protocol because of the iterative nature of qualitative studies will be transparently described in the full report. Transferability may be limited as this study takes place in 1 clinical setting (ie, the CAMH ED) given its unique characteristics as a stand-alone psychiatric ED. However, one approach to enhance transferability is to provide detailed contextual information about the study and the setting, so called "sending context" to readers [120]. It is suggested to provide a clear description of culture and context, selection and characteristics of participants, data collection, and process of analysis [119]. Therefore, readers of the study report can make judicious transfers and inferences and apply the study findings to other settings.

XSL•FO
RenderX

Ethical Considerations

Ethics approval for phase 1 was obtained from the Research Ethics Board of the CAMH (REB 2023/078). Recruitment and data collection in phase 1 have started. All participants are provided with both written and oral information about the study, which includes details on the voluntary nature of participation and their ability to ask questions or withdraw from the study at any time without having to provide reasons. After reviewing the study procedures, all participants provide informed consent through an electronic platform (ie, REDCap) where they provide their signature before participating in audio recording. The study data will be deidentified before publication. Clinicians participating in phase 1 will receive a CAD $50 (US $36.44) e–gift card of their choice as compensation for their time and knowledge. At the end of the phase 1 interviews, clinicians are invited to express their interest in participating in phase 2. Ethics approval for phase 2 is underway at the time of writing and will be obtained from the Research Ethics Board of the CAMH.

Results

The protocol presents the entire structure of the research project involving 2 sequential studies, with the first phase feeding into the next. Ethics approval from the CAMH for phase 1 has been obtained, and we expect to complete recruitment and data collection for phase 1 no later than December 2023. We anticipate that each phase will last a maximum of 1 year.

Discussion

Expected Findings

In the end, we will have developed theory-informed implementation strategies to support CAMH ED clinicians' uptake and subsequent delivery of the Hope app to patients. These developed strategies will facilitate the implementation of the Hope app by addressing barriers and leveraging facilitators in the local context, thereby maximizing SPI delivery. The co-design approach is expected to ensure that strategies are targeted to meet the needs of knowledge users (ie, both patients and clinicians) and are feasible, acceptable, and appropriate for the CAMH ED. In addition, the strategies driven by the BCW will change clinicians' behavior and be compatible with their routine clinical workflow.

The patients' behavior after ED discharge is beyond the scope of our study and also beyond the control of the ED clinical team. However, we recognize that it is another significant contributor to the effective use of the SPI. Changes in clinicians' behavior in the ED can trigger a chain of behavior changes among patients and families. If patients and their families receive the safety plan through the Hope app in the ED, along with instructions on how to use it, as a result of successful behavior change within the ED team, this could hypothetically lead to changes in the behavior of patients and their families. After being discharged from the ED, patients may incorporate the app into their self-care routine, engage with its features, and review their safety plan and participate in self-reflection. However, if patients do not use their safety plan on their phones after ED discharge, it will not generate its intended benefits, and they may return to the ED in the event of another crisis (eg, a suicide attempt). Nevertheless, changes in patients' and families' behavior are beyond the scope of our study and also outside the control of the ED team. This falls into another important area for future exploration related to user engagement in health informatics.

Strengths and Limitations

The systematic and replicable reporting of the behavioral mechanisms of action behind the implementation strategies is a strength of this study. Furthermore, the proposed co-design process is highly collaborative. The design team members will work together in equal and active partnership. In addition, this research project can provide recommendations on how to involve multiple knowledge user groups and offer insights into how the collaborative approaches can be used and adapted to other areas within the health informatics literature. However, this study does not intend to generate generalizable implementation strategies for an app. Instead, the findings can be adapted to different contexts, and we will take the necessary steps to ensure the transferability of this work outlined in the Trustworthiness section. We would also like to acknowledge the limitations of this study concerning digital equity. Digital equity encompasses more than the acquisition of digital literacy skills and ensuring affordability. This study does not address structural factors contributing to the digital divide, such as socioeconomic status and place of residence. Moreover, it cannot resolve the access divide, which reinforces our decision to keep the paper-based SPI in the ED as an option. Although we recognize that digital equity surpasses digital literacy, it is also important to acknowledge that equity must extend beyond ensuring affordability; even with access to technologies, the reported outcomes of using health technologies have been inconsistent [64]. In our study, we prioritize digital literacy and the engagement of various knowledge user groups in the design process, aiming to alleviate potential challenges associated with the app's use among individuals with limited digital skills. Finally, co-design team members will be self-selected, often motivated individuals, and their views may not be representative of diverse ED service users and clinicians at the CAMH.

Conclusions

This proposed work will contribute to the current literature by addressing several identified gaps. First, this work will contribute to the identified knowledge gap regarding the contextual implementation characteristics of ICTs for suicide prevention in clinical settings. Using the BCW, this work will also tease apart the nuanced influences of behavior change leading to ICT implementation. Second, this theory-informed and collaborative work will fill the methodological gap regarding nonrigorous implementation research for mental health apps.

Acknowledgments

As a doctor of philosophy candidate in health service research at the University of Toronto, HDS is supported by the Canadian Institutes of Health Research Doctoral Research Award, but the funding agency did not have any role in content development.

Data Availability

All data generated and analyzed in this study will not be publicly available in accordance with the Centre for Addiction and Mental Health ethical review guidelines as all data are securely stored on an internal server. However, they can be obtained from the corresponding author upon reasonable request.

Authors' Contributions

HDS, JZ, JT, and GS conceptualized the study. HDS designed the protocol, including data collection, analysis, and interpretation planning. HDS wrote the first draft of the manuscript and worked on revisions. GS supervised all phases of the work. All the authors (HDS, JZ, JT, and GS) critically reviewed and provided feedback on the manuscript.

Abstract

Background: Adolescents at risk for substance misuse are rarely identified early due to existing barriers to screening that include the lack of time and privacy in clinic settings. Games can be used for screening and thus mitigate these barriers. Performance in a game is influenced by cognitive processes such as working memory and inhibitory control. Deficits in these cognitive processes can increase the risk of substance use. Further, substance misuse affects these cognitive processes and may influence game performance, captured by in-game metrics such as reaction time or time for task completion. Digital biomarkers are measures generated from digital tools that explain underlying health processes and can be used to predict, identify, and monitor health outcomes. As such, in-game performance metrics may represent digital biomarkers of cognitive processes that can offer an objective method for assessing underlying risk for substance misuse.

Objective: This is a protocol for a proof-of-concept study to investigate the utility of in-game performance metrics as digital biomarkers of cognitive processes implicated in the development of substance misuse.

Methods: This study has 2 aims. In aim 1, using previously collected data from 166 adolescents aged 11-14 years, we extracted in-game performance metrics from a video game and are using machine learning methods to determine whether these metrics predict substance misuse. The extraction of in-game performance metrics was guided by literature review of in-game performance metrics and gameplay guidebooks provided by the game developers. In aim 2, using data from a new sample of 30 adolescents playing the same video game, we will test if metrics identified in aim 1 correlate with cognitive processes. Our hypothesis is that in-game performance metrics that are predictive of substance misuse in aim 1 will correlate with poor cognitive function in our second sample.

XSL•FO
RenderX

Results: This study was funded by National Institute on Drug Abuse through the Center for Technology and Behavioral Health Pilot Core in May 2022. To date, we have extracted 285 in-game performance metrics. We obtained institutional review board approval on October 11, 2022. Data collection for aim 2 is ongoing and projected to end in February 2024. Currently, we have enrolled 12 participants. Data analysis for aim 2 will begin once data collection is completed. The results from both aims will be reported in a subsequent publication, expected to be published in late 2024.

Conclusions: Screening adolescents for substance use is not consistently done due to barriers that include the lack of time. Using games that provide an objective measure to identify adolescents at risk for substance misuse can increase screening rates, early identification, and intervention. The results will inform the utility of in-game performance metrics as digital biomarkers for identifying adolescents at high risk for substance misuse.

Introduction

Background

Despite existing evidence-based interventions, many adolescents continue to misuse substances [1]. In 2021 alone, over 1 in 5 adolescents aged 12-17 years misused substances (illicit drugs and alcohol or tobacco products) [2] and 2 million adolescents had a substance use disorder [2]. Adolescent substance misuse, defined as "the unhealthy use of alcohol or drugs to relieve stress, alter reality or bring about pleasure" [3], increases the risk of developing a substance use disorder. Adolescents with substance use disorders are more likely to engage in criminal activity, contract sexually transmitted infections, develop comorbid mental disorders, and die early [4]. In addition, between 2019 and 2020, there was a 44% increase in drug-involved deaths among adolescents aged 10-19 years [5]. The negative consequences arising from substance misuse underscore the need to identify at-risk adolescents early to deliver timely prevention and treatment interventions.

Less than 10% of adolescents in need of substance use treatment receive it [6] in the setting of poor screening uptake and referral for treatment [7]. Many adolescents with substance misuse are not identified early, and barriers in screening adolescents for substance misuse contribute to this. The American Academy of Pediatrics and the Substance Abuse and Mental Health Services Administration recommend universal screening to identify at-risk adolescents. Yet, fewer than half of primary care providers [8] and fewer than a fifth of School-Based Health Center providers [9] screen adolescents for substance misuse [8,9]. Identifying at-risk adolescents early and delivering effective prevention interventions can prevent substance misuse-associated morbidity and mortality [10,11]. Barriers to screening adolescents for substance misuse include the lack of time, concern that adolescents will not be forthcoming about misuse, discomfort with conducting screening, and difficulty with providing a confidential space to conduct screening [8,12-15]. Innovative solutions that address or mitigate these barriers and lead to early identification of at-risk adolescents are urgently needed.

Digital tools hold great potential to mitigate identified barriers in screening for substance misuse given the ubiquity of mobile devices. These digital tools can be accessed anywhere and include mobile phones, wearables such as smart watches or Fitbits, mobile or web-based apps, and game software. Serious games—"games designed for a primary purpose other than play" [16]—are frequently used by over 95% of adolescents [17]. Serious games are increasingly being used for delivering health interventions among adolescents [18,19] and, more recently, are also being used for assessment of mental health outcomes [20,21]. During gameplay, in-game metrics reflective of performance in the game are being collected by the game software [18,22]. These metrics may reflect digital biomarkers of health outcomes [22].

Digital biomarkers are "consumer-generated physiological and behavioral measures collected through connected digital tools that explain, influence or predict health-related outcomes" [22,23]. Although most studies investigating the utility of digital biomarkers for health screening and monitoring have focused more on data collected from mobile phones [24,25] and wearables [26,27], games offer another source of data that could potentially measure digital biomarkers [22]. In-game performance metrics [18], such as the amount of time to complete a game task, accuracy of choices in a game task, or style of gameplay (ie, choosing a game task without attention to outlined rules), may reflect cognitive processes such as working memory, processing speed, and inhibitory control [22]. These cognitive processes (working memory and inhibitory control) affect in-game performance and can therefore be measured using in-game performance metrics [28,29]. Deficits in working memory [30,31] and inhibitory control [32] are also associated with substance misuse among adolescents [33] and may explain by up to 33% of the variance in future risk of substance misuse [33]. As such, in-game performance metrics may reflect digital biomarkers of cognitive function, which may be used in predicting adolescents at risk for substance misuse. Digital biomarkers have been used to predict health risk among adults [34,35] and adolescents [25,27]. Prior studies have also investigated the utility of digital biomarkers for a range of psychiatric disorders [24,26,34,36,37]. In these studies, the digital biomarkers captured were primarily from phone or

XSL•FO
RenderX

wearable sensors and included measures such as movement, location, sleep, heart rate, and social interaction through call or text logs [24-27,34,37]. Although games are increasingly being used for measuring health outcomes such as cognitive function [38], their utility as digital biomarkers is yet to be widely investigated. In addition, all of the studies that have investigated the utility of game-based digital biomarkers have focused on adults [21,39,40]. A study by Dechant et al [39] demonstrated that participants with social anxiety exhibited in-game behavior that was different compared to participants without social anxiety. Specifically, participants with social anxiety were more likely to have their avatar stand at a larger distance to nonplayer characters in the game. In another study by Gielis et al [40], they investigated the utility of in-game performance metrics to identify adults with mild cognitive impairment (MCI). Adults identified as having MCI took more time to think about a move and made more errors in the game compared to adults without MCI.

To the best of our knowledge, we are not aware of any studies that have investigated the utility of game-based digital biomarkers for adolescent substance misuse. Given the easy access to games and the high level of motivation and engagement with games among adolescents [17,41,42], game-based digital biomarkers hold promise for risk identification among adolescents. The use of games as a screening tool could also mitigate barriers in screening since these games can be deployed without supervision and can be completed in private. In addition, prior studies have indicated that adolescents are more forthcoming when completing digital screeners compared to provider interviews and prefer this form of screening [43]. Finally, future apps of game-based screening and monitoring tools could integrate with the electronic health record to make results readily accessible to providers.

Study Objectives

This paper describes the protocol for a proof-of-concept study to develop and test a predictive model for identifying adolescents at risk for substance misuse using in-game performance metrics. The primary objective of this study is to identify game-based digital biomarkers of cognitive risk factors implicated in the development of substance misuse among adolescents using available in-game performance metrics from an existing serious video game intervention, *PlayForward: Elm City Stories*, developed by the play2PREVENT Laboratory in partnership with Schell Games (hereafter referred to as *PlayForward*) [19].

Methods

Overall Study Design

The purpose of this pilot study is to identify game-based digital biomarkers of cognitive risk factors implicated in adolescent substance misuse by developing and testing a machine learning predictive model. This study is led by a team with expertise in machine learning, game design, cognitive function, adolescent substance misuse, and the conduct of pilot trials. This study's team demonstrates a team science approach to solving public health problems with investigators from Yale University, Carnegie Mellon University, and International Business Machines Corporation.

Aim 1

Objective

The objective of aim 1 is to identify game-based digital biomarkers of adolescent substance misuse.

Overall Study Design of Aim 1

Using data collected in a previous study [19], we will determine specific in-game performance metrics—digital biomarkers—that more strongly associate with a high risk for substance misuse. Adolescents will be grouped in 2 groups—high and low risk for substance misuse—based on their baseline responses to questions about substance misuse behaviors (eg, "in the past 30 days, have you used cannabis?" and "How sure are you that you can refuse if a friend offers you alcohol and you do not want it?"). We will have 2 prediction tasks (substance misuse and self-efficacy to refuse drugs). For each task, we will identify an effective prediction model by testing 6 machine learning classification models (eg, logistic regression, random forest, decision trees, support vector machine, gradient boosted decision tree, and neural networks). We will assess the feasibility of using a logistic regression model to compute a digital biomarker score for each adolescent that ranges from 0 to 1, where an adolescent with a higher score has a higher substance misuse risk.

Data Source

PlayForward is an evidence-based video game intervention developed in the play2PREVENT laboratory for HIV prevention and reduction of high-risk behaviors such as substance misuse [18,19,44,45]. *PlayForward* includes 12 Challenge Stacks or levels (the narrative and story-based components of the game) and 5 minigames (People Sense, Refusal Power, Me Power, Priority Sense, and Know Sense). Each of the minigames has 10 levels. The minigames are designed to help the adolescent develop and practice adaptive skills—such as learning to say no to an invitation to use drugs—that can be translated into real life. Players earn stars and points during gameplay, which allow them to advance in the game. *PlayForward* was tested in a randomized controlled trial of 333 adolescents, aged 11-14 years, where 166 adolescents were assigned to play the *PlayForward* video game [19]. At baseline, self-report data on substance misuse and self-efficacy to refuse drugs were collected. During gameplay, data related to their performance in the game (Table 1) were collected by the game software and later stored as log files. The game developers (Schell Games) developed reference files for decoding information stored in the log files.

XSL•FO
RenderX

Table 1. Potential in-game biomarkers.

Minigame or subsection of minigame	Potential in-game biomarkers	Hypothesized neurocognitive domains (DSM-5[a])
People sense		
Deciding friends: checking out each person's information	• Time spent checking peer's characteristics • Correctly sorting peers into the right social or friendship circles • Time spent completing social or friendship circles	• Working memory, attention, inhibitory control, and processing speed • Working memory and decision-making • Working memory and processing speed
Accepting or rejecting invites	• Correctly accepting or declining invitations based on risk and social circles • Proportion of accepted unsafe invitations	• Working memory, decision-making, and judgement • Decision-making, and judgement
Refusal power		
Think	• Correctly identifying the type of peer pressure	• Decision-making and inhibitory control
Prepare	• Correctly choosing reasons to say no	• Decision-making and inhibitory control
Refuse	• Time spent completing the sentence portion of minigame	• Working memory and processing speed
Priority sense	• Number of times priority dropped to zero	• Working memory
Know sense	• Total credibility score at the end of the minigame	• Working memory, decision-making, and processing speed

[a]DSM-5: Diagnostic and Statistical Manual, 5th Edition.

Data Extraction and Analysis

Three authors (KA, MGJ, and IGdlV) played the *PlayForward* game and reviewed the literature and gameplay guides for *PlayForward* to identify in-game performance metrics that likely used cognitive function and could therefore be potential in-game digital biomarkers of cognitive function (Table 1). We have identified 285 in-game performance metrics (eg, the number of times the player lost the minigame; Multimedia Appendix 1). One of the authors (SK) extracted all identified in-game performance metrics from log files into a CSV file and uploaded this into R statistical software (R Foundation for Statistical Computing) [46]. In-game performance metrics that are found to predict substance misuse risk following analysis will be identified as digital biomarkers for adolescent substance misuse risk.

In total, 2 outcomes (described in the assessments section below)—substance misuse and self-efficacy—to refuse drugs will be used in 2 prediction models. Based on adolescent baseline response to questions on substance misuse and self-efficacy to refuse drugs in a previous study [19], a substance misuse score and self-efficacy to refuse drugs score have been derived. For each score, adolescent participants are categorized into 2 groups (high risk and low risk) based on the score distribution. A preliminary examination of the log files of the 166 participants who played the *PlayForward* game resulted in dropping 6 log files due to file errors. As such, analysis of aim 1 will occur with a final sample of 160 participants.

Outcome Measures

Substance Misuse

In total, 20 questions on cigarette, alcohol, and drug use behaviors from the Youth Risk Behavior survey [47] were administered to 11- to 14-year-old adolescents in the *PlayForward* randomized controlled trial at baseline [19].

Questions included whether participants had ever tried using cigarette, alcohol, or other drugs (marijuana, cocaine; inhalants; over-the-counter drugs; and nonprescribed prescription drugs such as opioids, methamphetamines, and injection drugs); substance use in the previous 30 days; and age at first use (for cigarette and alcohol).

In total, 15 questions on ever use and past 30-day use (for substances other than alcohol or cigarette) had options of yes, no, and decline to answer. In total, 2 questions on age at first use (for cigarette and alcohol) had 9 options: "I have never smoked a whole cigarette/I have never had a drink of alcohol other than a few sips"; 8, 9, 10, 11, 12, 13, and 14 years or older; and decline to answer. Further, 1 question on past 30-day use of cigarettes had 8 options: I did not smoke cigarettes during the past 30 days, less than 1 cigarette/day, 1 cigarette per day, 2-5 cigarettes/day, 6-10 cigarettes/day, 11-20 cigarettes/day, more than 20 cigarettes/day, and decline to answer. Furthermore, 1 question on past 30-day use of alcohol had 8 options: 0 days, 1 day, 2 days, 3-5 days, 6-9 days, 10-19 days, 20 or more days, and decline to answer.

In addition, if participants answered "no" to a particular question about having ever used cigarette or alcohol or drugs, they skipped subsequent questions about past 30-day use and age at

XSL•FO
RenderX

first use (for cigarettes and alcohol). A participant could skip up to 9 questions.

Coding

For this age group, we considered any type of substance misuse to be high risk. As such, if any adolescent answered "yes" to any of the above questions, we coded them as high risk. Based on this criterion, 107 (66.9%) of 160 adolescents were low risk because they answered "no" to all the substance misuse questions.

Self-Efficacy to Refuse Drugs

In total, 10 questions from the Drug Use Resistance Self-Efficacy [48] scale were used to calculate a score. The Drug Use Resistance Self-Efficacy scale asks questions relating to confidence in one's ability to refuse drugs in a variety of situations. The options to each question include "not sure at all," "not very sure," "pretty sure," and "definitely sure." Each option was recoded as follows: "definitely sure"=0, "pretty sure"=1, "not very sure"=2, and "not sure at all"=3. As such, scores could range from 0 to 30, and higher scores meant lower self-efficacy to refuse drugs. In this sample of 160 adolescents, scores ranged from 0 to 27 with a mean of 2.38 (SD 4.40). Adolescents were grouped into 2 groups (high risk and low risk) based on the score distribution. Adolescents with a total score of 0 were considered low risk (n=82, 51.2%), whereas adolescents with a total score greater than 0 were considered high risk (n=78, 48.8%).

Analyses

Machine learning models [49] will be used to predict each outcome. We will use k-fold cross-validation [50] to evaluate the performance of 6 machine learning classification models (logistic regression, random forest, decision trees, support vector machine, gradient boosted decision trees, and neural networks) to predict each of the outcomes. These 6 models are representative of a range of popular classification models that have been previously used in substance use research [51]. These models vary in their underlying mathematical approaches and often offer reasonable to good performance across a variety of data sets. For example, while regression models are easy to implement, the underlying assumption is that predictors are independent [51]. Decision trees on the other hand do not require elaborate preprocessing but perform relatively worse than other models [51]. Support vector machine performs well using unstructured data but requires extensive tuning [51]. The primary evaluation metric used will be the area under the receiver operating characteristic (AUROC) curve [50]. For each outcome, the model with the AUROC value closest to 1 is the one that has the best ability to discriminate between risk classes, across all classification threshold levels ranging from 0 to 1 [50]. Ideally, an AUROC value of greater than 0.7 can be achieved by the best model. We will also report the sensitivity and specificity for a range of classification thresholds. In the event that AUROC values are similar across candidate models, it may be useful to identify the best model as the model that offers the most appropriate trade-off between sensitivity and specificity, even if the AUROC value of that model may not be the highest [50,52]. Existing screening tools for substance use have sensitivity ranging from 0.71 to 0.94 and specificity ranging from 0.87 to 0.97 [53,54]. As such, to identify an adolescent at risk for substance misuse, we want to achieve comparable sensitivity and specificity above 0.7. Given the risk of negative outcomes such as an overdose that can occur with adolescent substance misuse, a model that produces a higher sensitivity compared to its specificity would be consistent with existing recommendations for substance use screening tools [53]. For the best model identified for each outcome, we use Shapley additive explanations [55,56] to explain the relative importance of the features used to predict the outcome class (ie, high risk vs low risk). We will define features (ie, predictor variables used to inform the classification) from in-game performance metrics. When selecting features to be used for classification, the variance threshold method will be used to remove features with 0 (or low) variance because they are unlikely to be useful for discriminating between classes [49]. We will reduce multicollinearity between features by selectively removing a subset of highly correlated features before performing classification [49]. In addition, we will assess in-game metrics for multicollinearity and drop in-game performance metrics with a variable inflation factor larger than 10 [57].

Aim 2

Objective

The objective of aim 2 is to determine the association between identified digital biomarkers and cognitive function.

Overall Study Design of Aim 2

We will test the hypothesis that digital biomarker scores will negatively correlate with cognitive function scores. To test this hypothesis, we will conduct a pilot study using a new sample of 30 high school adolescents aged 14-15 years. After screening, consent, and baseline assessments, adolescents will play the *PlayForward* game. To validate the model developed in aim 1, the digital biomarkers identified in aim 1 will be extracted following completion of gameplay, and a digital biomarker score will be derived. We will then test the association between the computed digital biomarker score and cognitive function.

Participants and Source

Adolescents from 1 to 3 Connecticut high schools will be recruited. To be eligible for this study, participants must (1) attend a high school in Connecticut, (2) be aged between 14 and 15 years, (3) be willing to sit for 60 minutes per session to play the game, and (4) be able to provide assent and parental or guardian consent. Following screening, eligible adolescents who provide parental consent and assent will complete baseline assessments. Adolescents who complete baseline will be grouped into high-risk and low-risk groups based on their response to assessment of substance misuse, depression, and anxiety. High risk will be determined using their report at baseline of monthly use of any substance (alcohol, tobacco, marijuana, prescription drugs, inhalants, illegal drugs, and synthetic drugs), a score of >2 on the Patient Health Questionnaire-2 [58], and a score of >2 on the Generalized Anxiety Disorder 2-item scale [59]; low risk will be determined by no substance use in the past year, <2 on the Patient Health Questionnaire-2, and <2 on the Generalized Anxiety Disorder 2-item scale. We chose a higher age range (14-15 y) for aim 2

XSL•FO
RenderX

(in contrast to the age range of 11-14 y in aim 1) to ensure that we can recruit a high-risk sample (adolescents with substance misuse).

Recruitment and Informed Consent

This study will take place in high schools where the laboratory has established partnerships and has conducted trials in the past. Adolescents in participating high schools will be informed about this study. Adolescents who express interest will be provided a flyer with a QR code to complete a contact form if interested in participating in the study. Parents of interested adolescents who complete the contact form will be contacted to obtain parental permission. Following parental permission, adolescents will be screened for eligibility for participation in this study through a Qualtrics (Qualtrics) survey. Eligible adolescents will be asked to provide assent prior to enrollment into this study.

Data Collection and Storage

We will use Qualtrics, a web-based data collection software to obtain parental permission and adolescent assent, screen adolescents for study eligibility, obtain demographic information, and generate a study ID. Study IDs will be automatically generated after the adolescent has screened as eligible. PsyToolkit [60,61], an open source, web-based psychological instrument will be used to administer baseline assessments and conduct the tasks of cognitive function. PsyToolkit has been used in studies measuring working memory and response inhibition in adolescents [62,63] and has been shown to produce comparable results to tasks conducted in a laboratory [64]. Baseline assessment and task performance scores will be retrieved from the PsyToolkit website.

Gameplay data collection will be stored on iPads (Apple Inc) during gameplay. Following study completion, data for each participant will be retrieved from Qualtrics and PsyToolkit into a CSV file and merged by participant ID. Data from iPads will also be retrieved as log files. All retrieved data will be stored on secured data storage locations on the Yale server. Data collection will occur between April 2023 and February 2024.

Assessments and Cognitive Tasks

Table 2 [48,58,65-70] lists measures to be used for screening and administered at baseline. All listed measures have been validated among adolescents.

Table 3 [71-74] lists cognitive tasks to be completed by adolescents at baseline. All listed cognitive tasks have been validated among adolescents.

Table 2. List of screening and baseline assessments for aim 2.

Construct	Name of questionnaire and reference	Number of items	Screening	Baseline
Demographics	Age, sex, and school name	—[a]	✓	—

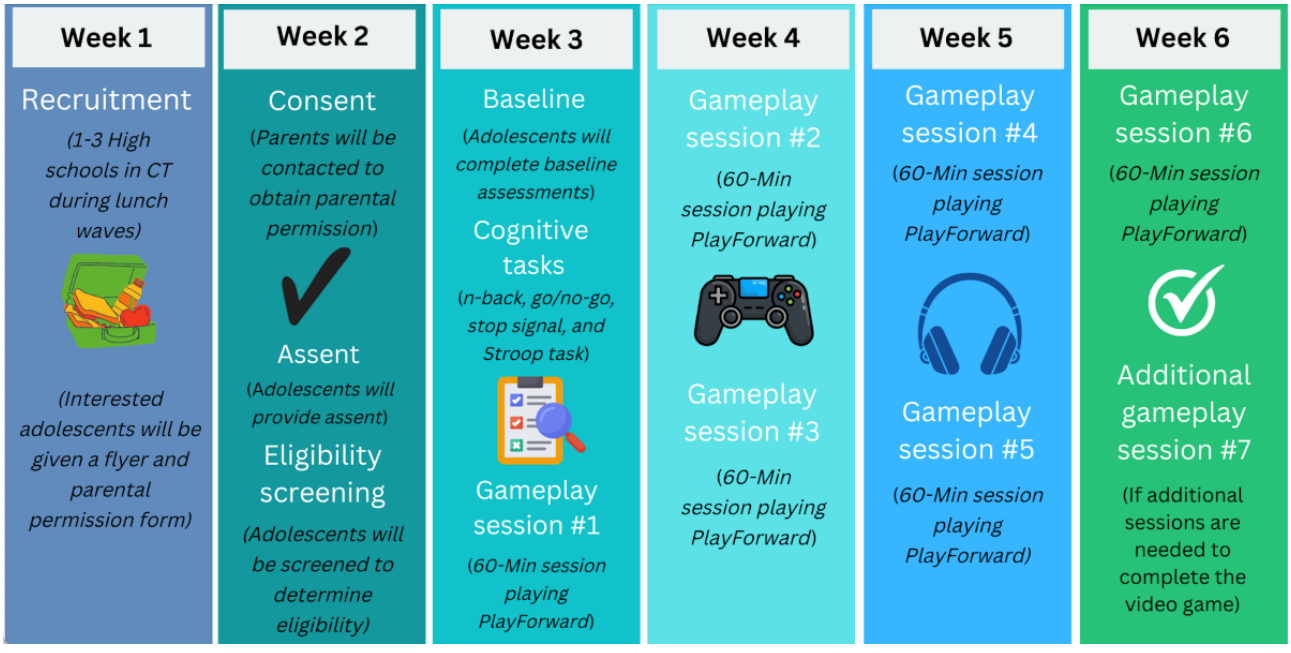
Table 3. Baseline cognitive tasks.



Construct or cognitive task and reference	Description	Metrics recorded
Working memory		
n-back task, Pelegrina et al [71]	The 2-back task will be used. In the 2-back task, a series of letters will be shown to participants in a sequential order. Participants are to click a prespecified key on their device if the letter shown matches the letter shown 2 turns back.	• Percentage of correct matches • Percentage of missed matches • Percentage of false alarms • Mean response time
Inhibitory control		
Go or no-go task, Bezdjian et al [72]	In the go or no-go task, participants are asked to click the spacebar when they see the "go" sign but do nothing when they see the "no-go" sign.	• Response speed • Number of errors • Mean response time
Stop-signal task, Kulendran et al [73]	In the stop signal task, 2 arrows, 1 pointing to the right and the other pointing to the left, will be shown in random order. In the first round, without the stop signal, the participant will click a prespecified key when the left pointing arrow is shown and a different prespecified key when the right pointing arrow is shown. In the second round which includes the stop signal, participants are to stop from clicking the arrows when the red signal appears.	• Mean response time • Error rate
Selective attention, processing speed, and cognitive flexibility		
Stroop task, Stroop [74]	In the Stroop task, names of different colors (blue, green, yellow, and red) will be printed in either of the 4 colors. Participants are to use prespecified keyboard keys to identity the color in which the word is printed in and not the meaning of the word. If the word "yellow" is printed in green, the correct response would be to click on the key that corresponds to green.	• Mean response time for congruent and incongruent stimuli

Study Setting and Study Flow

Figure 1 outlines study procedures. After obtaining verbal parental permission and adolescent assent, participants will be provided with their study ID to log-in to PsyToolkit to complete baseline procedures, which include 7 validated questionnaires and 4 performance-based cognitive tasks as described above.

Following the completion of baseline assessments or tasks, all enrolled participants will be provided a National Institutes of Mental Health–approved information sheet about the teen brain with resources on finding help. In addition, all participating schools have a school-based health center where students can seek help. Enrolled participants will use iPads to complete the entire *PlayForward* game over 6 to 7 sessions lasting 60 minutes each (the average number of 60-min sessions needed to complete the *PlayForward* game is 6). Gameplay sessions will occur 1 to 2 times/wk. The order in which the 4 cognitive tasks will be presented to participants will be random and generated by PsyToolkit. Adolescents will be compensated US $50 following the completion of baseline and US $70 after the completion of this study.

Figure 1. Aim 2 procedures. CT: Connecticut.

Statistical Analyses

Primary Outcomes

Working memory: the percentage of correct matches, percentage of missed matches, and percentage of false alarms from the 2-back task will be used to compute a working memory score.

Inhibitory control: the response speed and number of errors from the go or no-go task and average response time from the stop-signal task will be used to compute an inhibitory control score.

Secondary Outcomes

Selective attention and processing speed: the average response time from the Stroop task will be used to compute the selective attention score.

Predictors

In-game performance metrics extracted in aim 1 will also be extracted in aim 2. We will test if specific in-game performance metrics are predictive of cognitive function (working memory and inhibitory control) measured by performance-based tasks in a sample of adolescents (n=30).

Planned Analyses

The model trained in aim 1 will be applied to the data collected in aim 2, and digital biomarker scores will be computed such that higher scores equate to higher risk for substance misuse. We will carry out a test of correlation (r) to determine the correlation between the digital biomarker score and (1) working memory score, (2) inhibitory control score, and (3) selective attention score.

Power

With an expected moderate correlation of 0.5 between in-game performance score and validated measures of cognitive function [28], a total of 29 participants will provide 80% power at the .05 2-sided significance level. A larger sample size will yield conventional levels of statistical significance for lower correlation coefficients (n=30 for r=0.5 and n=47 for r=0.4). For this pilot project, we anticipate a correlation of 0.5 based on prior validation studies comparing game-based cognitive assessment to standardized assessment [75-77].

Ethical Considerations

The Yale institutional review board approved this study and its procedures on October 11, 2022 (IRB #2000033084). This study is covered by a Certificate of Confidentiality from the National Institutes of Health. Given the sensitive nature of this study, a Health Insurance Portability and Accountability Act waiver and waiver of written parental consent was obtained.

Results

This study was funded by the National Institute on Drug Abuse through the Center for Technology and Behavioral Health at Dartmouth Pilot Core in May 2022. For aim 1, we completed cleaning of in-game log files in preparation for data extraction. In total, 166 log files were initially available for data extraction. Following data cleaning, 6 files were excluded for reasons such as the data storage files were corrupted, the data structure of log files was different from the rest of the files, and it was impossible to determine the reason for this difference. As such, a final sample of 160 is being used for analysis. The number of extracted in-game performance metrics is 285 (Multimedia Appendix 1). The R software [46] was used in extracting metrics from game log files, and codes are being stored on GitHub. Analyses are currently underway. For aim 2, data collection is ongoing and is projected to end in February 2024. Currently, we have enrolled 12 participants. Data analysis for aim 2 will begin once data collection is completed. The results from both aims will be reported in a subsequent publication, which we expect to publish in the winter of 2024.

Discussion

Adolescent substance misuse is a predominant public health problem. However, most adolescents at risk for substance misuse are not identified early [78]. Early identification of high-risk adolescents can inform the delivery of targeted interventions that prevent the development of negative outcomes. However, identifying adolescents at risk for substance misuse is not routinely done due to a myriad of factors. Although mobile phones and wearable devices have been used to identify and measure digital biomarkers for health outcomes [24-27], the use of games is less widely studied. The use of game-based assessment for mental health purposes has been on the rise and may be used to capture potential biomarkers of health outcomes that can be used for screening and monitoring [22]. The use of games for risk identification offers a promising solution as these can be deployed without the need for provider supervision, can offer privacy to the adolescent completing the game-based screener, and has benefits over self-report data as it would provide a more objective assessment of risk.

In this proof-of-concept study, we will test the utility of in-game performance metrics—digital biomarkers—to identify adolescents at risk for substance misuse. We will also test the hypothesis that adolescents with poor cognitive function will perform worse in the game and be at higher risk for substance misuse. We will be assessing aspects of cognitive function that are implicated in the development of substance misuse and impacted by substance misuse. We build on prior studies that have successfully used game metrics to measure cognitive function [38,40] and extend prior knowledge in the field by applying it to substance misuse. Games offer an engaging way to assess a wide range of factors among adolescents, most of whom play games [17]. This study has several strengths. To the best of our knowledge, we will be the first to test the utility of in-game performance metrics to be used as digital biomarkers of substance misuse. We will also be the first to investigate game-based digital biomarkers in an adolescent population.

This study has several limitations. We are using a game that was not initially designed to measure cognitive function. As such, the game metrics may be poor representations of working memory and inhibitory control. However, other studies have demonstrated that performance metrics collected in a game could be useful in predicting cognitive functions [38,40]. We are using a game that is designed to change behavior related to substance use risk. As such, this game may not be ideal as an

XSL•FO
RenderX

assessment tool since the tools' predictive ability may wane with repeated use in the setting of positive behavior change. However, other studies have documented that even games designed primarily for assessment can change cognitive processes in ways that can threaten the validity of the game-based tool [79,80]. We chose to use this game-based intervention due to the availability of existing data for this proof-of-concept study, which, if successful, will provide preliminary data for future development of a game-based assessment tool for substance misuse risk. Another limitation is that the initial sample on which the prediction model will be trained has a low prevalence of substance misuse. This imbalance may limit the performance of the prediction models to predict substance misuse. To address this, we will use data augmentation methods such as Synthetic Minority Oversampling Technique [81]. In addition, our eligibility criteria for aim 2 will allow us to recruit a sample of adolescents with higher risk for substance use than in aim 1, which may enhance the performance of the model.

Despite limitations, this study represents a novel and likely highly impactful examination of the use of digital games as not only interventions but also potentially as screening and data collection tools. If found to be successful in predicting substance use, it will inform the future design of game-based assessment tools for substance misuse risk. With their broad level of reach and high engagement, games could seamlessly provide data on adolescent substance misuse risk and help to close the gap in screening and early intervention, leading to improved health outcomes in adolescents.

Data Availability

The data set containing the relevant in-game metrics extracted are included in this published paper in Multimedia Appendix 1 (n=285).

Authors' Contributions

KA contributed to study conceptualization and design, identification of relevant in-game performance metrics, analyses, writing, review, and editing. CHC contributed to study conceptualization, analyses, and paper review and editing. JM contributed to paper writing and drew Figure 1. YTC contributed to study conceptualization and reviewed and edited the paper draft. ZCL contributed to study conceptualization. SK contributed to data extraction, analyses, and paper preparation. MGJ contributed to study conceptualization and identification of relevant in-game performance metrics. IGdlV contributed to study conceptualization and identification of relevant in-game performance metrics. FAU contributed to paper preparation. RAM contributed to data preparation and paper preparation. LEF contributed to study conceptualization and paper editing and review. All authors reviewed and approved the final paper.

Conflicts of Interest

LEF is the Founder and on the Board of Directors of a Yale company, Playbl, that distributes game products. CHC is an employee and shareholder of IBM. The other authors have no conflicts of interest to disclose.

Abstract

Background: The increasing use of information technology in the field of health is supposed to promote users' empowerment but can also reinforce social inequalities. Some health authorities in various countries have developed mechanisms to offer accurate and relevant information to health care system users, often through health websites. However, the evaluation of these sociotechnical tools is inadequate, particularly with respect to differences and inequalities in use by social groups.

Objective: Our study aims to evaluate the access, understanding, appraisal, and use of the French website *Santé.fr* by users according to their socioeconomic position and perceived health status.

Methods: This cross-sectional study involves the entire French population to which *Santé.fr* is offered. Data will be collected through mixed methods, including a web-based questionnaire for quantitative data and interviews and focus groups for qualitative data. Collected data will cover users' access, understanding, appraisal, and use of *Santé.fr*, as well as sociodemographic and socioeconomic characteristics, health status, and digital health literacy. A validation of the dimensions of access, understanding, appraisal, and use of *Santé.fr* will be conducted, followed by principal component analysis and ascendant hierarchical classification based on the 2 main components of principal component analysis to characterize homogeneous users' profiles. Regression models will be used to investigate the relationships between each dimension and socioeconomic position and health status variables. NVivo 11 software (Lumivero) will be used to categorize interviewees' comments into preidentified themes or themes emerging from the discourse and compare them with the comments of various types of interviewees to understand the factors influencing people's access, understanding, appraisal, and use of *Santé.fr*.

Results: Recruitment is scheduled to begin in January 2024 and will conclude when the required number of participants is reached. Data collection is expected to be finalized approximately 7 months after recruitment, with the final data analysis programmed to be completed around December 2024.

Conclusions: This study would be the first in France and in Europe to evaluate a public health information service, in this case the *Santé.fr* website (the official website of the French Ministry of Health), according to users' socioeconomic position and health status. The study could discover issues related to inequalities in access to, and the use of, digital technologies for obtaining health information on the internet. Given that access to health information on the internet is crucial for health decision-making and empowerment, inequalities in access may have subsequent consequences on health inequalities among social categories. Therefore, it is important to ensure that all social categories have access to *Santé.fr*.

Introduction

Digital Technologies and Health

The health sector is characterized by an exponential use of digital health technology that serves both for care and for coordination among professionals and facilities and for health care system users (eg, health information, appointments scheduling, and communication with caregivers). Digital health technologies are intended to enhance the autonomy of users, including patients and individuals who use these technologies to support the health of their relatives. This implies that users, whether for themselves or for their loved ones, should have access to health information that enables them to better manage health-related concerns.

Although digital health is promising in terms of technology, its increasing use can lead to unintended negative consequences [1-3]. Indeed, digital health technology can mitigate some geographic location–related barriers, but access to, and the use of, these technologies can be influenced by various factors, including socioeconomic position. Geographic location and socioeconomic position remain important factors influencing the use of digital health technologies.

Individuals' socioeconomic characteristics and their overall health status can affect how different social groups adopt digital health technologies [4]. Consequently, the growing digital divide may worsen existing social health inequalities. The COVID-19 pandemic has accelerated and amplified the digital divide [5]. The lockdown showed that many people were at a loss when faced with the necessity of carrying out web-based procedures. This health, social, and economic crisis has amplified the risks of digital exclusion. Existing digital tools, such as telemedicine and health websites, have been useful in enabling remote medical consultations or keeping up to date with the spread of the virus. By contrast, countless websites are designed according to technical criteria, rather than on the basis of the experience of users in all their diversity [5]. Therefore, it is important to carefully examine the unexpected, undesirable, and negative consequences of digital health to understand its real impact on people and ensure that public health policies address these issues [1-3].

Social Gradient in Access to Digital Health

Studies highlight a social gradient in the access, use, and appraisal of digital health technologies in other countries [6,7], but data are lacking in France, where individuals belonging to the working classes have less access to computers and are less likely to search for health information on the internet [8].

More recently, using data from the *Baromètre Santé* study conducted between 2010 and 2017, French researchers showed that the profile of health information seekers versus nonseekers has remained consistent over time [9]. Seekers were more likely to be younger, more educated female individuals, with higher household incomes and holding executive positions. In 2017, as in 2014, general health websites remained the top source of information (38.6%), followed by social media and commercial websites, whereas institutional websites ranked as the third source (8.1%) [9]. These authors recommended that health authorities should improve citizens' digital health literacy and provide reliable and accessible sources of web-based health information.

In response to this issue, some health authorities in different countries have progressively developed mechanisms to provide relevant, accurate, and useful information to health care system users, often through health information websites [10,11]. However, the use of these new sociotechnical tools has been poorly assessed, particularly in terms of differences and inequalities in use among social groups.

Evaluation of Health Information Websites

The literature includes several studies that have evaluated the quality of health information websites. Some studies have primarily focused on specific information related to particular diseases [12-23] or prevention measures [24-28], whereas other studies have analyzed general health information websites [29-35].

Studies evaluating the quality of health information websites often use automated tools and manual evaluations by professionals. These assessments focus on various criteria, such as readability, the ease of use, reliability, and the quality of information. Tools such as Flesch-Kincaid [14,18,21,22,30,36-41], Flesch Reading Ease [12,18,21,28,30,36-38,41], Simple Measure of Gobbledygook [14,18,21,22,24,30,40], Gunning Fog Index [14,21,22], Coleman-Liau Index [14,21,22], and Automated Readability Index [14,21] measure reading comfort. The Health on the Net Foundation Code of Conduct assesses reliability [17,30,36,42], and the DISCERN tool evaluates health information quality [19,20,28,38,42,43]. The Lida instrument assesses design and content [12,19,37,40], whereas the Clear Communication Index, a tool developed by the Centers for Disease Control and Preventions, evaluates written health materials [32,44]. Some studies also include user perspectives to evaluate website usability and information quality [45,46].

Access to clear and understandable health information is important for informed decision-making, but many health websites are difficult to navigate and read, especially for those with low literacy levels [12,32,37,47]. This can lead to health inequalities [39] and delay the adoption of appropriate health behaviors. Although government websites are usually easier to read [14], improvements are still necessary. Website design and content can also present barriers to use [48]. Few studies focus on the evaluation of a single website, and evaluations often overlook users' sociodemographic characteristics, health status, and health literacy levels. Therefore, it is important to conduct evaluations that take into account these factors to identify any population groups facing barriers to accessing and understanding health information on these websites.

To make health information websites accessible and user-friendly, it is important to involve users in the evaluation process [32]. Understanding users' needs and preferences can ensure that the information provided is clear, relevant, and actionable [39]. It is crucial to assess issues related to the accessibility of health information to ensure that all individuals can take advantage of the wealth of health information available

XSL•FO
RenderX

on the internet, given the growing focus on patient empowerment in health [48].

Santé.fr, the Website of the French Public Health Information Service

In France, the *Santé.fr* website is a public service website that provides general health information selected for its quality and usefulness. This website is under the Ministry of Health's responsibility, and its mission is to provide free information on health care as well as medical and social services to the public. The information is adapted and accessible to people with disabilities and aims to encourage citizen participation in health choices, improve patient management, and simplify the adoption of preventive behaviors.

> *Santé.fr serves as a reference health website and offers access to resource directories, prevention and health education information services, and more. It is accessible anytime and anywhere, making it a reliable and convenient source of health information.*

As *Santé.fr* is an information and support tool for users, it is crucial to track and evaluate its use and identify any disparities among different population groups. Therefore, it is important to explore the experiences and evaluations of *Santé.fr* users to determine to what extent the information provided meets their needs and expectations. The objective is to ensure that *Santé.fr* proves to be a genuine advantage for users and does not exacerbate the existing social inequalities by promoting the use of a tool that is inaccessible or unsuitable for a portion of the population because disparities in the access, understanding, appraisal, and use of digital health technology can worsen social health inequalities, depending on individuals' social position.

Objectives of the Study

The main objective of this study was to evaluate the access, understanding, appraisal, and use of *Santé.fr* by users according to their socioeconomic position and health status. Our specific objectives were to (1) determine users' profiles in terms of the access behavior, understanding, appraisal, and use of *Santé.fr* based on their socioeconomic position and health status; (2) examine the association between users' socioeconomic position and health status and their access, understanding, appraisal, and use of *Santé.fr*; and (3) determine the reasons why users of *Santé.fr* use this service.

Methods

Research Design

The *Évaluation du service public d'information en santé* (the *Santé.fr* website) *selon le statut socio-économique de ses utilisateurs* (evaluation of the public health information service [the *Santé.fr* website] according to the socioeconomic status of users) study is a cross-sectional observational study of the French population using *Santé.fr*. It will use mixed methods, that is, it will combine quantitative and qualitative research methods [49]. The study period will last 1 year so that there will be enough time to collect the necessary quantitative and qualitative data.

Study Population

The study target population is the entire population to which *Santé.fr* is offered, that is, the general French population. The source population is made up of all health care system users, whether or not they use *Santé.fr*; the respondents to this study; and the study sample. All inhabitants of metropolitan France and the *Départements et régions d'outre-mer et collectivités d'outre-mer* (overseas departments and regions and overseas communities) will be concerned by this study. The quantitative and qualitative study inclusion criterion is as follows: any adult (aged ≥18 y) living in metropolitan France or *Départements et régions d'outre-mer et collectivités d'outre-mer*.

Recruitment

The quantitative study will include both users and nonusers of *Santé.fr* who visit the website and voluntarily complete the questionnaire. Before participation, all participants will receive comprehensive and adequate information through an information note. *Santé.fr* users are individuals who have previously consulted *Santé.fr* or are visiting it for the first time when completing the questionnaire. Nonusers of *Santé.fr* are individuals who, although aware of this public health information service, have never accessed it before coming across the questionnaire or were not previously familiar with it.

The questionnaire will be self-administered by *Santé.fr* users, using a computer-assisted web interviewing method (ie, completed on the web). An article on *Santé.fr* will be developed to present the research team and the study to participants and to share the external link to the questionnaire. A poster will be designed to encourage users to participate in the study. The article and the questionnaire will be displayed on *Santé.fr* at several navigation levels (eg, thumbnail on the home page, contextual message block, end of an article, and thematic folder) to increase access to the questionnaire. Users connecting to *Santé.fr* will be able to click directly on the poster and reach either the article or the questionnaire. Users will decide whether to participate in the study. A communication plan will be elaborated by the research team to disseminate the study as much as possible.

The qualitative study will include individuals, who may or may not be users of *Santé.fr*, with a variety of profiles, including different sexes, age groups, geographic origins, and socioeconomic positions. Specifically, socioeconomic position will be assessed based on criteria such as education level, occupational category, and income level.

Participants will be recruited through the following channels:

- Relatives or persons in the professional and personal environment of the research team will be requested to identify interested individuals.
- Snowball method: the research team members will ask some of their contacts to identify people they know from different geographic locations and ask them to agree to be contacted by the research team.
- Associations such as Emmaüs Connect, Point Information Mediation Multi Services, and La Mednum will be contacted to identify individuals with digital difficulties. Emmaüs Connect helps individuals experiencing social and

XSL•FO
RenderX

digital insecurity to access essential web-based tools. La Mednum helps to develop mediation and digital inclusion programs all over France, as does Point Information Mediation Multi Services.
- Assistance will be requested from the France Assos Santé network, an interassociative organization that represents health system patients and users and defends their interests, to identify patients or users of the health care system.
- Additional resources may be used.

For the quantitative study, a sample size calculation was performed. As we had no information on the proportion of *Santé.fr* users, we calculated the number of participants necessary according to the estimation formula in the case of an expected prevalence of 50% with a risk of error α of 5% and a precision of 5%. A sample of 385 people was deemed necessary. For the qualitative study, we estimate conducting 30 interviews, taking into account feasibility and the need for a wide range of respondent profiles.

Data Collection

Quantitative Study

Overview

A questionnaire was developed according to the literature to collect the necessary quantitative and qualitative data to address the objectives. The 5-section questionnaire, described in detail in the following subsections, is available in Multimedia Appendix 1. A feasibility test of the questionnaire will be conducted to ensure that the questions are clear, simple, and understandable.

Section 1: Access or Use

This section includes questions to determine whether users or nonusers have the necessary equipment (computer, tablet, smartphone, and internet connection) to access the internet and the general skills needed to use the internet effectively on these devices. The questions also explore their interest in using the internet to find health information and seek to understand how often they use *Santé.fr* for health information. To develop these questions, we used questions from the French *Baromètre Santé* periodic surveys and the Website Quality Evaluation Tool [50]. The *Baromètre Santé* surveys have been conducted since 1992 to better understand French people's knowledge, behavior, beliefs, and practices concerning health [51].

Section 2: Understanding

This section consists of questions related to users' ability to find and understand health information on *Santé.fr* and their ability to evaluate, in general, health information presented on the internet. These indicators will help determine whether *Santé.fr* is accessible and user friendly. Some items from the eHealth Literacy Scale (eHEALS), discussed in the *eHealth Literacy* subsection, were used [52]. We also used questions from the *Baromètre Santé* periodic surveys [51], the DISCERN tool [53], a systematic literature review by Sun et al [54] on relevant criteria and indicators for evaluating the quality of health information on the internet, and a critical analysis of evaluation criteria for health websites [55].

Section 3: Application

This section concerns the appraisal and adoption of *Santé.fr* by users, either for themselves or for relatives. These questions assess whether this website helps users to make informed decisions about their own health. The questions on the intention of users to reuse *Santé.fr* and to recommend it to relatives will allow us to evaluate their satisfaction and to assess their degree of confidence in the provided information. To develop these questions, we were inspired by the technology acceptance model [56] as well as items from the eHealth Impact Questionnaire [57] and items used in the study by Kang and An [33], which evaluated health-related sites for older adults and assessed whether the sites take into account factors that affect older adults' intention to use them for health information seeking.

Section 4: Sociodemographic and Economic Characteristics

This section collects the respondents' sociodemographic and economic characteristics. The questions cover their indirect geographic origin or native area (and that of their parents), their job status (employed or not) and socioprofessional category or social position, their economic and financial situation (income, origin of income, social benefits, and self-declared financial situation), and their geographic place of residence (postal code and the name of the town of residence). These variables will make it possible to estimate the respondents' socioeconomic situation. These questions were inspired by data on socioeconomic situations collected from the French Constances study [58].

Section 5: Health Status

This section includes questions to evaluate the respondents' perceived health status, addressing the general, physical, and psychological dimensions of health as well as the presence of an illness or chronic health problem. To develop these questions, we were inspired by the questions from the *Enfants et familles sans logement* (Children and families experiencing homelessness) survey [59] and the periodic *Baromètre Santé* surveys [51].

eHealth Literacy

To calculate a digital health literacy score for each respondent and to be able to compare the total scores between *Santé.fr* users and nonusers, the eHEALS items are used [52]: in their original form for nonusers of *Santé.fr* and adapted for users of *Santé.fr* to match the digital tool being evaluated. The corresponding items are presented in Multimedia Appendix 2 and are distributed in the questionnaire's different sections.

Qualitative Study

To explore users' and nonusers' perceptions regarding their access, understanding, appraisal, and use of *Santé.fr*, as well as their general use of the internet for searching and using health information, semistructured individual interviews will be conducted. The interview guide will be developed based on the questionnaire used in the quantitative study. Regarding the interview's organization, an initial telephone contact with the participant will allow us to briefly explain the study to them, obtain their consent to participate in the interview, and set up an appointment for the interview. The participant's main characteristics will also be collected during this first contact by

XSL•FO
RenderX

the interviewer to ensure a wide-range sample. If a participant agrees to participate in the study and has never consulted *Santé.fr*, the interviewer will ask them to navigate through the website before the interview and browse the health topics of interest. On the day of the interview, if the participant has been able to access *Santé.fr*, the interviewer will ask them to describe their overall experience and ask the interview guide questions. If a participant has not been able to access the website, the interviewer will ask them to explain why, which will be considered a result per se.

These interviews will take place via videoconference, telephone, or face-to-face, depending on the participants' preference, at a time and date of their choice.

Focus groups will also be conducted by the research team. The objective is to enable the participants to provide their reactions to the *Santé.fr* website. Participants will have to navigate the website and share their experience: what they think of *Santé.fr* in general, the difficulties or problems faced, the elements to be improved according to them, their ability to carry out a search and obtain answers to their questions, whether the navigation is easy, and so on. Participants may or may not already know each other and have varied sociodemographic profiles.

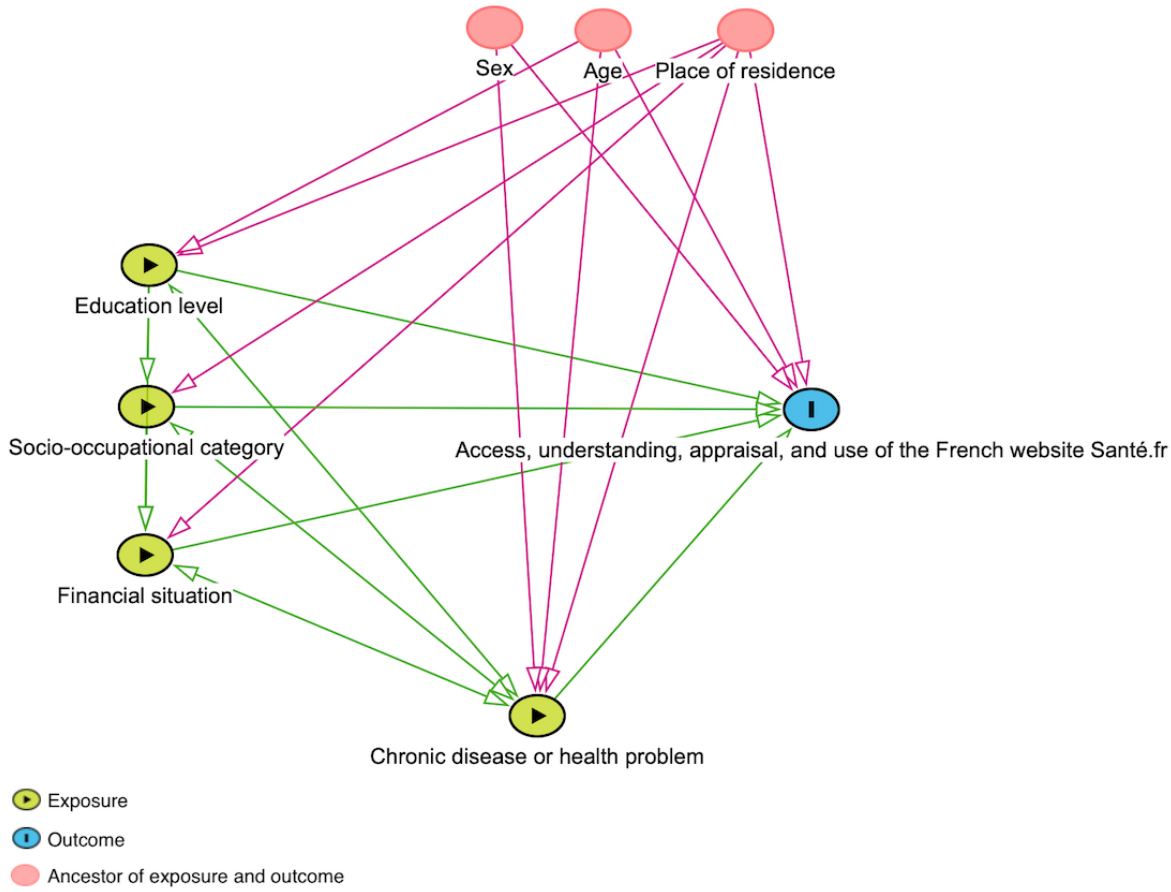
Statistical Analysis

Quantitative Analysis

Descriptive Analyses

The sociodemographic and socioeconomic characteristics, health status, and digital health literacy score measured by the eHEALS will be described. The variables related to the access, understanding, appraisal, and use of *Santé.fr* will also be presented. Qualitative variables will be analyzed using frequencies and proportions, whereas the digital health literacy scores will be described using mean and SD as well as median and IQR.

A validation of the dimensions of access, understanding, appraisal, and use of *Santé.fr* will be conducted to ensure their reliability and validity. This validation process will involve assessing the internal consistency of items as well as evaluating convergent and discriminant validity. To assess internal consistency, the Cronbach α coefficient will be calculated. In addition, correlation analysis will be conducted to examine the relationships among variables and to evaluate convergent and discriminant validity.



Principal component analysis will be performed for each dimension, using the variables specific to that dimension as active variables. Subsequently, ascendant hierarchical classification will be conducted based on the 2 components of principal component analysis to characterize homogeneous users' profiles based on their access, understanding, appraisal, and use of *Santé.fr*. The sociodemographic, socioeconomic, and health status variables will be used as illustrative variables to characterize users' profiles.

Analytical Analyses

On the basis of the results of the dimension validation in the descriptive part of the statistical analyses, different approaches will be used for the analytical analyses. If the dimension (ie, access, understanding, appraisal, and use of *Santé.fr*) is validated, a quantitative score will be used as a continuous variable. However, if the dimension is not validated, a specific questionnaire variable related to that dimension will be used instead. Depending on the nature of the outcome variable, different regression models will be developed. If the outcome variable is continuous, a linear regression model will be conducted. If the outcome variable is binary, a logistic regression model will be performed. In the case of a variable with >2 categories, a multinomial logistic regression model will be applied. Regardless of the model used, the explanatory variables will include education level, socio-occupational category, and financial situation. Confounding variables such as sex, age, and place of residence will also be included in the analyses to account for potential biases. This approach follows an etiological explanatory perspective, for which a directed acyclic graph will be used (Figure 1).

XSL•FO
RenderX

Figure 1. Directed acyclic graph applied to the relationships between socioeconomic position and health status and the access, understanding, appraisal, and use of Santé.fr.

All quantitative analyses will be conducted using RStudio (version 2023.03.1+446; Posit Software, PBC).

Qualitative Analysis

The first step of the qualitative analysis will consist of transcribing all interviews and focus groups. The analysis grid will be constructed from the interview guide and the focus groups and completed inductively based on new items that may appear during the transcripts analysis. Using NVivo 11 software (Lumivero), the interviewees' comments will be classified within each preidentified theme or themes emerging from the discourse and compared among types of interviewees to understand the reasons why people access, understand, evaluate, and use (or do not) *Santé.fr*. A profile analysis of people with similar responses will be conducted to see whether any profile types emerge.

Mixed Analysis

Quantitative and qualitative data will be collected simultaneously using the convergent parallel design approach. The analyses will then be combined to meet the overall objectives of the study.

Ethical Considerations

The data collection and processing implemented in this research conforms to the *Commission nationale de l'informatique et des libertés* (National Commission of Informatics and Liberties) reference methodology MR-004 (research not involving human persons, studies, or evaluations in the health field).

An information note at the beginning of the questionnaire informs participants about the study, its objectives, its progress, the processing of personal data, and their rights. By completing the questionnaire, the participants implicitly agree to share their data for scientific purposes. For the interviews, the participants will give their oral consent.

Personal data will be processed to analyze the results of the research in relation to its objectives. The data collected will be recorded in a digital file that complies with several data security and confidentiality conditions. The data will be deidentified (ie, anonymized) using the following techniques: we have ensured that the nature of the response modalities is broad enough to prevent the recognition of the person who completed the questionnaire (such as age group and income group); we do not collect nominative data; and we assign a numerical identifier specific to the study to pinpoint the respondent that is known only to the research team.

No compensation will be offered to users for participating in the study.

XSL•FO
RenderX

Results

Recruitment is scheduled to begin in January 2024 and will conclude when the required number of participants is reached. Data collection is expected to be finalized approximately 7 months after recruitment, with the final data analysis programmed to be completed around December 2024.

Discussion

Difficulties and Limitations of the Study

The first difficulty concerning the quantitative part of the study could be linked to the recruitment of participants, given that participation in the study will be on a voluntary basis. Despite our efforts to aim at a wide dissemination at several navigation levels on *Santé.fr* (eg, thumbnail on the home page, contextual message block, end of an article, and thematic folder) to multiply access to the questionnaire, the response rate could prove to be too low to allow statistical analyses to be conducted. For the time being, owing to the different waves of the COVID-19 pandemic, the current pop-in dedicated to screening and vaccination against COVID-19 and appearing on any page after a few minutes of navigation could not be removed and replaced by a message presenting the study. It would therefore be advisable to provide maximum visibility for the study on *Santé.fr*; for example, a pop-in would make it possible to make the study visible to each user and thus increase the chances of response. Moreover, as Santé.fr users prefer to access the website on their mobile phones, if the study does not appear on the home page on mobile phones, the number of respondents could be insufficient can be used.

By contrast, people who feel uncomfortable using the internet could also have difficulties accessing the questionnaire. A lack of motivation or time to complete the questionnaire as well as a low interest in digital health topics and research could decrease the response rate to the study. Compensation for participating in the study could give users a reason to complete the questionnaire.

For the qualitative study too, the lack of sufficiently diverse respondents could be a challenge. In addition, the risk of social desirability bias in the interviewees' responses to the interviewer could be an issue.

Strength of the Study

This study would be the first of its kind in France and, more widely, in Europe to focus on the evaluation of a digital health information website according to users' socioeconomic position.

The study that we intend to set up is thus essential because it will make it possible to fill a gap in the existing literature. More precisely, it will allow us to discover the issues related to inequalities in access to, and the use of, digital technologies to obtain health information. This study will give an insight into the digital divide that accounts for the poor access to these digital health information services for people who do not have access to the necessary material conditions such as digital devices and an internet connection. This study will discover the social inequalities that affect the access, understanding, appraisal, and use of health information found on the internet, particularly among people with lower levels of education, income, and digital health literacy.

As access to health information on the internet is crucial for health decision-making and for people's empowerment, if inequalities in access are discovered by this study, then they may also be related to inequalities in the health status of social groups. It would therefore be important to ensure that all social groups have equal access to *Santé.fr*, a quality digital health information service offering reliable health information.

With regard to our research subject, using mixed methods is a relevant choice because it will allow us to combine quantitative methods (questionnaire) and qualitative methods (interviews and focus groups). The quantitative methods will make it possible to obtain an overview of access to *Santé.fr* and to measure specific indicators (access, understanding, appraisal, and use) that constitute the digital health literacy determinants. The combination of these 2 methods will give a complete and more accurate view of this evaluation through quantitative results and user experiences that may be influenced by users' socioeconomic position. Reasons for the use or lack of use can be obtained through the qualitative component of the study.

Directions for Future Research

This study could serve as a feasibility study for collecting data on the French population's habits regarding the use of the internet to access health information, which could be incorporated into general national health surveys for regular monitoring purposes as well as *Santé.fr* follow-up surveys.

Acknowledgments

The authors thank the public service of health information of the French Ministry of Health and Jérôme Wittwer from Bordeaux University. The authors also thank the Conseil Régional de Nouvelle-Aquitaine for its financial support (2017- 1R30222 - 00013233) as well as the Bordeaux University.

Authors' Contributions

ME, with IM's contribution and under the direction of VR, designed the protocol and the study design. ME, IM and VR elaborated the main conceptual ideas. ME, VR and IM developed the questionnaire and the interview guides. SD provided critical expertise on the statistical analysis plan. ME, VR and IM wrote the manuscript. All authors contributed to finalizing the manuscript and read and approved the final version. VR and IM supervised all the steps involved in elaborating the protocol and the manuscript. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: The COVID-19 pandemic revealed that with high infection rates, health services conducting contact tracing (CT) could become overburdened, leading to limited or incomplete CT. Digital CT support (DCTS) tools are designed to mimic traditional CT, by transferring a part of or all the tasks of CT into the hands of citizens. Besides saving time for health services, these tools may help to increase the number of contacts retrieved during the contact identification process, quantity and quality of contact details, and speed of the contact notification process. The added value of DCTS tools for CT is currently unknown.

Objective: To help determine whether DCTS tools could improve the effectiveness of CT, this study aims to develop a framework for the comprehensive assessment of these tools.

Methods: A framework containing evaluation topics, research questions, accompanying study designs, and methods was developed based on consultations with CT experts from municipal public health services and national public health authorities, complemented with scientific literature.

Results: These efforts resulted in a framework aiming to assist with the assessment of the following aspects of CT: speed; comprehensiveness; effectiveness with regard to contact notification; positive case detection; potential workload reduction of public health professionals; demographics related to adoption and reach; and user experiences of public health professionals, index cases, and contacts.

Conclusions: This framework provides guidance for researchers and policy makers in designing their own evaluation studies, the findings of which can help determine how and the extent to which DCTS tools should be implemented as a CT strategy for future infectious disease outbreaks.

KEYWORDS

contact tracing; digital tools; citizen involvement; COVID-19; infectious disease outbreak; framework; mobile phone

Introduction

Background

One of the most essential strategies to help mitigate the spread of infectious diseases is contact tracing (CT) [1], which was the driving strategy leading to the global eradication of smallpox and is still used to control the transmission of infectious diseases, such as the regularly resurging Ebola [2]. Studies conducted during the COVID-19 pandemic have also shown CT to be effective in preventing a substantial number of new infections [3,4]. CT traditionally consists of 3 phases: identification (first

XSL•FO
RenderX

phase) and notification (second phase) of the contacts of individuals with COVID-19 and monitoring the health (third phase) of individuals with COVID-19 and their contacts. These tasks are generally conducted by public health services (PHSs) that are responsible for CT in many countries.

In 2020, the new SARS-CoV-2 coronavirus led to an unexpected global disruption at various levels, owing to the substantial morbidity and mortality it caused and the ease at which it spread. Although the Netherlands and many other Western countries were previously designated as being within the most prepared tier for handling epidemics and pandemics [5], the COVID-19 pandemic exposed weaknesses in the ability to contain the spread of the virus even within this tier. As has been reported in many countries worldwide, the high infection rates have caused CT for COVID-19 to be labor-intensive and time-consuming, and health services have been overwhelmed [6,7]. The potential of digital tools to rapidly access and transmit information to large numbers of individuals is being explored and used as ways to help contain the spread of the coronavirus and reduce the burden on overwhelmed health services [8,9].

Proximity-Based Apps

Given the increased use of smartphones, many mobile apps have already been developed for detecting those who have been in close proximity to and possibly exposed to a person with an infection [9]. The first such well-known app for COVID-19 was developed in Singapore (TraceTogether) [10]. This app and many other apps that were subsequently developed, including the Dutch CoronaMelder [11,12], use Bluetooth, Wi-Fi, or GPS to detect individuals who have been in close proximity to those who have contracted COVID-19 within a critical time frame of infectiousness [13,14]. Positive effects of proximity-based apps in containing the virus have mainly been shown by modeling studies, and a few real-life studies have found some promising preliminary results when comparing Bluetooth-based and other proximity-based apps with traditional CT [15-17]. Using such apps may identify at least twice as many infected cases as traditional CT does and could potentially help to avert hundreds of thousands of positive cases owing to the feature of being able to notify individuals who are presymptomatic [18]. However, proximity-based apps require a high adoption rate by the general population (irrespective of whether they are infected with SARS-CoV-2) to be effective. Besides privacy concerns [19-21] and interoperability issues between countries [22,23], however, there are practical implications and expectations from citizens to be effective, such as needing to carry a smartphone wherever one goes, continually keeping Bluetooth on, and correctly following the instructions and abiding by the measures upon receiving a notification of having been in contact with a positive case. As the data from these proximity-based apps are generally not shared with health services conducting CT, these apps do not directly alleviate the burden of traditional CT experienced by public health professionals (PHPs). PHPs will still not have insight into the contacts that have been identified and who need to be informed and will therefore still need to conduct CT as usual when they have contact with positive cases (henceforth, referred to as index cases).

Digital CT Support Tools

To complement traditional CT and proximity-based apps in helping to contain the virus, there are other types of tools that have been developed and are continuing to be developed. These tools are referred to as digital CT support (DCTS) tools and enable citizens to assume at least some of the tasks required for traditional CT. As has been reported with proximity-based apps, people may also have some privacy concerns, regarding the privacy of their own and their contacts' personal data in the tool and what happens when these data are transmitted to the PHP conducting CT. When compared with traditional CT and proximity-based apps, DCTS tools offer unique advantages. They can alleviate the work of PHPs, by potentially shortening the time needed in traditional CT to collect contact details from them over the phone and to notify their contacts. Other possible benefits are more time for index cases to be able to recall more contacts they may have exposed and higher chance of recording more accurate contact details, compared with when sharing this information during a phone call with the PHP. Depending on the national CT measures being implemented, index cases may also notify and convey the correct instructions to their contacts more rapidly than if this responsibility is left to PHPs. A functionality in the tool that enables the index case to indicate to the PHP which contacts have already been notified would save PHPs time in having to reach the contacts themselves. DCTS tools that enable index cases and contacts to assess and monitor their own symptoms are already well known; in some cases, they can send these data to PHPs for further support, thereby contributing to the monitoring phase (third phase) of CT [24-26]. Much less attention has been given to DCTS tools that mimic the first 2 phases of CT: identification and notification of contacts.

During the COVID-19 pandemic DCTS tools were developed that had proximity-based and contact diary features where index cases themselves could actively collect their contacts and their contacts' personal details [27]. Once this information had been gathered by the index case, they could choose to share it with a PHP. An app developed in the Netherlands (GGD Contact app), for example, had an interactive functionality enabling index cases to directly receive data from and share data with the municipal PHSs that are tasked with CT [28]. Data collected by the index case (eg, the test date and information about contacts) could be transmitted directly into the case management system used by the PHPs conducting CT, theoretically saving data entry time for the PHP. Another functionality in this app enabled the index case to retrieve contact details, such as telephone numbers, directly from the standard contact list already stored on their mobile phone.

When using such a DCTS tool during the first phase of CT, the index case recalls the contacts whom they may have exposed to the virus and enters information into the tool (eg, website or app) about the type of contact (eg, whether the contact is a partner or household member); nature of the meeting with the contact (eg, whether they were closer than 1.5 meters for >15 min); and finally, their contact details, such as telephone numbers and email addresses. The index case can then share this information with the PHPs conducting CT. During the second phase of CT, the index case or the PHP informs the

XSL•FO
RenderX

contacts about their possible risk of infection and provides them with instructions about the steps to take to mitigate the further spread of infection (eg, to quarantine). Instructions may be provided in these DCTS tools customized to the type of contacts identified by the index case; these instructions can subsequently be shared by the index case with the relevant contacts. The index case can also use this DCTS tool to indicate which contacts they have notified and have provided with instructions. This information can also be shared with the PHP.

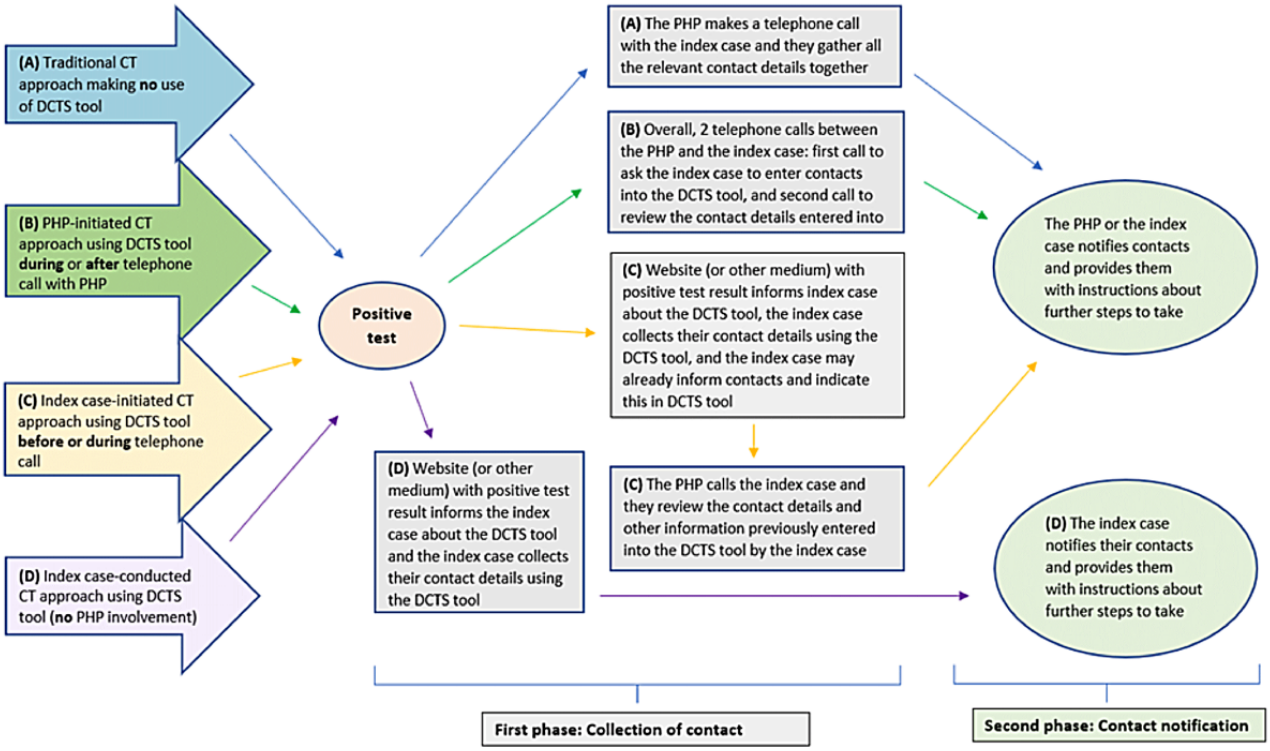
Besides the traditional CT approach (approach A in Figure 1), we distinguish 3 main approaches representing differing levels of citizen involvement that could potentially be taken with respect to DCTS tools for this process (approaches B to D in Figure 1). In traditional CT (approach A), the PHP plays the greatest role and the index case plays the smallest role. Going from approach B to approach C and finally approach D, the efforts of the index case in the CT process increase.

In approach B, using DCTS tools (PHP-initiated CT), the PHP calls the index case to start the CT process. Together, they complete a questionnaire to gather relevant demographic and medical details about the index case. The index case is then asked if they are willing to enter their relevant contact details into the DCTS tool, such as a designated website or app. The PHP and index case arrange a new appointment shortly afterward to review the contacts that have been provided by the index case, to determine whether additional information is needed and to agree on who will inform the contacts and provide them with instructions about further steps to take.

In approach C, using DCTS tools (index case–initiated CT) may be more efficient for CT (eg, alleviating the burden experienced by PHPs and increasing the speed of CT), as the index case is made aware of the DCTS tool before the call with the PHP during which the CT process is initiated. The designated medium to communicate test results to citizens (such as a website or email) can direct index cases to enter their contact details into the DCTS tool. This information is then ready to be discussed and shared digitally before the call with the PHP. This approach could lead to increased accuracy in contact details (such as telephone numbers), as these will not be conveyed verbally during the phone call. During the call, the provided information can be checked; additional details can be shared, if necessary; and further steps can be discussed.

In approach D, using DCTS tools (index case–conducted CT), the entire CT process is transferred into the hands of citizens or at least to a selection of citizens with low risk. In this situation, there is no contact at all between the PHP and the index case. The index case independently uses the DCTS tool to help recall and notify relevant contacts about their possible exposure risk and provides contacts with appropriate instructions already programmed in the tool. This could potentially free up time for PHPs to focus on index cases with greater health risks or with limited access to DCTS tools. This approach may be beneficial if the virus variant is very infectious (leading to high numbers of index cases) but relatively less severe with regard to its effects on morbidity and mortality.

Additional features of DCTS tools could facilitate the recording of events that the index case had attended or venues they had visited during the period that they were infectious, where they may have exposed groups of people. This recording of events could occur by various means, each varying in terms of privacy and ease of use, including digital tracking of attendees, scanning of a QR code by attendees, or self-reporting by index cases. Information regarding the event, such as its name, location, and address; phone numbers; time it occurred; and how many people were possibly exposed could be recorded. These details could be transmitted to the PHP conducting CT or directly to a representative of the event, so that they could alert the other attendees about their exposure risk.



Irrespective of the extent of PHP involvement, enabling the index cases to notify their contacts and provide them with instructions themselves may lead to an earlier awareness and more rapid action by contacts, compared with traditional CT, and ultimately mitigate the further spread of the virus. This type of technology requires more effort by citizens; however, its success will depend heavily on the ability and willingness of citizens to actively contribute in this manner, by mimicking the traditional CT process in a digital way.

It is currently unknown whether DCTS tools that encourage citizens to support the CT process (approaches B to D) could contribute to a more effective and efficient CT process; reduce the workload of PHPs; and ultimately, help to mitigate the spread of infectious diseases, such as COVID-19. It is therefore important that evaluations are performed to determine empirically the added value for public health with respect to the current COVID-19 pandemic and potential future infectious disease outbreaks.

Frameworks about how to evaluate proximity-based apps and the effectiveness of CT in general have been published already [29-31], but none, to the best of our knowledge, have been published about how to assess the effectiveness of DCTS tools. This paper presents a framework for how DCTS tools can be assessed when compared with traditional CT, with regard to various important factors that are necessary to curb the transmission of infectious diseases, such as increasing the speed and comprehensiveness of the CT process and relieving the burden on PHPs. This framework may be useful for researchers and policy makers to help determine the extent to which DCTS tools would have a positive impact on CT during future infectious disease outbreaks and to make evidence-based decisions regarding the implementation of these tools (eg, in conjunction with traditional CT and proximity-based apps).

Methods

Overview

The evaluation framework was developed by researchers from the National Institute for Public Health and the Environment (*Rijksinstituut voor Volksgezondheid en Milieu*; RIVM) in the Netherlands, in collaboration with municipal PHSs conducting CT. The idea for a framework for DCTS tools was partly based on an evaluation model that was developed for measuring the effectiveness of the Dutch proximity-based app [32]. A team of scientific experts from various disciplines including infectious disease control, epidemiology, health behavior, data privacy, and technical innovations was established to provide advice to the research team conducting the study. Evaluation topics and accompanying research questions were formulated to assess the potential effects of using the Dutch DCTS tool. These topics and their rationale were based on the experiences of PHPs and the CT indicators already developed by infectious disease experts at RIVM [33]. A previous concept of the framework was presented several times to various expert groups, including the Ministry of Health, Welfare, and Sport and medical nurses and physicians specialized in infectious diseases, who were working in the municipal PHSs. They provided feedback and suggestions leading to adjustments in the framework. The framework was further refined and developed into this research paper by reviewing the relevant international and national scientific literature on CT.

In this paper, the evaluation topics and research questions have been embedded within an outcome evaluation and a process evaluation, which are considered to be beneficial for evaluating the effectiveness, efficiency, validity, and usability of an intervention [34]. The research questions formulated under the *Outcome Evaluation* section are designed to measure the effects of the DCTS tools on CT, including the number of contacts identified and informed, speed at which this process occurred, accuracy and comprehensiveness of the information provided, number of positive cases detected among contacts, and actual time spent by PHPs on CT when these tools are used. The research questions formulated in the *Process Evaluation* section are designed to examine whether the DCTS tool was used as intended by index cases and PHPs and to expose any unintentional factors influencing its effectiveness. The process evaluation consists of examining the adoption rate of the tool; demographics of the users of the tool and those of their contacts; and user experiences of index cases, their contacts, and PHPs.

First, we discuss some legal, ethical, and technical issues to be considered before the evaluation study can be conducted. Next, we present the finally established framework containing the evaluation topics, research questions, and rationale behind each of them. In addition, we suggest and describe the potential study designs, methods, and measures that may be used to explore and answer the research questions (Multimedia Appendix 1). Finally, we discuss the implications of the framework for various types of future infectious diseases.

Legal, Ethical, and Technical Feasibility

Overview

Before starting an evaluation process, it is important to explore the legal, ethical, and technical possibilities when it comes to collecting citizen data, transferring the data to a research data management system, and analyzing and storing the data. The use of technology in general is increasing rapidly, and increasing

XSL•FO
RenderX

amounts of personal data are being shared globally to help organizations improve their services, reach more clients, and generate more income. This flow of data also comes with the risk of misuse and theft of personal information. Even during emergency situations leading to substantial morbidity and mortality, it is broadly considered important that any type of CT and the collection and storage of personal information is conducted in an ethically responsible and secure manner and that individuals' data are protected [35]. Various countries and regions have legal frameworks in place for the handling of personal data, including the Personal Information and Electronic Documents Act in Canada, Health Insurance Portability and Accountability Act in the United States, and General Data Protection Regulation (GDPR) in Europe [36].

Legal Feasibility

If a digital intervention such as the DCTS tool is implemented, there should be transparency to the public about how their data will be used and if and how the data will be transmitted to a centralized CT system, protected from hacking, and stored safely [37]. There are established laws when it comes to citizens sharing their personal data. When index cases in the Netherlands download the DCTS tool, for example, they are required to indicate that they have read the terms and conditions, which include the use of their personal data. These state that the use of personal data is necessary in the interests of public health and that these data are handled in accordance with GDPR [38]. They also state that the data sent and received by the users are encrypted and conveyed via a secure server. Users are informed that they can send and receive data for up to 48 hours after the DCTS tool is activated. They are notified that their data will be deleted after 2 weeks from the web portal (that is linked to the centralized database). They are also informed that they are not obligated to provide personal information but that doing so will serve the process of CT.

Ethical Feasibility

In a similar manner to providing data for CT, there must be transparency and clear communication to individuals regarding which personal data will be used by researchers in the evaluation study, how their data will be transferred to a research database, how secure the database will be from hacking and misuse, how long the personal data will be stored before deletion, what data will be anonymized, and how the data will be used for evaluation purposes. There must be good collaboration with the health services collecting these data from index cases to ensure that all parties understand the purpose and relevance of conducting the evaluation study. Judicial advice must be sought regarding the ethics of obtaining limited personal data that are collected by health services for purposes other than CT, such as research, as stated in article 6 (4) of GDPR and how these data can best be anonymized. Morley et al [39], for example, have considered these aspects when it comes to implementing proximity-based apps, by developing guidelines consisting of 16 questions to be answered, to help ensure their ethical justification.

Technical Feasibility

In conducting evaluation studies, researchers will be dependent on the stability and consistency of the data that are obtained from the digital tool. However, technology is constantly changing; the tool they plan to evaluate may have changes to its algorithms, features removed or added, or updates made, or its implementation may even be discontinued [40]. It is therefore important that potential barriers are anticipated and that there are contingency plans in place during the writing of their research protocols. As the data collected for CT will pertain to potentially millions of people, it will be of practical importance to consider, before starting the evaluation, how this vast amount of data can best be transmitted, stored, organized, and analyzed for research purposes and who should be able to access the data. The advice of cybersecurity experts will be essential to ensure that the data provided by index cases are safe and protected. Ideally, the principles of the Privacy by Design approach should be adhered to, where privacy is assured by default within the design of IT and data storage systems, throughout each phase from data collection, transmission, storage, and elimination [41].

Ethical Considerations

The development of this study framework did not involve human participants. This study is part of the larger project Strategic Program of the RIVM (SPR IZB2.0 S/070008), which was conducted in accordance with the Declaration of Helsinki—Ethical Principles for Medical Research involving Human Subjects. Ethical clearance was obtained from the Medical Ethics Review Committee of the University Medical Centre Utrecht. The Committee confirmed that the Medical Research Involving Human Subjects Act (WMO) does not apply to this project (reference 21/062).

Results

Framework and Rationale Behind Evaluation Topics

In this section, we have first presented the evaluation framework in Table 1. It contains an overview of the evaluation topics and research questions, divided into an outcome evaluation and a process evaluation. The rationale behind each of these evaluation topics and research questions has been discussed. Tables S1 and S2 in Multimedia Appendix 1 contain potential study designs, methods, and other considerations that may be helpful for examining the research questions.

XSL•FO
RenderX

Table 1. Outcome and process evaluation framework for comparing the use of digital contact tracing support (DCTS) tools (approaches B to D) with traditional contact tracing (CT; approach A)[a].

Evaluation topics	Research questions
Outcome evaluation	
Speed	What are the effects of DCTS tools (approaches B to D) when compared with traditional CT (approach A) regarding the length of time between the positive test result and having notified all relevant contacts about the further steps to take?
Comprehensiveness	What are the effects of DCTS tools (approaches B to D) when compared with traditional CT (approach A) regarding the number of contacts and the completeness of contact information provided by the index case?
Contact notification	What are the effects of DCTS tools (approaches B to D) when compared with traditional CT (approach A) regarding the proportion of contacts notified and provided with instructions?
Positive case detection	What are the effects of DCTS tools (approaches B to D) when compared with traditional CT (approach A) regarding the number (and proportion) of positive cases detected among identified contacts?
PHP[b] workload	What are the effects of DCTS tools (approaches B to D) compared with traditional CT (approach A) when it comes to time, effort, and human resources?
Process evaluation	
Diverse demographic adoption and reach	How do demographic groups differ with regard to those who adopt DCTS tools (approaches B to D) and those who experience traditional CT (approach A) among (i) index cases and (ii) contacts who are reached by PHPs and by means of these tools?
Experiences of index cases	What are the experiences and views of index cases regarding DCTS tools (approaches B to D) when it comes to aspects such as their usability, effectiveness, and information security? Why do some index cases choose not to use these tools?
Experiences of contacts	What are the contacts' views toward and experiences with receiving instructions from the index case? What CT approaches (A to D) do contacts prefer? To what extent do contacts adhere to the instructions?
Experiences of PHPs	What are the experiences and views of PHPs conducting CT with DCTS tools (approaches B to D) with respect to aspects such as their usability? What are PHPs' views about leaving the CT process completely in the hands of index cases?

[a]For each question, the various approaches to using this technology can be compared (Figure 1).

[b]PHP: public health professional.

Outcome Evaluation: Evaluation Topics and Rationale Behind the Research Questions

Speed: Effectiveness of DCTS Tools in Terms of the Duration of the CT Process

Some infectious agents, such as the virus leading to COVID-19, can spread extremely quickly from one person to another, which makes it important that those at risk are identified as quickly as possible, preferably before symptoms occur, to prevent them from inadvertently spreading the virus to others. A systematic review and meta-analysis revealed that the average incubation periods for COVID-19 caused by the Alpha, Beta, Delta, and Omicron variants were 5, 4.50, 4.41, and 3.42 days, respectively [42]. Considering that one can be infectious from 2 days before symptoms appear, identifying the contacts of a person who has tested positive must be done as quickly as possible. A DCTS tool may enable the rapid retrieval of existing contact details stored in the standard contact list on a mobile phone or the index case can enter the contact details manually into a DCTS tool. As index cases can inform their contacts themselves and send them customized guidelines using the DCTS tool according to the type of contact, the contacts may be informed either before or shortly after the call with the PHP with the correct information. It is plausible that DCTS tools may, therefore, help to save time and lead to contacts testing themselves for COVID-19 immediately, seeking medical help, going into quarantine, or being aware of exposure to and possibly having acquired the virus. In contrast, index cases may be unable, hesitant, or unwilling to notify their contacts themselves, which would lead to contacts not being aware of their exposure on time and possibly spreading the virus to others. It is therefore important that the time between receiving the positive test result and having notified all relevant contacts is evaluated. The average duration of the CT process can be compared among those using the various DCTS tool approaches (approaches B to D) and those experiencing traditional CT (approach A).

Comprehensiveness: Effectiveness of DCTS Tools in Terms of the Number of Contacts Identified and the Completeness of the Information Provided

For CT to be effective, it is important that no exposed contacts or at least as few as possible are left unidentified or with missing contact details. The potential number of contacts identified will likely depend on the memories of index cases, their willingness to share contact details, availability of these contact details, and ease with which these details can be shared [43]. The average numbers of contacts shared by index cases will also possibly be influenced by public precautionary measures implemented at the time of the study, such as working from home or avoiding too many visitors. PHPs may be trained to ask index cases the right questions while conducting traditional CT to elicit as many contacts as possible. However, it is also plausible that the use

XSL•FO
RenderX

of DCTS tools may buy more time for index cases to calmly jog their memories and remember everyone they have recently encountered. This may lead to them remembering more contacts than they would have with traditional CT and to retrieving more accurate contact details, such as telephone numbers and email addresses. It would be beneficial, therefore, to compare the number of contacts (with complete and accurate information) between those using DCTS tools (approaches B to D) and those undergoing the traditional CT process (approach A).

Contact Notification: Effectiveness of DCTS Tools in Terms of the Proportion of Contacts Notified and Provided With Instructions

Solely collecting a list of contacts and sufficient contact details will not ensure effective CT. Contacts also need to be notified and provided with instructions about what steps to take. Although there are contacts that will appreciate being notified about their possible exposure, index cases may have concerns about causing discomfort for them, by notifying them about the steps they need to take [44]. Having to quarantine can be associated with negative feelings, such as anxiety, loss of freedom, loneliness, anger, and boredom and can have a financial impact [45,46]; thus, conveying instructions to contacts who may not have been infected will not be an easy task. Index cases may also feel hesitance in notifying contacts themselves, owing to possible stigma and feelings of shame. In contrast, index cases may prefer notifying their contacts themselves, owing to hesitance in sharing personal contact details with the PHP. The more contacts that are notified and informed with instructions, the more likely the virus can be controlled. It is important, therefore, to evaluate DCTS tools (approaches B to D) by examining the number of contacts that are notified and provided with instructions, compared with traditional CT (approach A).

Positive Case Detection: Effectiveness of DCTS Tools in Terms of Detecting Positive Cases Among Contacts

The main aim of CT is to identify infected cases before they have the chance to transmit the virus to others. Measuring the ability of a CT strategy to identify the number of contacts who have contracted the virus is therefore important to determine how effective it is [47]. For the same reasons described previously, an increased number of contacts may or may not be notified earlier with the help of DCTS tools, compared with traditional CT. It is plausible that if more contacts are notified earlier, they will also take a self-test or be tested by the PHS immediately, and greater number of positive cases will be identified sooner. If the DCTS tool has such a functionality, it may enable the identification of contacts who become new index cases by matching identical identification numbers. It would be beneficial to examine whether DCTS tools (approaches B to D) have any value compared with traditional CT (approach A) with respect to the average number and proportion of identified contacts per index who have tested positive for the infectious agent, such as SARS-CoV-2.

PHP Workload: Effectiveness of DCTS Tools When It Comes to Time Spent by PHPs, Effort, and human resources

CT during the COVID-19 pandemic has required huge amounts of resources (in terms of staff, time, and required efforts) to keep up with cases and to conduct CT thoroughly [6]. The consequences can be that those conducting CT are overburdened and have less time to conduct CT comprehensively and for other health care tasks. In many countries, individuals from other professional fields, medical students, and volunteers have been trained to work as contact tracers to keep up with the number of infected cases [7]. It is unknown what the effects would be on the PHP workload if the index case, using a DCTS tool, takes over part of the process by identifying their own contacts, collecting contact details, and then informing the contacts themselves. Although there could be some work for PHPs, if they need to check whether contacts have indeed been notified and provided with the correct instructions, for example, in theory, the index case conducting most CT themselves could save time for PHPs and possibly lead to a more comprehensive and effective CT process. This could also reduce the need for more human resources and having to hire individuals from other fields with limited experience in CT and leave those who can conduct CT skillfully to handle the groups that have higher risk and are more vulnerable.

Process Evaluation: Evaluation Topics and Rationale Behind the Research Questions

Diverse Demographic Adoption and Reach: Differences Between Demographic Groups of Index Cases and Contacts Across the Various CT Approaches

Ideally, DCTS tools will appeal to and be of use to all relevant segments of the population in terms of, for example, age, ethnicity, education, income, and health status. The use of digital technology, however, tends to be associated with and is easier to use for younger, more highly educated, wealthier, and healthier people [12,48,49]. There are some sociodemographic disparities when it comes to contracting the SARS-CoV-2 infection, degree of experiencing severe respiratory disease after contracting the virus, and mortality owing to the virus, all to the disadvantage of older people, ethnic minority groups, and those with lower incomes [50-52]. Although the Netherlands, for example, is a wealthy country with relatively little income inequality compared with many other countries, a study using national statistics data covering the early months of the pandemic (March 2020 to June 2020) found that those with the lowest incomes were twice as likely to die from COVID-19 as those with the highest incomes [53]. It will be beneficial to take all these sociodemographic factors into account when assessing the effectiveness of DCTS tools. It is also plausible that such a tool facilitating more citizen autonomy in CT could enable index cases to be a bridge to those in sociodemographic groups that are normally hard to reach when it comes to health care. In instances where traditional CT is being conducted alongside the use of DCTS tools, it is also possible that mainly low-risk index cases will conduct CT themselves with the DCTS tool, leaving more time for PHPs to focus on traditional CT with higher-risk groups. Regardless of the effects of the DCTS tool,

XSL•FO
RenderX

it is advisable to examine whether DCTS tools can contribute to diminishing the health disparities caused by the infectious disease.

Experiences of Index Cases: Experiences and Views of Index Cases Regarding DCTS Tools When It Comes to Aspects Including Usability, Effectiveness, and Information Security

The success of CT by means of such DCTS tools will depend on the ability and willingness of index cases and PHPs to actively participate in and support the CT process. Supporting and motivating individuals to be involved will be key to making CT with DCTS tools effective. It will be of interest to examine the views of index cases toward becoming more involved in the CT process as a citizen and what they think about using DCTS tools to facilitate this process.

Traditionally, two main types of citizen involvement have been distinguished: (1) patient participation, in which a person contributes to their own health care, and (2) public participation, where a person contributes to the health care of others in the public domain [54]. The type of participation required for DCTS tools appears to have some elements of both types. Using this technology requires that index cases not only assist in their own care and those close to them but also contribute to protecting public health by actively helping to contain the infectious disease. Some benefits associated with citizen participation in health care are increased empowerment, improved patient experience, lower health costs, and decreased burden on and improved health care services. One review reported that although many people felt a collective responsibility to participate in CT for infectious diseases, including COVID-19, there was also some mistrust and concerns about their privacy [55]. This review concluded that individuals appeared to be motivated by contributing to public health in general but especially if there was some personal benefit to it.

Besides gaining further insight into individuals' general feelings toward citizen involvement in CT, it will be important to examine the experiences and views toward using DCTS tools for this purpose. Such technology should ideally be considered user-friendly, useful, and sufficiently trustworthy for index cases to be willing to enter personal data and details pertaining to their contacts.

There are likely to be similar factors expressed by users of proximity apps that could also influence the adoption of DCTS tools, such as privacy and trust issues, perceived personal and social benefits, and perceived ease of use [56], but there may also be other experiences to explore that are unique to users of DCTS tools. To gain further understanding of these experiences, it is important to hear from both the users of the tools themselves and from those who are unable or have chosen not to use them.

Experiences of Contacts: Experiences and Views of Contacts Regarding the Various CT Approaches When It Comes to Receiving and Following Instructions

Involving citizens more in the CT process depends not only on the ability and willingness of index cases but also on the ability and willingness of contacts to be notified and to follow the instructions. Contacts may have questions about or disagree with the instructions or feel they cannot follow them and may need additional support from PHPs [57]. Contacts may also prefer being notified verbally instead of digitally or may not appreciate being notified by an index case instead of a PHP. A previous Dutch study conducted among PHPs before the COVID-19 pandemic showed that although PHPs recognized the potential of a digital system in which index cases could play a large role in identifying and informing their contacts, there was some concern that contacts may not be provided with the correct instructions, that the contacts would not take these instructions seriously if they did not come directly from a PHP, or that contacts may be left with unanswered questions and worries that could best be discussed with a PHP [58]. It is essential to examine whether the manner in which contacts receive instructions affects their feelings toward and acceptance of these instructions and their ability to follow them.

Experiences of PHPs: Experiences and Views of PHPs Regarding DCTS Tools, Including Their Usability and Transferring the CT Process Into the Hands of Citizens

As PHPs conducting CT have traditionally played the largest role in this process, their opinions about transferring all or a part of the CT process into the hands of citizens will be invaluable. They can be asked about their views regarding the willingness and ability of index cases to identify all relevant contacts and provide them with the correct information. According to a joint World Health Organization and European Centre for Disease Prevention and Control meeting report, countries anticipate that the CT of the future may require an approach that is more focused on groups that are vulnerable and at high risk [59]. PHPs may need to play an important role in determining which index cases can assume the CT role themselves with DCTS tools and which index cases would benefit more from traditional CT. Gaining some insight into how they will make these decisions, how they may encourage index cases to use the DCTS tool, and their views in general about involving citizens more in CT will be beneficial. It will also be important to examine their views regarding the usability (including user-friendliness) of DCTS tools; they can be asked about the features needed in DCTS tools to maximize their adoption by index cases. To provide context for and help to explain their views, it will be helpful to collect personal PHP characteristics. Their age and how long they have been conducting CT, for example, may influence their views in general about using new technology.

Study Designs

To conduct the evaluation of DCTS tools, it is important to consider appropriate study designs and methods by which these study questions could be answered as optimally as possibly, despite the backdrop of a pandemic. The varying types of research questions will require a mix of study designs that need to be combined to answer all those questions. Some questions will require the quantitative examination of data collected from CT case management systems. These data may be obtained from centralized case management systems used by PHPs for CT or they may come from more decentralized databases collecting data from DCTS tools at a more local level, bypassing

XSL•FO
RenderX

PHS. Other research questions will require the quantitative and qualitative assessments of information provided by users of DCTS tools themselves (index cases and PHPs) and their contacts, by means of surveys or interviews. In Tables S1 (outcome evaluation) and S2 (process evaluation) in Multimedia Appendix 1, study designs, methods, study measures, and relevant points of consideration are proposed, to answer each of the research questions outlined in the framework.

Discussion

Summary

The aim of this study was to develop and present a framework containing a set of research questions and accompanying study designs that may be valuable for a complete assessment of the identification and notification of contacts in CT using DCTS tools. Our framework is divided into an outcome and a process evaluation that assess the effects of DCTS tools, when compared with traditional CT. For the outcome evaluation, relevant topics to examine are the speed and comprehensiveness of the CT process, proportion of contacts who are notified and provided with instructions, proportion of contacts who test positive, and PHP workload (in terms of time, effort, and human resources). For the process evaluation, it is important to examine the demographics of those using the tools when compared with those who experience traditional CT and hear about the personal experiences of index cases, contacts, and PHPs when it comes to using these tools.

DCTS tools combine the advantages of digital technology with the ability and willingness of citizens to play a role in protecting their own health and that of others by assuming all or a part of the CT process themselves. The main added value of DCTS tools for CT of COVID-19 was that citizens could alleviate the work of PHPs when there were high numbers of cases. These types of tools could be of benefit to curb other future infectious disease outbreaks with high infection rates. For smaller-scale infectious disease outbreaks, particularly those with short incubation periods or those that are very infectious (requiring rapid CT), those leading to large numbers of contacts (requiring time, memory, and accuracy by the index case to collect contact details), and those associated with stigma (requiring more discrete or anonymous CT), DCTS tools could also potentially be of value [44]. Infectious diseases such as mpox (monkeypox) and sexually transmitted infections may have some stigma attached to them, forming a potential barrier to sharing contacts' details with a PHP or notifying contacts [60-62]. DCTS tools can assist with partner identification and notification [63]. If index cases are uncomfortable with notifying contacts themselves or prefer to stay anonymous, contact details can be collected using the tool and shared with the PHP. The PHP can then reach out to the contacts and notify them, while enabling the index cases to remain anonymous. If index cases are concerned about sharing their contacts' details with the PHP, contact notification could bypass the PHP, and the tool could facilitate the notification of and provision of instructions to contacts by the index cases themselves. If index cases prefer to stay anonymous, they could inform their contacts anonymously using an additional feature in the tool.

DCTS tools could theoretically be customized to any infectious disease for which CT is conducted, for example, by containing disease-specific information to help cases identify potential contacts who are at risk of exposure and through notification messages to advise contacts about further steps to take. DCTS tools may have added value when it comes to CT and curbing a wide range of future infectious disease outbreaks, and this framework can be used to measure the extent to which they are effective.

Conclusions

This framework was developed to help researchers and policy makers design studies for their own evaluation of DCTS tools. The findings of these evaluation studies can provide guidance in determining how and the extent to which DCTS tools should be implemented as part of the CT strategy used for future infectious disease outbreaks.

Acknowledgments

The authors acknowledge the Strategic Program of the National Institute for Public Health and the Environment [*Rijksinstituut voor Volksgezondheid en Milieu* (RIVM); SPR IZB2.0 S/070008] for its funding. The funder had no role in the design of the study; collection, analysis, and interpretation of the data; and writing of the manuscript. The authors would also like to acknowledge the expert groups from the Ministry of Health, Welfare, and Sport and physicians working in municipal public health services for their insights and contributions to this study. The authors are also grateful to Akke van der Meer, Irene Veldhuijzen, and Rosa Joosten for their helpful feedback to and discussions regarding the study.

Authors' Contributions

RB, NH, YBH, RC, HMG, and MLS played substantial roles in the design of the study and in the writing of the manuscript. RB drafted the manuscript and incorporated all further feedback. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: While digital health innovations are increasingly being adopted by health care organizations, implementation is often carried out without considering the impacts on frontline staff who will be using the technology and who will be affected by its introduction. The enthusiasm surrounding the use of artificial intelligence (AI)–enabled digital solutions in health care is tempered by uncertainty around how it will change the working lives and practices of health care professionals. Digital enablement can be viewed as facilitating enhanced effectiveness and efficiency by improving services and automating cognitive labor, yet the implementation of such AI technology comes with challenges related to changes in work practices brought by automation. This research explores staff experiences before and after care pathway automation with an autonomous clinical conversational assistant, Dora (Ufonia Ltd), that is able to automate routine clinical conversations.

Objective: The primary objective is to examine the impact of AI-enabled automation on clinicians, allied health professionals, and administrators who provide or facilitate health care to patients in high-volume, low-complexity care pathways. In the process of transforming care pathways through automation of routine tasks, staff will increasingly "work at the top of their license." The impact of this fundamental change on the professional identity, well-being, and work practices of the individual is poorly understood at present.

Methods: We will adopt a multiple case study approach, combining qualitative and quantitative data collection methods, over 2 distinct phases, namely phase A (preimplementation) and phase B (postimplementation).

Results: The analysis is expected to reveal the interrelationship between Dora and those affected by its introduction. This will reveal how tasks and responsibilities have changed or shifted, current tensions and contradictions, ways of working, and challenges, benefits, and opportunities as perceived by those on the frontlines of the health care system. The findings will enable a better understanding of the resistance or susceptibility of different stakeholders within the health care workforce and encourage managerial awareness of differing needs, demands, and uncertainties.

XSL•FO
RenderX

Conclusions: The implementation of AI in the health care sector, as well as the body of research on this topic, remain in their infancy. The project's key contribution will be to understand the impact of AI-enabled automation on the health care workforce and their work practices.

Introduction

Background and Rationale

There has recently been a rise in the use of artificial intelligence (AI) and automated technologies within health care that come with the promise of increasing efficiency and improving clinical workloads [1]. These AI technologies are already being shown to perform tasks previously entirely within the scope of human clinicians, from reading scans to replacing entire clinical consultations [2-4]. Despite the potential for AI to result in organizationally valuable outcomes, research shows that this is not always the case [5]. Many organizations invest effort, resources, and time into emerging technologies yet do not experience desired results, ultimately deeming these initiatives unsuccessful. It is evident that for AI implementation to be successful, the interrelationship between individuals, technologies, and the system should be observed holistically. It is important to take this holistic view into account because, as with the industrial revolution or more recent waves of digitization, workers who experience their role directly impacted by automation or digitization can either be empowered to "work at the top of their license" or feel even further disempowered and left behind.

Investigating the impact of such technologies on individuals is paramount in the current context of the global health care workforce crisis. Clinicians' well-being is at risk, with studies to date showing that several factors can contribute to poor acceptance and adoption, leading to a negative impact on workloads and thus well-being. There are many definitions of well-being, and in this study, we define the term, in the context of the workplace (based on the Stanford Professional Fulfillment model) [6], as "the degree of intrinsic positive reward we derive from our work, including happiness, meaningfulness, contribution, self-worth, satisfaction, and feeling in control when dealing with difficult problems at work."

This has great implications given the burnout epidemic and is becoming increasingly important to address after the recent COVID-19 pandemic, which took an unprecedented toll on an already pressurized system [7-9]. Burnout has been described as a "work-related syndrome" commonly characterized by high levels of emotional exhaustion, depersonalization, and dissatisfaction with one's career and is associated with high turnover rates [10]. In this study, burnout is seen as an element within the broader concept of well-being when the negative impact on one's well-being is at its extreme. The World Health Organization (WHO) projects a global needs-based shortage of health care workers at over 14.5 million in 2030 [11]. This workforce shortage has been deemed the "biggest, most pressing threat to the viability of services for people who need them" within the National Health Service (NHS) [12]. A bidirectional link between burnout and medical errors resulting in clinician distress has been observed, while conversely, better physician well-being was associated with improved patient satisfaction, improved treatment, and lower rates of hospital-acquired infections [13]. Thus, it is essential to find ways to improve well-being, for the benefit of the individual clinician, for patient care and safety, and to reduce provider costs [6].

Electronic health records (EHRs) are one example of an innovative tool that promised to empower clinicians; however, they have ended up being the focus of multiple studies of technologies' negative impact on physician well-being [14,15]. The increased use of EHRs in health care organizations coincided with the need for prompt clinical data entry, and the lengthy and onerous clinical documentation process has been widely reported to have added to clinician frustration and, in many cases, been perceived to have added to administrative workload and time spent documenting rather than providing patient care [16,17]. Other dramatic changes in the ways clinicians work have been brought about with telemedicine [18], with studies also exploring the challenges of implementing AI, focusing on managers' or users' perspectives [19-21].

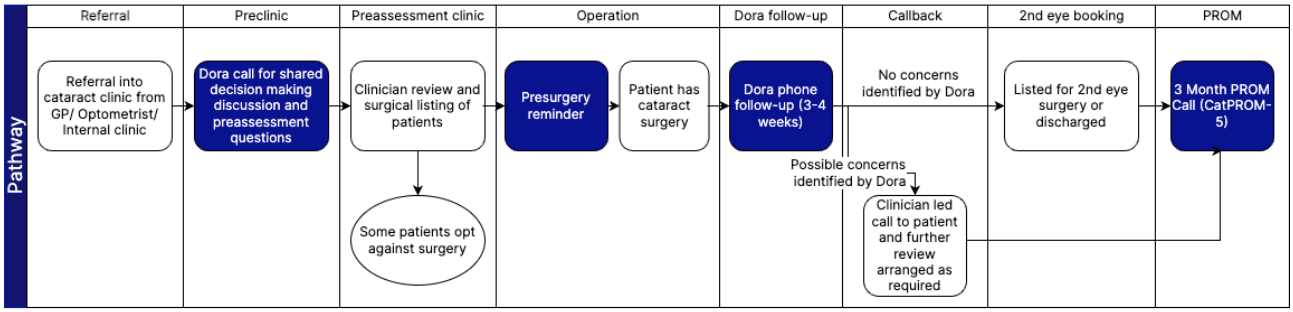
To date, research around burnout has mainly focused on doctors and nurses, with limited emphasis on other health care staff [22-24] and a holistic understanding of AI-enabled automation adoption. Some studies have shown several work system factors having a significant impact on predicting clinician burnout, including excessive workload, lack of job control through poor perceived autonomy and flexibility [11], misaligned values and expectations, lack of intrinsic motivation, and high administrative burden [9]. Other work system factors include workflow interruptions, poor technology usability that adds to the considerable workload and hinders workflow processes, moral distress, and time pressure. Recent research shows that health care staff perceive AI-driven tools to have the potential to help prevent burnout [25], and therefore, understanding the clinical environment and the impact of automation is crucial to improving the quality of care and patient safety.

The rising tide of AI-enabled digital health solutions places a growing emphasis on understanding the systemic impacts of implementing such technologies in health care and the

XSL•FO
RenderX

subsequent impact on individuals. This study seeks to explore how staff members are impacted before and after the implementation of an autonomous clinical conversation agent in a routine elective care pathway.

Intervention Used



This study will examine the impact on staff of the implementation of a UK Conformity Assessed-marked autonomous, voice-based, natural-language clinical assistant, "Dora" (Ufonia Ltd). Dora is simple and easy to use [3], as patients answer a telephone call they receive with no need for an internet connection, a smartphone, or a web interface. The technology can have a consultation with patients over the telephone, and thus the entire clinical conversation is tasked to Dora, which replaces the human conversation. For example, the key elements of a postoperative conversation in the cataract pathway with Dora are as follows:

- Greetings and introduction
- Confirmation of the identity of the patient
- Validated cataract follow-up questions
- Opportunity for the patient to ask Dora questions
- Decision regarding next steps of care
- Questions about acceptability (Net Promoter Score)
- Closure of the call

The technology has already demonstrated acceptability with patients in the cataract follow-up pathway, where it can reduce the number of patients needing a clinician-led consultation by up to 60% [3].

Clinicians do not use any new interface. The department simply lists patients for a Dora call. Once Dora has conducted the clinical conversation, the results are fed back to the clinical team, who receive outcomes through a static report that summarizes the key domains assessed and the resulting outcome. This report is usually in the form of either a structured PDF file or a CSV file, depending on the required workflow. The Dora call can be implemented at multiple time points along the cataract pathway, as demonstrated in Figure 1. Apart from the patient pathway demonstrated in the figure below, this study will aim to shed light on the extent to which tasks and work practices are transferred or redesigned as a result of the introduction of Dora.

Figure 1. Example of an end-to-end Dora patient pathway for cataract surgery. PROM: patient-reported outcome measures.

NHS South East (NHS-SE) has commissioned the regional use of Dora in the cataract pathway. Cataract surgery is the most common operation in the NHS, with over 450,000 procedures per year. Dora can have multiple conversations with patients, from preoperative assessment to postoperative review to assessing patient-reported outcome measures. The technology promises to automate these often stereotyped clinical interactions, potentially reducing the burden on clinicians multifold by replacing the conversation as well as automating the subsequent clinical documentation. In a pathway with Dora, rather than a clinician needing to consult every patient, only those with clinical concerns identified by Dora need a clinician review. This increases staff capacity while removing the stressors associated with repetitive routine conversations and administrative tasks such as documentation, targeting a major cause of clinician distress [26,27].

Theoretical Framework

It is acknowledged that perception is a significant indicator of organizational readiness. Technology adoption theories, such as the Technology Adoption Model and diffusion of innovation theory, consider perception as a predictor of acceptance and use. These theories identified that previous experience, knowledge, and user skill sets influenced technology adoption in health care. For example, health care professionals willingly accepted the technology into their practice if it was aligned with professional values, was easy to use, trusted, and improved job performance [28,29].

While these perspectives could yield valuable insights, the sociotechnical system (STS) approach adds another dimension by acknowledging the interdependencies existing between organizations, individuals, and technology. This study adopts the STS perspective as a theoretical framework to analyze the impact of AI-enabled automation on the health care workforce and their work practices. The STS approach considers an organization as a work system with 2 interconnected subsystems: the technical dimension and the social dimension. The interactions between these 2 systems together produce the outputs of a work system, creating economic outcomes such as

XSL•FO
RenderX

efficiency, productivity effectiveness, and cost reduction, in addition to humanistic outcomes such as well-being and engagement [30]. It is argued that performance is maximized only when the interdependence of these subsystems is explicitly recognized [31]. Sociotechnological studies on health care and technology implementation found that stakeholders hold different perspectives depending on their goals and expectations. For example, the organization's goal of addressing workload productivity or maximizing financial performance may be different from a health care professional's focus on improving patient outcomes and clinical decision-making. When introducing new technology into the health care industry, the challenge is determining the best method for comprehending the perceptions of all stakeholders. While the technical dimension of digital technologies and AI is currently dominating research studies, the impact on engagement, acceptance, and well-being of the individual is less well understood [25,30].

Methods

Study Design

To investigate the complex interactions between structures, people, organizations, technology, and contextually specific issues, a mixed methods research orientation will be adopted. This involves collecting, analyzing, and combining qualitative and quantitative data to obtain "complete analysis" [32,33] in understanding the relationship between technology and people and subsequent impact that cannot be fully understood by using a single methodology (ie, either qualitative or quantitative) [34,35]. Novel findings facilitate further investigation and expand the depth and scope of the data obtained. Furthermore, a mixed methods approach is suitable to answer both explanatory and confirmatory research questions.

The study will last for 12 months and consist of qualitative and quantitative data collection methods over 2 distinct phases, namely phase A (preimplementation) and phase B (postimplementation). Longitudinal data collection will assist in forming a richer understanding of the context, drawing further insights into how the change (ie, the intervention) impacts the workforce over time. The unit of analysis is the activity itself (the impact of AI-enabled automation on multiple stakeholders within the health care workforce), and within this focus of interest, tensions and contradictions will be identified and given particular priority and importance.

Participant Recruitment

We will perform a multiple case study analysis as it favors the collection of rich data in multiple contexts, and the methodology allows for cross-case comparisons to clarify if the findings can be applied to several cases or are idiosyncratic to a single case. This will take place at multiple NHS hospital trusts. These sites represent a varied geographical location, baseline operational processes, management structure, demographics, and volume of patients. According to Benbasat et al [36], leveraging the case study approach is valuable for "problems... in which research and theory are at their early, formative stages and sticky, practice-based problems where the experiences of the actors are important and the context of action is critical." Furthermore, multiple case study analysis enables the establishment of patterns or links between constructs within and across cases, together with their underlying logical explanations.

Participants will include doctors, nurses, allied health professionals, and administrators in the department where Dora is being implemented. Invitations to participate will be sent out through email and informed consent will be gained from participants before data collection. We intend to adopt a purposeful sampling technique, complemented by the snowballing technique, to identify knowledgeable informants. Participants will be chosen based on their role and knowledge of the study topic, as well as their involvement in the Dora pathway.

The final number of interviews will be determined while analyzing the data. For example, when no new codes and themes are emerging from the data and the analysis does not yield new themes but confirms current ones, it would suggest that a theoretical saturation point is obtained [37] and no new data are required.

Data Collection

Multiple sources of evidence will be used, including semistructured interviews, focus groups, questionnaires, document analyses, and site visits, conducted by 2 researchers (SK and FZ). Using several forms of evidence enables the research team to understand the complexity of the context, obtain a rich data set, and facilitate triangulation, which improves the accuracy of the gathered data and enhances the credibility of the findings and conclusions [38]. Table 1 provides a summary of the methodology across the phases of intervention implementation.

XSL•FO
RenderX

Table 1. Summary table of methodology across phases of implementation.

Study and Dora implementation phases	Methodology	Description of workstream
Phase A: preimplementation		
	Structured survey	Distribute a survey to members of staff across multiple NHS[a] sites to collect quantitative data before Dora implementation. Questions will focus on perceived acceptability, benefits, usability, and challenges associated with Dora.
	Interviews and focus groups	Conduct focus groups and semistructured interviews to understand the preconceptions that staff hold about automation using Dora and its potential impact on their work practices and well-being. Field notes will be taken during the interviews and consolidated after.
Phase B: postimplementation		
	Structured survey	Distribute the same survey as in phase A to enable comparisons between the initial data gathered before Dora implementation and after, highlighting any changes on an individual level.
	Interviews and focus groups	Conduct similar focus groups and interviews as in phase A to explore emergent themes in more depth and understand the postimplementation impact of Dora.

[a]NHS: National Health Service.

The questionnaire is designed to collect descriptive data about user acceptability, awareness, and well-being to aid in the interpretation of the findings (Table 2 provides an overview of the survey components). Before distributing the survey, it will first be piloted and validated by experts in the fields of health and information systems to ensure that it accurately measures health care professionals' perceptions of the Dora intervention. The questionnaires will be complemented with focus groups and semistructured interviews (lasting between 30 and 60 minutes) to offset the lack of flexibility and depth of the survey and are developed to elicit critical process information that could add value to the survey data collected.

Table 2. Overview of questionnaire components and description.

Questionnaire component	Description
Demographics	Information about the hospital, job role, experience, work hours, age, gender, and ethnicity.
Dora involvement a understanding	Assesses the participant's role in the Dora pathway and their self-rated knowledge of the system.
Stanford Professional Fulfillment and Burnout Index	Measures intrinsic positive reward derived from work and symptoms of work exhaustion and disengagement.
Impact of Dora on burnout	Evaluates the perceived impact of Dora on burnout symptoms.
Perceived acceptability	Gauges the acceptability of the Dora system, including user satisfaction and the system's perceived value.
AI-related questions	Explores perceived benefits, performance anxiety, communication barriers, benefits, privacy concerns, liability, and risks.

Qualitative research methods involve the study of participants in their natural settings in order to interpret phenomena and the meanings individuals attribute to them. The fundamental goal is to understand participants from their own perspective [39]. To ensure trustworthiness, the study will be reported in accordance with the Consolidated Criteria for Reporting Qualitative Research (COREQ) 32-item checklist [40].

Preimplementation

A survey, based on the theoretical framework of acceptability and a validated well-being instrument (ie, Stanford Model of Professional Fulfillment), will be distributed to members of staff (both directly and indirectly affected by the intervention) across multiple NHS sites to collect quantitative data on well-being and perceptions before the implementation of Dora. The aim of the survey is to gain an understanding of how AI-enabled automation, introduced by the intervention in this study, is perceived by the health care workforce. Questions will be based on perceived acceptability, benefits, and challenges associated with the implementation of Dora. This phase will also involve a focus group and semistructured interviews (conducted face-to-face or remotely, depending on convenience) to gain an understanding of the preconceptions held regarding automation using Dora, the impact of automation on themes such as autonomy, as well as the impact this may have on staff's well-being. We will explore the system "as-is" to understand current ways of working, tensions and contradictions, and potential opportunities for Dora, to enable comparisons and further investigation. This will allow us to obtain baseline data to facilitate comparisons further into the study.

XSL•FO
RenderX

Focus groups enable participants to discuss this topic in greater depth and interact with, as well as react to, other participants [41], which can reveal shared opinions, reactions, and ideas on these phenomena. Field notes will be taken during the focus group and consolidated after.

The protocol used for the focus groups and interviews will be prepared based on the underlying constructs of the theoretical framework and literature review. These will provide a list of "intellectual bins" that structure the data collection and analysis [42]. Questions will largely be open-ended, giving participants the freedom to convey their personal views and experiences with respect to the socially complex context of AI implementation and automation in health care. The interviews will be conducted in a reflexive and responsive manner to enable the research team to follow up on insights and adjust the content of the interview accordingly. All interviews will be transcribed, annotated, and proofread. Furthermore, venting will be used, whereby interpretations and responses will be discussed with medical and academic professionals.

To enhance the robustness of the case studies, we will triangulate our findings by means of several evaluators (eg, researchers), multiple respondents, and different sources (ie, interviews, internal documentation).

Postimplementation

This phase involves the distribution of the same survey that was used in phase A as well as conducting a focus group and semistructured interviews with the same individuals contacted in phase A to explore emergent themes in more depth. This will enable comparisons between the initial data gathered before the implementation of Dora and the postimplementation, highlighting the changes that have occurred, if any, on an individual level.

Data Analysis

The interview and focus group data will be thematically analyzed by the research team, which includes 2 researchers who are experienced in analyzing qualitative data. The first phase will involve the researchers familiarizing themselves with the data by reading and rereading the transcripts and field notes (also known as the "data immersion phase"). The raw data will be transferred to a qualitative analysis software (NVivo; QSR International) where it can be coded (ie, systematized and labeled). In this research, NVivo will facilitate the management and organization of data and the merging of codes, where appropriate, as part of the analysis.

A third researcher will further analyze a subset of the data to identify concepts that may have been missed, offer an alternative perspective, and detect possible bias in data analysis. We intend to adopt an insider and outsider approach to our coding and analysis to ensure rigor and help reduce bias. Coding will be regarded as complete when consensus is achieved on each construct, aiming to achieve a high intercode reliability score between the coauthors and the outsider researcher.

Guided by the research questions and theoretical lens, a set of initial codes will be applied to the data, forming the first-order codes. There is a possibility of creating additional codes, derived from open coding [43], to gain an in-depth understanding of the impact automation has on staff and their work practices, as framed by the participants (ie, in an inductive manner). This process will be followed by performing axial coding, where codes are categorized and organized into interpretive concepts. Finally, we will perform selective coding by aggregating the second-order codes into overarching theoretical constructs. The process will involve us cross-checking our analysis and looking for contradictions instead of seeking coherent and conformity interpretations [44].

During the data collection and analysis period, the research team will meet frequently to discuss the codes, review emerging themes, and develop and question each other's ideas and underlying assumptions. The debriefings will enable us to develop a contextually specific shared understanding as well as determine a consolidated list of codes.

The quantitative data will be analyzed using quantitative analysis techniques to describe, explore, and examine the trends and relationships within the data. The results will be presented using charts and graphs to facilitate understanding.

Data Handling

Before the interviews, participants will be contacted in writing to explain the study, and they will be asked to confirm their willingness to take part, which will be taken as consent to participate. There is no need for deception of any form in the research, and an information sheet outlining the research aim, purpose, and objectives, the right to withdraw, confidentiality assurances, and researchers' contact details will be sent to all participants by email. With respect to the questionnaires, details about the study and a consent statement will be included at the start of the survey.

Data obtained from interviews will be anonymized and coded. Participants will be advised that any information given will be treated with strict confidence. All participants will be assured that their identity and names will not be included in later write-ups, work, or documents submitted or published.

Participants will be advised that they may stop being part of the study at any time without giving a reason, but information already collected by the research team will be kept.

Results

The evaluation received funding from the MPS Foundation in December 2022, and the study will last 12 months. The expected results aim to reveal the interrelationship between the autonomous clinical conversational assistant and those affected by its introduction in the pathway, seeking to understand task redesign, changes in responsibilities, impacts on well-being, tensions, benefits, and opportunities.

The implementation of AI-enabled automation relies on the trustworthiness of the system, and any sense of insecurity may be stressful to the individual, impacting their own well-being and subsequently affecting system success. Employees' attitudes and perceptions are argued to impact technology acceptance and attitudes toward change, which in turn affect the success of the intervention. Therefore, to achieve organizationally

XSL•FO
RenderX

desired results from the adoption of AI-enabled automation technology, managers and leaders need to understand the opportunities and threats associated with its implementation and the impact this has on their workforce and their work practices.

The results from the thematic analysis of the qualitative data will be presented as the main themes that have been realized in the pre- and postimplementation phases. The data from the questionnaires will be presented in graphical format for each domain that has been assessed (Table 2 presents the questionnaire components).

Discussion

Given the rising wave of AI-enabled digital health technologies, it has become paramount that the systemic impact of implementing such initiatives on individuals and the system overall be understood. AI advancements have created new possibilities for addressing a range of health care–related problems, with the promise of a positive impact on the working lives of frontline clinicians and other health care professionals. While most of the existing research on the impact of health information technology on well-being is concerned with clinicians' EHR use, our current understanding of how AI impacts different members of staff and their roles and responsibilities remains opaque [25].

The primary aim of this study is to examine the real-world impact of AI-enabled automation on clinicians and health care professionals who provide health care to patients in high-volume, low-complexity perioperative care pathways. The results aim to shed light on concerns stakeholders have regarding automation and the use of telemedicine solutions, perceived benefits, and how the intervention impacts their work practices, if at all. The study will also highlight critical sociotechnical factors impacting adoption and whether there are any differences across different members of the health care workforce, which may allude to how managers can successfully integrate such technology into their organization and address the impact of such challenges. The study aims to bring original and novel contributions to the current body of knowledge as well as yield critical practical implications.

A few limitations have been identified. First, the study will be conducted within the specific research setting of the United Kingdom; therefore, some findings and interrelationships between them may be mainly applicable to contexts that are similar to the United Kingdom. Another limitation, and possibly an interesting direction of future research, is that although we aim to explore perceptions and experiences before and after implementation, there is opportunity to explore if there are any further changes over time and how these affect usage and deployment as the system becomes further embedded into the context.

Acknowledgments

This work was supported by The MPS Foundation Grant Programme. The MPS Foundation was established to undertake research, analysis, education and training to enable health care professionals to provide better care for their patients and improve their own well-being. To achieve it supports and funds research across the world that will make a difference and can be applied in the workplace.

Data Availability

Data sharing is not applicable to this paper, as no data sets were analyzed for the creation of this study protocol.

Abstract

Background: Tobacco smoking remains the leading cause of preventable morbidity and mortality in the United States, with significant rural-urban disparities. Adults who live in rural areas of the United States have among the highest tobacco smoking rates in the nation and experience a higher prevalence of smoking-related deaths and deaths due to chronic diseases for which smoking is a causal risk factor. Barriers to accessing tobacco use cessation treatments are a major contributing factor to these disparities. Adults living in rural areas experience difficulty accessing tobacco cessation services due to geographical challenges, lack of insurance coverage, and lack of health care providers who treat tobacco use disorders. The use of digital technology could be a practical answer to these barriers.

Objective: This report describes a protocol for a study whose main objectives are to develop and beta test an innovative intervention that uses a private, moderated Facebook group platform to deliver peer support and faith-based cessation messaging to enhance the reach and uptake of existing evidence-based smoking cessation treatment (EBCT) resources (eg, state quitline coaching programs) for rural adults who smoke.

Methods: We will use the Integrated Theory of Health Behavior Change, surface or deep structure frameworks to guide intervention development, and the community-based participatory research (CBPR) approach to identify and engage with community stakeholders. The initial content library of moderator postings (videos and text or image postings) will be developed

XSL•FO
RenderX

using existing EBCT material from the Centers for Disease Control and Prevention Tips from Former Smokers Campaign. The content library will feature topics related to quitting smoking, such as coping with cravings and withdrawal and using EBCTs with faith-based message integration (eg, Bible quotes). A community advisory board and a community engagement studio will provide feedback to refine the content library. We will also conduct a beta test of the intervention with 15 rural adults who smoke to assess the recruitment feasibility and preliminary intervention uptake such as engagement, ease of use, usefulness, and satisfaction to further refine the intervention based on participant feedback.

Results: The result of this study will create an intervention prototype that will be used for a future randomized controlled trial.

Conclusions: Our CBPR project will create a prototype of a Facebook-delivered faith-based messaging and peer support intervention that may assist rural adults who smoke to use EBCT. This study is crucial in establishing a self-sufficient smoking cessation program for the rural community. The project is unique in using a moderated social media platform providing peer support and culturally relevant faith-based content to encourage adult people who smoke to seek treatment and quit smoking.

Introduction

Background and Significance

Tobacco smoking remains the leading cause of preventable morbidity and mortality in the United States, contributing to approximately 480,000 premature deaths annually [1]. This comes at a high economic cost to our society. Data from a recent national report showed that smoking-related illnesses cost the United States over US $600 billion in 2018 [2]. Evidence-based smoking cessation treatments (EBCTs) are greatly underused by people who smoke. For example, the use of state quitline coaching programs and pharmacotherapy enhances smoking quit attempts and cessation [3], but many people who smoke are unaware of or do not use state quitlines [4-6]. Schauer et al [7] analyzed data from the 2009 to 2010 National Adult Tobacco Survey and found that quitline awareness was 53.9% among people who smoke. Further, among individuals who attempted to quit smoking in the past year and had knowledge of the quitline's existence, their use rate was only 7.8%. Therefore, efforts to improve access, information, and acceptance of EBCTs are required.

Significant rural-urban disparities exist in the United States concerning tobacco smoking, smoking-related health outcomes, and smoking cessation treatment access. Adults who live in rural areas of the United States have among the highest tobacco smoking rates in the nation and experience a higher prevalence of smoking-related deaths and deaths due to chronic diseases for which smoking is a causal risk factor [8]. Trends from the last several years show that rural areas experience higher rates of smoking-related chronic diseases than their urban counterparts [9,10]. Compared to urban residents, people living in rural areas are generally older, have lower adherence to preventative screening [10-12], and face significant treatment barriers related to social determinants of health, which puts them at a higher risk of developing chronic diseases [13,14]. A lack of health care specialists in rural areas further exacerbates these barriers to seeking care [15,16]. For example, a recent study by the Centers for Disease Control and Prevention (CDC) found that people living in rural areas had lower rates of cancer diagnoses but experienced higher death rates for all cancer types when compared to people living in nonmetropolitan and metropolitan areas, highlighting rural patients' challenges in accessing necessary health care [17]. Rural communities face tobacco-related disparities that expose them to difficulty seeking access to smoking cessation treatment support, ultimately leading to a higher prevalence of chronic diseases. For example, rural communities have a higher rate of cigarette smoking than urban areas, a trend observed for both women (rural vs urban: 25% vs 13%) and men (rural vs urban: 29% vs 19%), but tobacco control policies and cessation efforts tend to favor urban areas more than rural areas [8]. Due to difficulties such as geography, infrastructure, and corporate barriers, those living in rural areas have difficulty accessing tobacco cessation services [8].

One approach for improving access and overcoming barriers to engagement in underserved populations is through the use of digital technology and social media platforms. There has been a growing recognition that leveraging digital technology could encourage the positive behavior change necessary to quit smoking and manage chronic conditions like cancer and heart disease. By doing so, barriers that impede access to EBCT can be lessened [18]. For example, the use of social media, such as Facebook, could be used to deliver smoking cessation behavioral interventions such as motivational interviewing (MI) and peer support and encourage the use of EBCT interventions. Facebook is the most used social media platform in the United States and has a broad reach. It promotes engagement and connection among peers that can be used in smoking cessation efforts at a relatively low cost. In addition, Facebook is a helpful tool for supporting smoking cessation through online communication and sharing of experiences among users. The experience allows users and study staff to share intervention-related pictures, videos, and images to encourage discussion. This represents a distinct advantage over face-to-face approaches or web-based services [19,20]. In recent years, many studies have used social media, including Facebook, for smoking cessation interventions. However, the use of Facebook to deliver EBCT with a

XSL•FO
RenderX

faith-based component developed by the community-based participatory research (CBPR) approach is lacking.

Another approach to improve access and uptake of evidence-based interventions is by culturally adapting them to fit the specific needs and contexts of individuals who underuse them. Studies have shown that the implementation of EBCT with community co-design and engagement enhances its receptivity and uptake [21]. One such effective approach is CBPR, a model that equitably involves community members, organizations, and academic researchers in all aspects of the research process. As a result, all partners can contribute their expertise with shared ownership and responsibility; knowledge gained is enhanced, and action is integrated to improve community members' health and well-being [22]. Evidence also shows that culturally relevant messaging delivered through CBPR approaches increases [23,24] study recruitment, EBCT resources acceptance, and cessation rates [25-27]. This approach is particularly important for hard-to-reach marginalized rural populations, by empowering them to be agents of maintained change in their communities. Therefore, our study will use the CBPR strategy to center rural end users to co-design the intervention to promote its maintainability and lasting impact in the rural community.

Numerous research studies have evaluated the effect of spirituality and religious beliefs on positive health behaviors. For example, these beliefs may help to reduce stress through engagement with coping skills and lifestyle factors such as improved diet, attendance to preventive care, exercise, and reduction in alcohol drinking, and so forth, which ultimately improves cardiovascular health and general well-being [28-31]. In addition, many studies have shown a negative correlation between faith-based involvement and cigarette smoking [32-37]. Research suggests that individuals participating in faith-based activities are less likely to smoke or begin smoking in the future [37,38]. Whooley et al [37] found that nonsmoking individuals who attended religious services less than once a month were at twice the risk of starting smoking compared to those who attended services regularly over 3 years. In addition, a study conducted by Kim et al [39] among Korean men found that church attendance may assist individuals in quitting smoking due to social prohibitions from other members of the congregation. The mechanism behind this phenomenon is theorized that religious attendance offers spiritual support, an essential source of resiliency, and reduces stress [31] that would otherwise perpetuate cigarette smoking [40]. In addition, faith-based congregants may provide peer support in the smoking cessation journey [31,41]. Since religious participation offers an avenue for smoking cessation and the faith-based CBPR approach has not been thoroughly evaluated among the rural population for smoking cessation, our study attempts to fill this research gap.

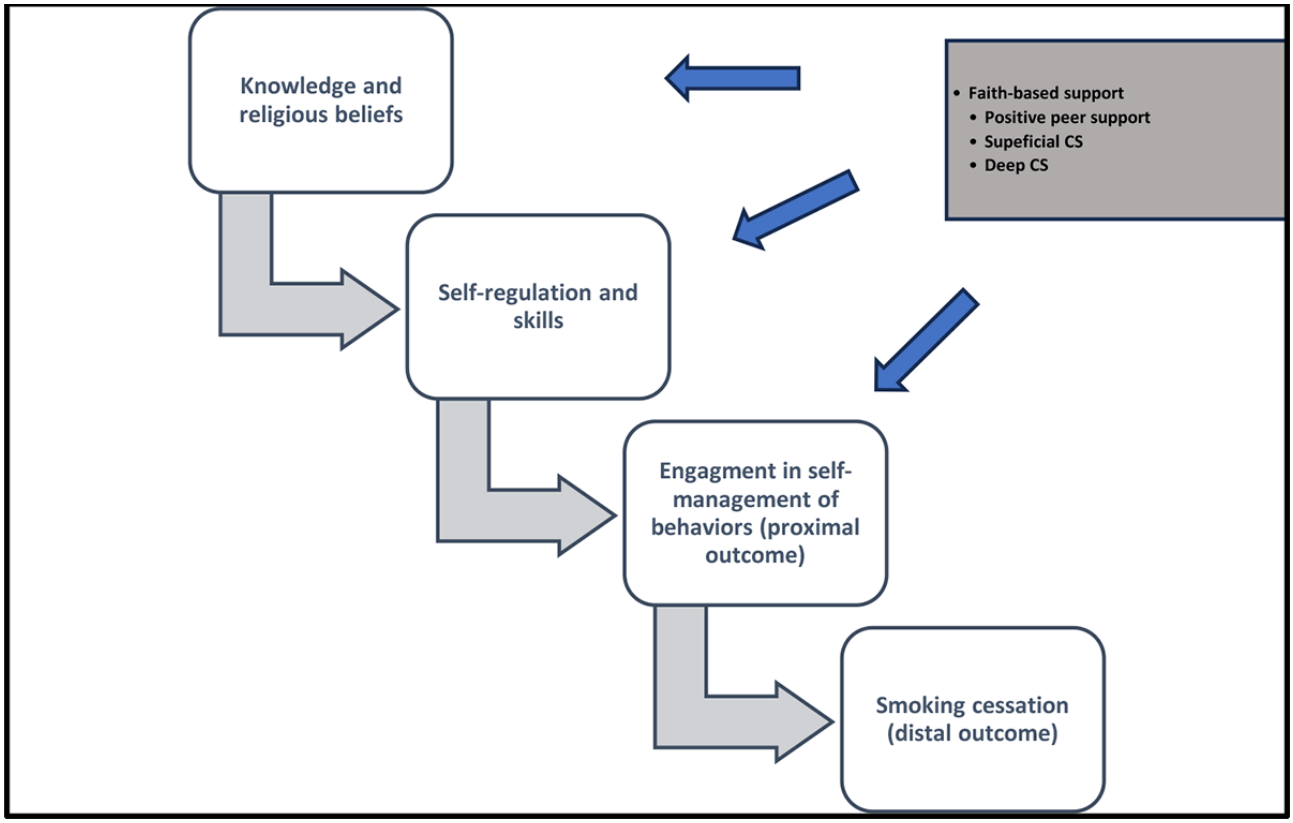
Participants' access to clinical trials in rural areas can be a challenge due to transportation barriers in traveling to clinical trial centers and the difficulties associated with spending several hours away from daily wages to participate in research studies. Therefore, participation rates in rural substance use treatment clinical trials are low. Decentralization of clinical trials using digital tools, as we propose in this study, could mitigate this problem.

Study Aims and Objectives

In this report, we describe a study protocol focused on developing and beta testing an innovative faith-based Facebook intervention for rural smokers. The overall objective of this study is to develop a private, moderated, faith-based Facebook group intervention platform using peer and pastoral support for rural people who smoke to enhance the use and reach of existing EBCT resources.

Our study-specific aims are (1) to describe the process we will use to develop a faith-based Facebook group intervention for smoking cessation that promotes access to and use of EBCT using the CBPR approach and (2) to assess the preliminary feasibility and uptake of the intervention with a 1-month beta test.

Methods



Theoretical Framework

We will use the Integrated Theory of Health Behavior Change (ITHBC) [42] and surface or deep structure [43] frameworks as guidance for intervention development (Figure 1). According to the ITHBC framework, an individual is more likely to engage in a behavior change when they understand the disease-related risk factors they are indulging in and if treatment recommendations (including minimizing risk factors) align with their personal beliefs. Therefore, the content of our intervention will be evidence-based (EBCT in this case) and will be prepared to increase the participants' knowledge about chronic diseases and their risk factors, such as smoking, to enhance their self-efficacy, outcome expectations, and goal congruence.

Self-regulation, a second key factor in making a behavior change, may be enhanced through increased knowledge and reflection on one's beliefs. Self-regulation involves setting goals, monitoring, reflecting, decision-making, planning, execution, self-evaluation, and managing emotions during change. We will design intervention content to facilitate self-regulation through Facebook posts aimed at increasing knowledge about smoking cessation content (eg, thoughts, intentions, and actions) in congruence with faith-based beliefs.

XSL•FO
RenderX

Figure 1. Theoretical framework. CS: cultural sensitivity.

The third construct, social facilitation, involves social support that encourages behavior change. Participants will receive supervised social support through Facebook engagement with peers on the same journey of smoking cessation. Before the desired outcome (distal outcomes) of smoking cessation, the individual will engage in several self-management behaviors (proximal outcomes), such as calling the state quitline and engaging in Facebook conversations and posts that take them to their final or distal outcome of smoking cessation. For this study, we plan to develop an intervention that will target proximal outcomes (distal outcomes not the scope of this study) of self-management behaviors, measured by actions such as calling a quitline and engaging in Facebook conversations and posts. As noted earlier, since proximal outcomes are influenced by an individual's knowledge, beliefs, and self-regulation skills, we will use evidence-based material and faith-based messages to facilitate proximal outcomes.

To ensure our messages are culturally aligned and faith-based, we will use the surface and deep structure framework [44,45]. Surface structure considers observable social and behavioral characteristics of participants, such as race, gender, and family structure, while deep structure takes into account cultural beliefs and values. Finally, we will use a planning framework based on the CDC recommendations for developing social media and other digital health communication tools [46] to guide the critical content components of Facebook messages, consistent with behavioral therapy.

Study Design

The study will use the CBPR approach and will be conducted at Mayo Clinic Health System, Eau Claire, Wisconsin. Before the start of the study, several small-group in-person and online meetings were held in the community with faith-based leaders of local churches to gauge their interest in forming a partnership and brainstorming the study idea. The local faith-based leaders agreed to collaborate and participate in the review of the study design and intervention materials and provide general input on faith-based topics. The pastors were informed that they will be part of the "core research team" and will approve documents including manuscripts, flyers, and other materials before publication and community dissemination. Our other partners for this study included the Mayo Clinic Center for Clinical and Translational Science (CCaTS), community engagement and rural health programs, and the Center for Health Equity and Community Engagement Research (CHCR) that will facilitate the formation of a community advisory board (CAB) and engage the services of the community engagement (CE) studio to get community feedback on the development of the intervention.

Recruitment

Community Advisory Board

The CAB will consist of 10-12 individuals from the community. We will ensure that the board comprises diverse individuals from different sexes, races, and age groups with fair representation. Print and e-flyers highlighting roles and responsibilities will be used to facilitate recruitment. The flyers will be posted on the Mayo Clinic display board and emailed or mailed to the community partner organizations, including church partners. CAB members will receive an honorarium of US $150 per meeting.

CE Studio

CHCR staff will assist in recruiting CE studio members, consisting of community members who represent end users of

XSL•FO
RenderX

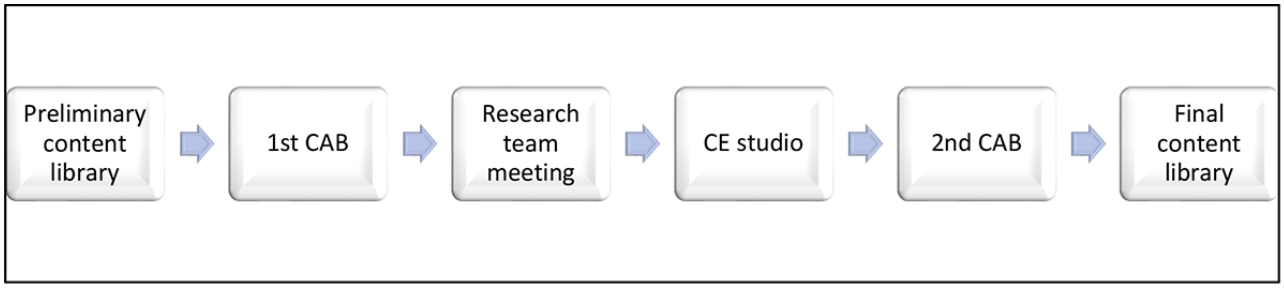
the intervention. Advertisement flyers will be used to facilitate the recruitment. The CE studio will consist of 6-8 rural community experts who will join a 1-time 90-minute online meeting to give feedback on the content of smoking cessation material for the faith-based Facebook intervention. Eligibility criteria for participation are as follows: (1) aged >18 years, (2) lives in the rural area of Wisconsin or Minnesota, (3) smoked at least 1 cigarette per day over the past 7-day period, and (4) Christian faith. Community experts will receive a US $50 visa card for their time.

Beta Test

A Facebook group size of 10 was the minimum number for optimal engagement in previous studies [47,48]. Thus, we will beta test the Facebook group with an estimated purposeful sample of 15 individuals who currently smoke and attempt to ensure that the sample comprises diverse individuals from different sexes, races, and age groups with fair representation. A 1-page information sheet or flyer codeveloped with the core research team and CAB will be posted on the Mayo Clinic display board and emailed or mailed to the community partner organizations, including local church partners. Study staff will administer an initial set of screening questions over the phone to screen for eligibility.

The eligibility criteria for participation are (1) aged >18 years; (2) smoked at least 1 cigarette per day over the past 7-day period; (3) have access to the internet on a mobile phone, computer, or tablet; (4) willing to create a Facebook account and willing to participate in the Facebook intervention for 1 month; and (5) either self-identify as a person of Christian faith or recognize that study posts will include Christian faith-based content, including Bible verses. Ineligible individuals (positive for smoking but unwilling to engage with Facebook intervention) will receive EBCT referral information via postal mail (printed materials) or email. The material will include information on their state tobacco quitline. Participants will also receive information on the National Cancer Institute's free population-level smokefree.gov website resources. The website, tailored to all readiness levels to quit smoking, includes a quitting guide, texting program, smartphone apps, online live chat, URL, and a toll-free number (1-800-QUIT-NOW) for state quitlines [26].

Procedures



Phase 1: Intervention Development

Our research team is comprised of rural health, substance use, and health disparities researchers, pastors from local churches, and rural patient advocates from the Mayo Clinic enterprise. We will compile the initial items for the content library by drawing on empirical research, existing literature, and our research team's combined clinical research and pastoral experience. We will use existing EBCT videos and other content postings from the CDC Tips from Former Smokers Campaign that promote the use of EBCTs to various disparate groups, including rural people who smoke. The preliminary content library will feature various topics related to quitting smoking, such as dealing with stress, nicotine withdrawal, cravings, personal health, and culturally relevant activities that can help smokers quit associated with relevant faith-based messages or bible quotes, for example, how prayer, faith, connection to others, grace, temptation, patience, forgiveness, and so forth, can support with the use of evidence-based smoking cessation intervention. The content topic will also discuss motivations for quitting, like the importance of family and preventing relapse, and encouraging EBCT, such as using state quitlines and pharmacotherapy. Each topic will have corresponding Facebook posts in text and embedded videos and images. Further, for each topic of content, a sample of the supplementary text is provided for Facebook group moderators (who will oversee the posting and engage participants in conversation) and a probe for generating further discussion or ways to respond to users' questions. Facebook group moderators will select posts based on ongoing group conversations and respond to individual posts and queries while posting for the entire group.

Phase 2: Community Members' Feedback

The preliminary content library will be evaluated for content validity through the guidance and advice obtained from CAB members and a CE studio [49,50]. The community feedback process consists of 3 critical steps. First, we will conduct a CAB meeting to gather feedback and input on the preliminary content library. The core research team will use this feedback to revise the content library further. Second, the CE studio will be used to obtain additional feedback on the revised content library. Finally, we will conduct the second and final CAB meeting, where we will thoroughly discuss the feedback provided by the CE studio and how we implemented feedback from the first CAB meeting. Their consolidated feedback will be incorporated with input from the core research team, and the content library will be considered final (Figure 2).

Figure 2. Community engagement plan for the development of the content library. CAB: community engagement board; CE: community engagement.

XSL•FO
RenderX

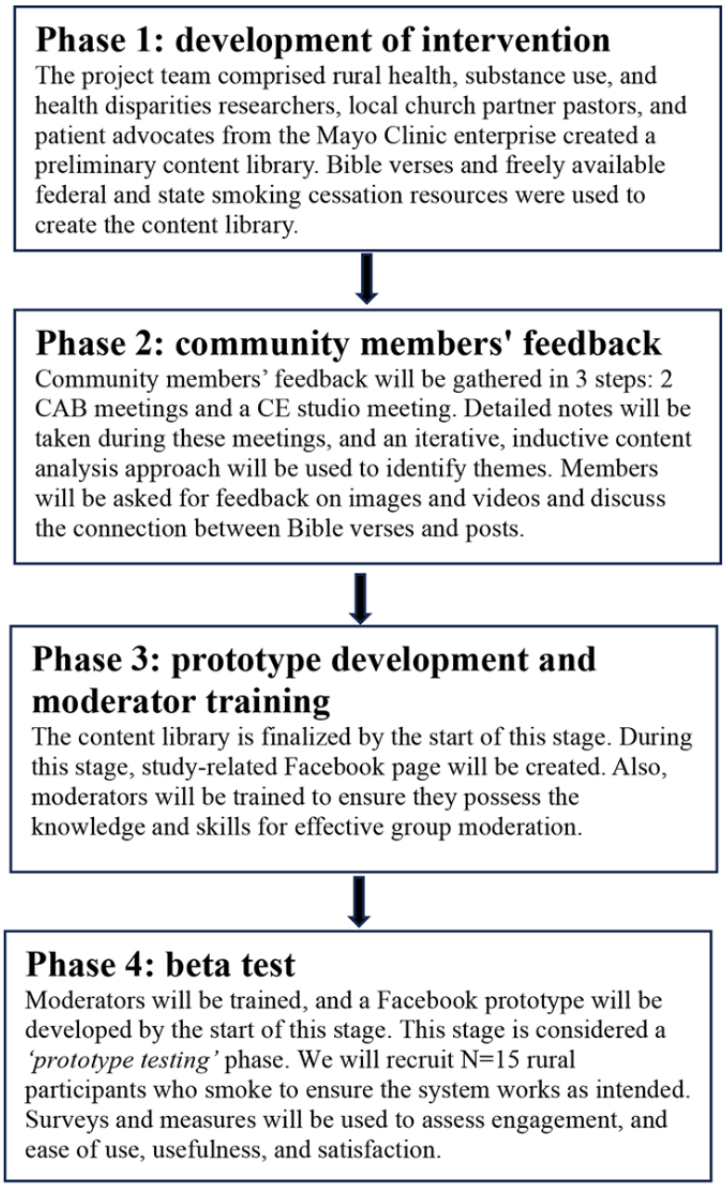
Community Advisory Boards

Each CAB member will receive the meeting agenda, an electronic version of the preliminary content library, and the Zoom (Zoom Video Communications) meeting link in preparation for the online meeting. The online CAB meeting will last for approximately 90 minutes and will be recorded. During the meeting, the study's principal investigator, PS, will summarize the study and facilitate introductions among the attendees. In addition, PS will present each topic within the preliminary content library and facilitate the discussion. During the discussion, each topic will be displayed, and members will provide feedback on the selected images or video, the bible quotes and their alignment with the associated Facebook post, and overall post understandability and relevance to the topics. Study staff (BT and CK) will take detailed meeting notes. The CAB members will also have an opportunity to provide open-ended feedback.

CE Studio

The CE studio will be a 90-minute online meeting facilitated by the CHCR staff. A CHCR staff will begin the meeting with introductions, and then PS will provide a 10 to 15-minute presentation of the study, and a CHCR staff will facilitate the discussion. Similar to the CAB, each topic will be displayed during the discussion, and community experts will provide feedback on the selected images or video, the bible quotes and their alignment with the associated Facebook post, and overall post understandability and relevance to the topics. A CHCR staff will take detailed notes and provide a summary at the end of the CE studio.

Phase 3: Prototype Development and Moderator Training



The Mayo Clinic Social Media Department will assist in creating a study-related Facebook page. The group will be private, hidden, and moderated to facilitate confidentiality. By this stage, the content library will be finalized, and additional postings, including Bible verses and images, will be added on an as-needed basis based on insights and feedback from CBPR processes. The moderators' interactions with group members are critical for sparking conversation among the group members. As a result, we will choose moderators who have knowledge of the Christian faith and are familiar with Bible verses. Given that our research team includes pastors from local churches, they will be consulted on an ongoing basis by the moderators if any guidance is required. The moderators will receive comprehensive training to ensure they possess the knowledge and skills for effective group moderation. The training will cover the principles of moderation, including the best ways to engage participants, promote appropriate conversations, and redirect engagement [51,52]. They will also be trained to handle challenging situations that may arise in a web-based group. Additionally, the moderators will participate in didactic training to learn basic communication principles, such as active listening, MI, and cognitive behavioral therapy. The ultimate goal is group participant interaction and partaking. Therefore, moderators will be encouraged to help generate daily interaction among members and not just post the content daily. Moderators will post 1 selection from the intervention content library every 1-2 days. In order to stimulate engagement from participants, the moderators will reply to the posts with 1-2 prompt questions (included in the content library) directed at specific individuals and using MI techniques. They will check the group several times daily to engage with participants and address inappropriate content or misinformation.

Phase 4: Beta Test

After completing baseline assessments, eligible participants will be emailed an invite link to the intervention Facebook group. Participants will be given instructions on how to register on Facebook. Those who already have a Facebook account can either create a new user profile or use the existing one to join the group. The research staff will ensure that the participants enroll in the group within 24 hours of receiving the link. If participants experience technical difficulties, the staff will assist them. The smokefree.gov resources will also be mailed to the participants. This phase will expose participants to 30 days of moderator postings and obtain feedback to ensure the system works as intended. In addition, we will conduct a preliminary assessment of feasibility and intervention uptake (engagement) to facilitate any needed refinements prior to future randomized controlled trial (RCT) (Figure 3).

XSL•FO
RenderX

Figure 3. Overview of the process to develop faith-based Facebook intervention prototype and beta test to help rural people quit smoking. CAB: community advisory board; CE: community engagement.

Measures

Overview

For aim 2, the beta testing phase, we will use an internet-based survey to measure the following. The participants in this study will receive a survey via email through REDCap (Vanderbilt University). The survey will be open for 7 days, and participants will receive 2 reminders to complete it. The email address on file is required for this process.

Baseline Smoking Characteristics

We will assess the average number of cigarettes per day, the age when the person started smoking, pack-years of smoking, the number of days the person smoked in the past 30 days [53], readiness to quit using the contemplation ladder [54], the average number of quit attempts in the past 30 days, and other commercial tobacco and nicotine product use.

Baseline Sociodemographic Characteristics

Sociodemographic measures selected from the PhenX Toolkit assessed age, sex, gender, ethnicity, race, education, employment status, and marital status [55].

Study Recruitment and Retention

Recruitment feasibility measures include the number of potential participants screened, the number of eligible participants, and the number of enrolled participants from the eligibility pool. Additionally, study retention will be evaluated by determining the proportion of participants who complete postintervention assessments.

Treatment Satisfaction

The satisfaction with the Facebook intervention will be measured in three domains: (1) perceived ease of use, (2) usefulness, and (3) satisfaction by using the Usefulness, Satisfaction, and Ease of Use (USE) questionnaire. The scale contains 13 items and participants will rate these items on a

XSL•FO
RenderX

5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). We will examine the Facebook intervention engagement patterns using Facebook metrics and qualitatively explore common topics that emerged in participant postings [56]. Additionally, we will include open-ended questions to gather more detailed feedback from users.

Intervention Uptake or Engagement

In order to measure the adoption of our intervention, we will use Facebook's objective engagement metrics such as views, reactions (such as likes and loves), comments, posts, and poll votes (where participants can make multiple selections). By calculating the total number of times participants engaged with the intervention, we can accurately assess its uptake.

Statistical Analysis

Aim 1 will have 2 CAB meetings and 1 CE studio session. Members will be asked to provide helpful feedback on the content's flow, understandability, and relevance. Detailed notes will be taken during these meetings, and an iterative, inductive content analysis approach will be used to identify themes. A total of 2 investigators will work together to code the responses, and a third investigator will resolve any disagreements until a consensus is reached. Aim 2 will summarize sample characteristics, social media usability measures, and most and least preferred concepts using descriptive statistics, including means, percentages, and frequencies. Open-ended responses will be summarized, and themes will be generated using content analysis as described in aim 1.

Missing Values

Because assigning missing data as smoking is not necessarily a conservative approach [57], we will also explore multiple imputation methods [58,59] to classify lost to follow-up as cigarette smokers or nonsmokers and conduct sensitivity analyses as appropriate.

Ethical Consideration

The study was deemed exempt by the Mayo Clinic Institutional Review Board (23-000837). The CAB members will receive a US $150 honorarium. CE studio community experts will receive US $50. The participants will receive US $25 for completing the baseline assessment and US $25 for the postintervention assessment. For the beta test phase, study data will be deidentified.

Results

The results of this project will lead to the development of a faith-based smoking cessation content library. In addition, we are planning a pilot 2-arm parallel group, RCT, which will include evaluation of control (mailed materials and smokefree.gov information) versus Facebook intervention (information mailed to the control group plus Facebook intervention developed during this study) among diverse populations.

Discussion

Principal Findings

Our study focuses on collaborating with community stakeholders to co-design a faith-based, peer-supported Facebook-delivered intervention prototype to address smoking cessation among rural people who smoke. This study is essential to a self-maintaining smoking cessation program for the rural population. We believe that Facebook group moderation is an important component of this program to increase participant engagement and provide behavioral support and access to cessation treatment resources and service linkages when required. In addition, the supervised Facebook group may lead to better peer support among participants who can learn from each other's experiences and share their smoking cessation journey.

No such Facebook group exists that uses faith-based support as a component and encouragement to use EBCTs such as quitlines and cessation pharmacotherapy. During the preliminary meetings, our community stakeholders have shown interest in being trained as moderators and ensuring the continuity of the proposed Facebook group so that the intervention is self-maintained within the community once the study is over.

Limitations

Our sample is restricted to the Midwest population and stakeholders, which may limit the generalizability to other rural populations. However, this phase is focused on prototype development, and future pilot study steps will pave the way toward larger, more generalizable evaluations of digitally enhanced interventions. Our study will recruit individuals with access to the internet and smart devices to access Facebook, which may lead to selection bias. For future studies, investigators may consider providing a loaner digital device to participants with no digital access to eliminate this selection bias.

Conclusions

Our study will provide preliminary steps, including possible challenges before the RCT for a faith-based, Facebook-delivered EBCT intervention for rural populations that smoke. Our study has a broader interest in faith-based stakeholders and potentially be self-maintainable within the community. This approach can potentially support rural communities by granting them access to community-based health care that is maintainable. Our study design has the capability to provide a tailored online intervention with fidelity. Furthermore, our study uses existing federal and state EBCTs, using available resources to aid in smoking cessation.

Acknowledgments

The study was funded by Mayo Clinic Health System, Rural Health Core of Center for Clinical and Translational Science, and the Robert A Winn Diversity in Clinical Trials Career Development Award, and funded by Bristol Myers SquibbFoundation, the

Abstract

Background: Recent advances in hardware and software enabled the use of artificial intelligence (AI) algorithms for analysis of complex data in a wide range of daily-life use cases. We aim to explore the benefits of applying AI to a specific use case in transplant nephrology: risk prediction for severe posttransplant events. For the first time, we combine multinational real-world transplant data, which require specific legal and technical protection measures.

Objective: The German-Canadian NephroCAGE consortium aims to develop and evaluate specific processes, software tools, and methods to (1) combine transplant data of more than 8000 cases over the past decades from leading transplant centers in Germany and Canada, (2) implement specific measures to protect sensitive transplant data, and (3) use multinational data as a foundation for developing high-quality prognostic AI models.

Methods: To protect sensitive transplant data addressing the first and second objectives, we aim to implement a decentralized NephroCAGE federated learning infrastructure upon a private blockchain. Our NephroCAGE federated learning infrastructure enables a switch of paradigms: instead of pooling sensitive data into a central database for analysis, it enables the transfer of clinical prediction models (CPMs) to clinical sites for local data analyses. Thus, sensitive transplant data reside protected in their original sites while the comparable small algorithms are exchanged instead. For our third objective, we will compare the performance of selected AI algorithms, for example, random forest and extreme gradient boosting, as foundation for CPMs to predict severe

XSL•FO
RenderX

short- and long-term posttransplant risks, for example, graft failure or mortality. The CPMs will be trained on donor and recipient data from retrospective cohorts of kidney transplant patients.

Results: We have received initial funding for NephroCAGE in February 2021. All clinical partners have applied for and received ethics approval as of 2022. The process of exploration of clinical transplant database for variable extraction has started at all the centers in 2022. In total, 8120 patient records have been retrieved as of August 2023. The development and validation of CPMs is ongoing as of 2023.

Conclusions: For the first time, we will (1) combine kidney transplant data from nephrology centers in Germany and Canada, (2) implement federated learning as a foundation to use such real-world transplant data as a basis for the training of CPMs in a privacy-preserving way, and (3) develop a learning software system to investigate population specifics, for example, to understand population heterogeneity, treatment specificities, and individual impact on selected posttransplant outcomes.

KEYWORDS

posttransplant risks; kidney transplantation; federated learning infrastructure; clinical prediction model; donor-recipient matching; multinational transplant data set

Introduction

End-stage kidney disease is growing globally affecting already up to 800 million (10%) people worldwide. Dialysis or kidney transplantation are current options for renal replacement therapy. There are 100,000 dialysis patients in Germany, and 50,000 in Canada [1,2]. In total, 1992 kidney transplantations in Germany and 1673 kidney transplantations in Canada were performed in 2021 [3,4]. Kidney transplantation is the preferred way of renal replacement therapy because it improves the quality of life for patients, extends life expectancy, and saves resources of the health care system [5-7]. However, there is a shortage in donor organs. As a result, in total 6593 patients in Germany and 3060 in Canada were on a waiting list for a suitable donor kidney in 2021 [4,8]. Despite the advances in medicine and improvement of short-term graft survival rates within the first year, long-term graft survival remains stagnant. It shows an attrition rate of approximately 5% annually after the second year resulting in reinitiation of dialysis or transplantation in approximately 50% of patients after 10 years [2,9]. After transplantation, regular follow-up visits especially in the first year are required to detect and prevent fatal outcomes, for example, infections, kidney rejections, or cancer due to over- or underimmunosuppression. Today, nephrologists lack adequate diagnostic measures for assessing and stratifying the individual patient's risk for posttransplant outcomes, for example, graft failure or rejection [10]. Early detection of patients at high risk would open an additional prevention path: clinicians would have the opportunity to initiate countermeasures earlier and prevent fatal outcomes.

The NephroCAGE consortium was initiated as a strategic lighthouse project supported by the national governments of Germany and Canada to combine medical and technical expertise to build a real-world demonstrator and evaluate the added value of artificial intelligence (AI) in a very specific medical use case from nephrology. It brings together worldwide excellence from transplant centers, academia, and industry from Germany and Canada to join forces as depicted in Figure 1. In total, 4 major clinical kidney transplant centers from both nations have contributed transplants to form the first-of-its-kind international NephroCAGE data set; it forms a longitudinal database of patient-level data from more than 8000 transplant cases over the past 2 decades. The NephroCAGE data set builds the foundation for detailed retrospective data analysis using AI learning techniques and the development of clinical prediction models (CPMs) for prospective identification of posttransplant outcomes of kidney transplant patients. With the help of the CPM predictions, clinicians are expected to improve the quality of care for future patients with kidney disease in Canada, Germany and worldwide by identifying individual patient risks even earlier than possible today.

Immunological differences play a key role in the development of organ rejection reactions, which might lead to graft failure or even graft loss [11,12]. It has been proven that transplant patients sharing compatible serologic human leukocyte antigen (HLA) types with the organ donor have better outcomes compared to patients with incompatible HLA types [13]. Today, only a subset of HLA genes is considered for matching of immunological factors from donors and recipients. The HLA genes located on chromosome six are responsible for encoding of proteins that fold complex structures, so-called epitopes. Today, it is known that checking for HLA compatibility requires in addition to pure genetic information also the assessment of the protein's 3D structure, which might trigger immunological response. However, current organ allocation algorithms in productive use include only very limited aspects of HLA compatibility, for example, number of mismatches per HLA, to reduce the immunological risk for graft rejection and donor-specific HLA antibodies [14,15]. Recently, new matching methods have been developed to optimize assessment of organ compatibility between donors and recipients incorporating more functional aspects, for example, on biological level and additional molecular specifics [16-18]. Selected methods showed improved precision in predicting immunological risk, some of them being also relevant for organ allocation [11,17,19,20].

The NephroCAGE consortium aims to show advantages of using molecular compatibility for matching of organ donors and recipients. Therefore, we aim to incorporate the latest research results on B cell and T cell epitope matching as a specific feature of our CPMs. Furthermore, we will investigate

XSL•FO
RenderX

the applicability of tree-based machine learning (ML) algorithms such as random forest (RF) and Extreme Gradient Boosting as a foundation for the development of CPMs trained on real-world transplant data in nephrology.

Therefore, access to high-quality real-world data is crucial to train and validate high-quality AI models for clinical use. At the same time, clinical data are considered as highly sensitive data, which typically cannot be exposed for training of AI models. The NephroCAGE consortium as the first of its kind has access to multicenter transplant data from 2 nations for the development of AI-based CPMs. One of our hypotheses is that AI-based CPMs combining both clinical and immunological data will lead to improved detection of patients at high risk for graft loss and rejection. Conversely, we will focus on data from patient follow-ups and immunological data, for example, presence of donor-specific antibodies (DSA) for HLA.

Over the past decades, hospitals and transplant centers have developed individual clinical information systems for management of their transplant patient data. As a result, data are scattered across multiple silos using various data formats, which makes multisite research a complex data management task. Thus, the use of standardized data formats, common data dictionaries, shared terminologies and ontologies, and open application programming interfaces (APIs) are required to facilitate the deployment and integration of innovative AI-based solutions into existing clinical IT systems.

Combining data from multiple clinical data sources for development of CPMs traditionally involves complex data preprocessing steps, for example, data harmonization, data transformation, enable semantic interoperability, legal agreements, and data privacy measures [21]. The use of a federated learning infrastructure (FLI) turns around the paradigm of centralized data storage: it enables transfers of algorithms to the data to perform local data processing, thereby keeping data at its original protected location [22,23]. In a decentralized FLI, network nodes located at collaborating transplant centers communicate on a peer-to-peer basis, that is, all network communication is performed between individual network partners without the need for any central instance. This raises the questions about how access control to the nodes is enforced, how CPMs are trained, and how to exchange CPMs between sites. Recently, distributed ledger technology (DLT) emerged to guarantee immutable transactions between untrusted parties. These transactions are kept in a consistent state through automated, algorithm-based consensus-building mechanisms, which eliminates the need for third-party trust enforcement [24]. The aggregation of models in FLIs, that is, the combination of individual CPM versions from different partners, is well-established for parameter-based AI approaches such as neural networks. However, only limited research investigates the aggregation of tree-based or kernel-based AI approaches, such as RFs or support vector machines, which are relevant for the given nephrology use case.

Figure 1. For the first time, the NephroCAGE consortium brings experts from nephrology, academia, and industry on both sides of the Atlantic Ocean together to investigate privacy-preserving ways to enable combination of real-world transplant data from Germany and Canada for design of clinical prediction models to predict the patient-specific probability for severe posttransplant risks.

Methods

NephroCAGE Consortium

The founding partners of the German-Canadian NephroCAGE consortium are depicted in Figure 1 and their functions in the consortium are outlined in the following:

- Transplant centers: Charité – Universitätsmedizin Berlin, McGill University Health Centre and Centre Hospitalier de l'Université de Montréal both located in Montréal, Quebec, Canada, and Vancouver General Hospital of the University of British Columbia are internationally known hospitals, each of them with kidney transplant centers covering large patient populations. For example, Charité performs about 200 transplants per year and covers major parts of North-Eastern Germany. Our hospital partners provide access to real-world clinical data, which is key for training and evaluation of CPMs. Furthermore, they provide access to clinical subject-matter experts, drive the clinical focus and lead the development of a clinical demonstrator to evaluate our findings.
- Academia: All university hospital partners are universities affiliated. Furthermore, the Karlsruhe Institute of Technology and the Hasso Plattner Institute for Digital Engineering contribute international expertise in software engineering, AI technology, and digital health. Academic partners contribute through applying the latest AI research findings for building CPMs and to design and implement the NephroCAGE FLI enabling a privacy-preserving way of combining transplant data.
- Industry: PIRCHE AG is an internationally operating company headquartered in Berlin, Germany, having expertise in donor-recipient HLA molecular compatibility assessment. Thus, PIRCHE will work on integration of molecular donor-recipient matching incorporating HLA data from HLA laboratories.

Ethical Considerations

All methods were carried out in accordance with relevant guidelines and regulations in the participating countries Germany and Canada. The project was approved by the following ethics committees: (1) Charité – Universitätsmedizin Berlin (EA4/104/21) and (2) Research Ethics Board of the McGill University Health Centre and Centre Hospitalier de l'Université de Montréal research center (MP-37-2022-8003). Available data are retrospective data obtained from patients, who gave their informed consent prior to their transplantation for the use of their data for retrospective analyses. All data will be handled in accordance with the corresponding data protection regulations, that is, the European General Data Protection Regulation and the Personal Information Protection and Electronic Documents Act, respectively. Data access was given to clinicians after deidentification only. Prior to the use of data for CPM training, data were in addition pseudonymized to minimize any eventual reidentification risk. There were neither specific compensations nor benefits provided to patients by the NephroCAGE consortium for the use of their data. We use retrospective data, which were gathered during routine care.

NephroCAGE Data Set

Table 1 provides an overview of the NephroCAGE data set, which consists of more than 8000 transplant patient cases across the past 2 decades with an average age of 51.7 years. Approximately two-thirds of the transplanted patients in our data set are male and one-third are female patients, which aligns with the sex distribution known from related studies [25]. Table 2 provides a summary of available categories of transplant data in our NephroCAGE data set.

Data of transplant patients resides in individual hospital information systems (HIS), for example, laboratory information management system, digital pathology system, or patient management system. For example, patient data are collected during dialysis, at transplantation, and for each of the individual follow-up visits after successful transplantation. Before we can use such data for training of CPMs, each clinical site needs to extract relevant data from their internal source systems and transform them into the common NephroCAGE data schema [26]. Some of the clinical transplant centers have already performed extraction of data from internal sources and its harmonization to a common data schema, for example, due to the presence of a local clinical data warehouse. As a result, local efforts for extraction and harmonization of data are reduced at these sites. Extraction and harmonization of data should be automated to establish a reproducible process to allow the continuous integration of new transplant data into the NephroCAGE data set. Thus, the NephroCAGE data set can also be used for answering future research questions in the clinical domain nephrology.

In the NephroCAGE consortium, we have conducted the following steps to make transplant data available for development of CPMs. All clinical sites defined a study protocol and applied for approval by their individual institutional review boards. It involved the detailed description of required data attributes and what kind of algorithm and models will be implemented on the data, for example, the following details were provided: the goal of the project, research hypotheses, patient cohort description, list of variables, incorporated data protection regulations, exclusion criteria, and methods in particular details about the incorporated AI methods and epitope matching algorithms.

Each clinical transplant center has to identify and extract relevant transplant data from their local HIS. Figure 2 depicts the involved process steps per category of data from top to bottom. After data extraction and format harmonization, the quality of retrieved data needs to be assessed by subject-matter experts. For example, selected cases need to be checked for inconsistencies in reported data. We will only address inconsistencies that occurred as part of the data extraction process. If data are confirmed to be inconsistent in the primary system, we have to exclude the patient case from further processing until these inconsistencies are addressed by the clinical transplant centers. Furthermore, outliers will also be removed from further processing.

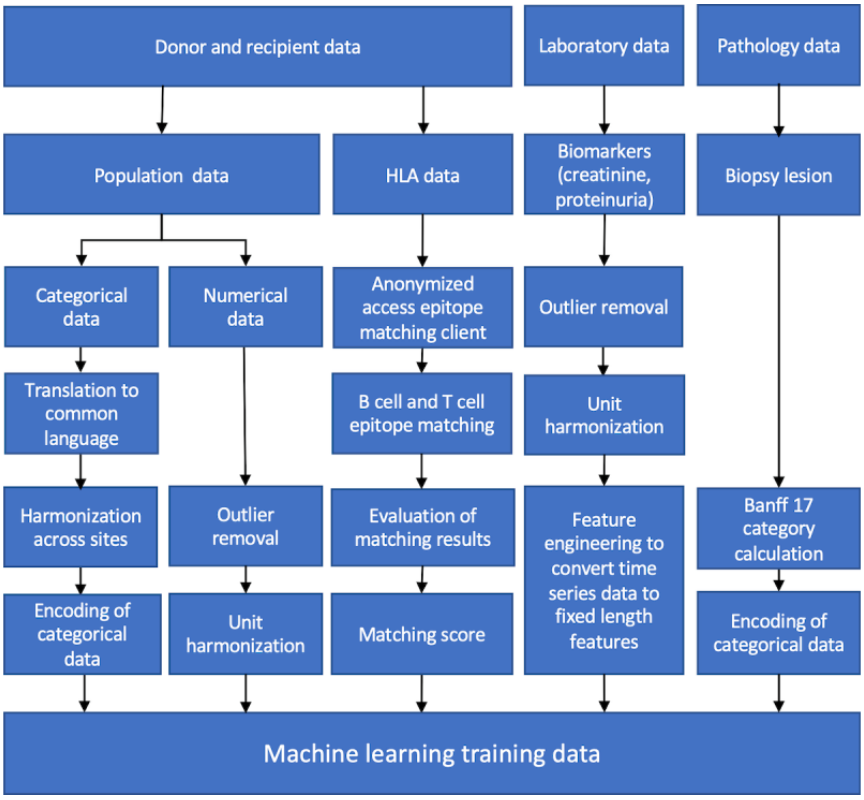
[c]UBC: University of British Columbia.

Table 2. Categories of transplant data available within the NephroCAGE consortium.

Data category	Description	Selected examples
Recipient data	Measurements of patient data for transplant procedure	Weight, age, sex, HLA[a] data, transplantation date, type of dialysis, time on dialysis, number of transplantations, delayed graft function, cold ischemia time, death date, DSA[b], and MFI[c] of DSA
Donor data	Measurements of donor data for transplant procedure	Weight, age, sex, and HLA data
Laboratory data	Laboratory values, for example, blood and urine	Creatinine, proteinuria (ratio and dip stick), albumin, and CRP[d]
Pathology reports	Medical pathology report	Rejection diagnosis, Banff lesion scores, and Banff diagnostic categories
Clinical notes	Information collected during clinical examination	Diagnoses, symptoms, medical history, physical examination, and written medications
Medications	Information relevant to immunosuppressants	Encoded medication using ATC[e] codes
Hospitalization data	Details about hospitalizations and clinical assessments	Admission and discharge date, blood pressure, urine volume, pulse rate, and temperature
Follow-up data	Details acquired during regular follow-ups	Weight, blood pressure, urine volume, pulse rate, temperature, and DSA

[a]HLA: human leukocyte antigen.

[b]DSA: donor-Specific antibodies.



[c]MFI: mean fluorescence intensity.

[d]CRP: C-reactive protein.

[e]ATC: anatomical therapeutic chemical classification.

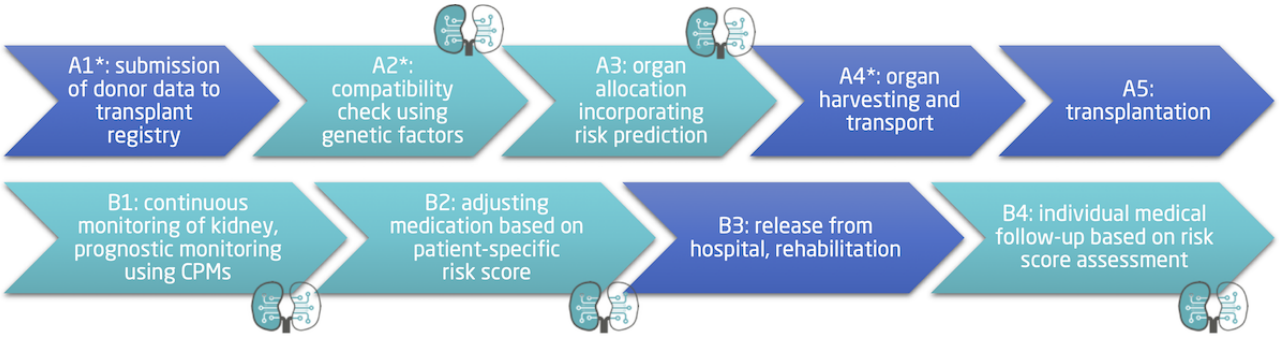
Figure 2. Selected process steps involved in extraction and harmonization of data from NephroCAGE transplant centers to form the NephroCAGE data set. HLA: human leukocyte antigen.



Improving the Kidney Transplantation Process

Figure 3 outlines selected clinical steps in the traditional kidney transplantation process: pre- and posttransplant. If a new organ becomes available via organ donation, its specifics are added to a transplant registry (A1), compatibility checks are conducted (A2), for example, blood group, HLA compatibility, and an allocation decision is taken incorporating donor and recipient specifics (A3). While the organ is retrieved from the donor and transported to the transplant center of the recipient (A4), the recipient is prepared for transplantation (A5). After surgery, the function of the donor organ is closely monitored incorporating common laboratory values (B1) and required medication is set up (B2). After a period of recovery, the patient's release from the hospital is possible, and rehabilitation can start (B3). Regular follow-up appointments for monitoring of kidney function are required to identify eventual risks for the patient and the graft as early as possible (B4).

We will incorporate B cell and T cell epitope matching for donors and recipients as well as our CPMs to provide new insight for clinicians to decide on a donor kidney allocation in steps A2 and A3. If the decision is made for transplantation, the data from surgery and the recipient's lab data from the hospital stay will be used as input for the CPMs design in steps B1 and B2. Thus, our CPMs can help to provide patient-specific risk scores to clinicians, for example, to adjust immunosuppressant medication accordingly, and improves continuous posttransplant patient monitoring in step B4.

Figure 3. Top: selected clinical process steps taken pretransplant. NephroCAGE aims to enhance the current compatibility assessment between donor and recipient by incorporating genetic testing providing the foundation for advanced organ allocation to minimize the risk of incompatibility of human leukocyte antigen between donor and recipient before organ allocation. Bottom: posttransplant, the function of the graft will be monitored continuously. Comparing data with historical references using the NephroCAGE CPMs enables the definition of a patient-specific risk score to develop clinical end points of interest. As a result, medication and follow-up appointments can be adapted to allow fine-grained monitoring by clinicians. CPM: clinical prediction model.

Molecular-Genetic Matching

Recently, several algorithms to predict molecular HLA compatibility have been proposed. These algorithms model different immunological pathways of allorecognition. Eplet matching translates HLAs into a set of conformational epitopes, toward which the recipient may form HLA antibodies based on the absence of a corresponding self-epitope [16,17,27,28]. Activation of B cells via conformational epitopes is known to require substantial T cell activation. The model provided by PIRCHE predicts linear T cell epitopes, that may be targeted by the hypervariable T cell receptors. Thus, a combination of specific methods has been shown to further improve histocompatibility prediction [29]. Following this strategy, NephroCAGE aims to combine molecular antibody and T cell epitope matching in a CPM. We aim to implement the molecular matching algorithm as a cloud-based software as a service (SaaS) due to high requirements for storage and computing hardware. The use of a SaaS solution allows flexible control of service quality and user experience. However, submitting genetic data to the SaaS provider may cause conflicts with privacy regulation dependent on local legislation.

Within the NephroCAGE consortium, we aim to develop an open-source command line client for anonymization of HLA data of recipients and donors. For computing the molecular matching scores for donor-recipient pairs, common strategies reducing the resolution of shared information, for example, binning or shuffling, are not applicable given the requirement to obtain exact in silico test results. Therefore, the accurate donor-recipient pair HLA typing will be supplemented by obfuscated HLA data sets. This process considers HLA domain-specific information about haplotype and allele frequencies complicating the identification of individuals in the transmitted data set for the service provider and potential intruders. The molecular matching scores will be correlated to transplant outcome compared to results shown in the literature. Considering these findings as a baseline, we will validate modifications to the prediction pipeline, including a peptide cleavage prediction model.

Using ML for CPMs

Various related work showed that AI approaches based on medical input data can result in accurate and robust statistical models to predict patient outcomes [30-34]. For example, supervised tree-based ML algorithms, for example, RF and Extreme Gradient Boosting, have shown promising results for classification tasks for posttransplant risks, for example, for graft failure, patient survival, or graft loss within a certain time period [35-40]. However, most of the existing approaches were research-driven and had only limited access to real-world medical data for their work, for example, using the Scientific Registry of Transplant Recipients data set [41]. Loupy et al [42] developed a risk score for kidney transplant recipients in context of a multicenter study making use of multivariable Cox regression analysis to predict graft loss in patients. Among others, they incorporated the following features: estimated glomerular filtration rate, proteinuria, histology, and HLA antibody [42]. Furthermore, recently advanced approaches based on neural networks making use of large proteomic databases occurred for assessment of immunogenicity and probability to generate antibodies [27,43,44].

From a clinical perspective, NephroCAGE aims to prevent the occurrence of adverse posttransplant end points, for example, loss of function, graft failure, and patient death. Nowadays, regular monitoring is applied to help identifying individual risk factors as early as possible. The use of digital patient records in hospitals for more than a decade provides the data foundation for our work because they form a longitudinal database of historic patient cases, medical decisions, therapies, and disease progression. Today, historical case data are only rarely used for current patient care. Our research hypothesis is that the analysis of historical cases can help to derive prognostic predictions for the individual patient risk to reach severe clinical end points. Based on the analysis of patient-specific parameters, a current patient case will be assigned to a group of similar, historic patient cases.

We will use the existing real-world data from historic patient cases from our clinical partners as a foundation for the definition of specific CPMs per clinical end point of interest [45,46]. Together with our clinical experts, we have defined specific CPMs to predict selected short- and long-term posttransplant events, for example, transplant failure and organ rejection. For example, a CPM trained for prediction of graft failure will cover whether this event will happen (yes or no) within 1 year (short-term) or 5 years (long-term). Such a CPM will predict a floating-point probability $p \in [0,1]$, which will be mapped to positive and negative outcome classes. We will minimize the complexity of CPMs by incorporating the principle of data economy, that is, we will only use a minimal set of clinical parameters required to achieve a stable prediction quality. Therefore, we will make us of automatic and manual feature selection approaches to identify most descriptive features for the specific end point from the provided input data set [48-50]. Among others, our CPMs will make use of the following input parameters: recipient and donor data, laboratory values, biopsy results, medication, hospitalization records of the recipient, and HLA compatibility score. Recipient data include sex, weight, height, age at transplantation, end-stage kidney disease, HLA compatibility data, age at graft failure, cause of graft failure, age at death, and many others. Different kinds of follow-up data, for example, weight, and blood pressure, as well as laboratory values, for example, serum creatinine and daily protein-urea. In the case of kidney rejection or failure, a biopsy is performed and analyzed by a pathologist. For interpretation of renal allograft biopsies, Banff classifications are also available in the NephroCAGE data set.

Once a CPM has been trained at a clinical site, it will be shared with other clinical partners in Canada and Germany for validation and continuous training. CPM release versions will be packaged and deployed for execution to individual clinical sites using Docker containers. Thus, comparable small CPMs are exchanged whilst sensitive transplant data do not leave their protected clinical sites.

The current clinical transplantation process outlined in Figure 3 depicts multiple steps where prognostic predictions provided by NephroCAGE CPMs can support clinicians. In the following,

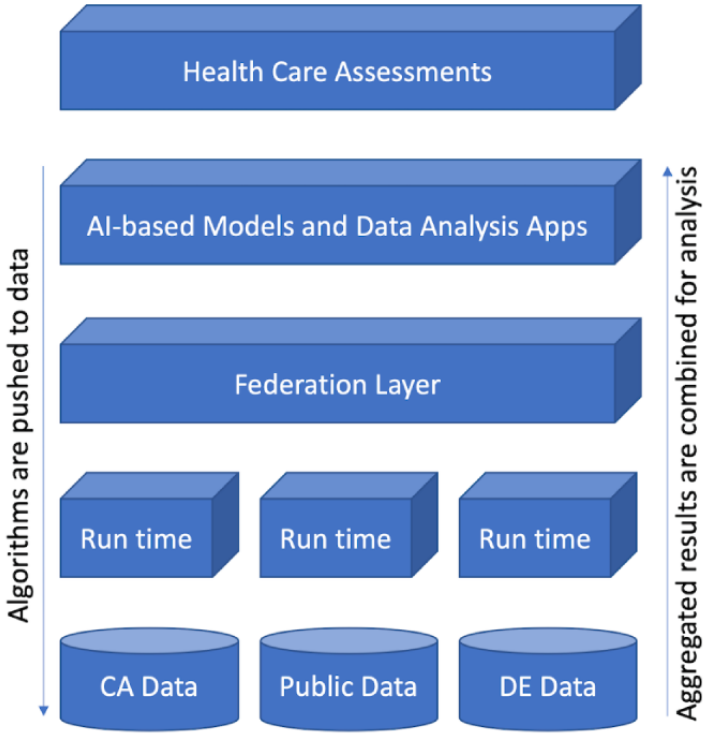
XSL•FO
RenderX

we distinguish between pre- and posttransplant use of NephroCAGE CPMs: (1) pretransplant: the use of CPMs prior to transplantation can support more advanced genetic matching of donor and recipients and provide helpful insights for organ allocation; and (2) posttransplant: after transplantation CPMs can also incorporate patient-specific details on the graft function, for example, by including the latest prognosis, which provides a more specific view on the graft. We will focus on binary classifiers predicting short-term (1 year) and long-term (up to 8 years) outcomes post transplantation.

Patient-Specific Risk Score

The use of patient-specific risk scores is well known in medicine, for example, Glasgow Coma Scale, acute physiology and chronic health evaluation, and sepsis-related organ failure assessment for intensive care patients [51-53]. Risk scores are often used to stratify patients at risk or to predict selected aspects for patient care. They are often designed to use multiple values, for example, latest observational and laboratory values, and combine them toward a single numeric value for a selected clinical outcome. When a patient has a follow-up appointment or encounters any complication, latest data can be incorporated to update the patient-specific risk score.

We aim to define a patient-specific risk score for selected posttransplant events to provide additional insights for nephrologists during posttransplant care. The risk score is a low-dimensional metric representing the overall risk of developing posttransplant complications and will contribute to steps B1, B2, and B4 of the clinical process outlined in Figure 3. It will be calculated by combining the outcome of multiple CPMs and additional patient-specific parameters into a single clinical parameter. Thus, it can support clinicians in continuously monitoring selected kidney function parameters or initiating adequate action as early as possible. Based on the risk score, we will be able to classify patients into low-, medium-, and high-risk patients comparable to a traffic-light schema. Patients classified as high-risk patients will require increased systematic monitoring to prevent complications as early as possible, whereas patients classified as low-risk patients are not expected to develop severe events in the near future. This helps to use the available clinical workforce more efficiently, especially in times of a shortage of skilled labor.



NephroCAGE FLI

Figure 4 depicts the building blocks of the NephroCAGE FLI, that is, from bottom to top: local transplant data accessed by local FLI runtimes, a federation layer for exchange of CPMs and data, as well as AI-based model making use of the NephroCAGE FLI to support clinicians in gaining medical insights. Each NephroCAGE clinical partner will join the NephroCAGE FLI by installing and configuring a local NephroCAGE FLI runtime environment on a dedicated host. After transplant data have been extracted from local clinical systems and harmonized, the host running the local FLI runtime environment is granted access to the data. Afterwards, the training of CPMs can be performed on the local data set. Once a stable CPM version becomes available, it will be released for sharing between partners using the NephroCAGE FLI. As a result, pretrained CPMs can be exchanged via the NephroCAGE FLI to facilitate model training even across country borders.

We will use DLT such as an Ethereum blockchain network to have decentralized storage for communicating model updates and code between clinical transplant centers without the need for a dedicated central authority [54]. For support of model training, we will implement an institutional incremental learning approach, where members retrain models one after another and compare different collaborative learning mechanisms with each other [23]. The aggregation of model values is well-established for parameter-based approaches like neural networks. However, only limited research investigates the aggregation of tree-based or kernel-based approaches like RFs or support vector machines, which are relevant for the NephroCAGE use cases.

XSL•FO
RenderX

Figure 4. Building blocks of the NephroCAGE FLI. From bottom to top: individual clinical transplant centers from Germany and Canada contribute with more than 2 decades of transplant data enriched by publicly available data, for example, population and research data. Data are only accessible through local runtimes of the NephroCAGE FLI per clinical site, enabling training and sharing of model results whilst keeping data protected. All local FLI runtimes are interconnected through a federation layer, for example, providing access to a data repository for sharing model code and a DLT persistence to store transaction data. The federation layer provides harmonized data access by exposing an API, for example, for training and deployment of AI models and site-spanning data analysis. The results of the CPMs can be assessed by subject-matter experts, for example, to derive patient-specific risk scores for severe posttransplant risks. AI: artificial intelligence; API: app programming interface; CA: Canadian; CPM: clinical prediction model; DE: German; DLT: distributed ledger technology; FLI: federated learning infrastructure.

Deployment and Integration Into Clinical Information Systems

An expert-facing web app will be developed by the consortium as clinical demonstrator. It will be designed using a representation state transfer (REST) API, which allows integration into existing clinical information systems, for example, T-Base at Charité [55]. The NephroCAGE clinical demonstrator will be used by clinicians to gain insights into patient-specific risk scores including additional information for prospective treatment. Therefore, selected data about individual patients will be exchanged with the CPM to calculate the individual probability for posttransplant risks. As a result, we will provide our CPMs in a local deployable way, that is, the CPMs will be executed by the clinical partners, to preserve privacy of any kind of patient data. Furthermore, the clinical demonstrator will serve as an evaluation platform to identify features that can be intervened in to improve outcome.

To facilitate the integration into existing clinical IT infrastructures, we will follow widely adopted internet protocols (HTTP and HTTPs) and well-known software development paradigms for the development of our CPMs and the clinical demonstrator. Therefore, we will develop the NephroCAGE CPMs as modular software components in Python providing an open API to expose their provided functionality for integration into existing software systems. Thanks to the API of the CPMS, the incorporated programming language and software stack remains transparent for the use of the client app. Through the API a stable software interface describing the required in- or output parameters is available, which will facilitate the integration into our clinical demonstrator and other existing clinical software systems. The REST software paradigm guides the development of web app upon established internet protocols [56]. Hence, RESTful APIs could be designed independent of the existing system with which they will be integrated, making them highly decoupled and modular. We will make use of REST API in our CPM design because it will build on well-established communication protocols for exchange of messages and therefore facilitates the integration into existing clinical IT systems. The execution environment for CPMs requires a diverse set of software dependency to function. Virtualization tools, such as Docker (Docker), can support the packaging of CPM software code, automatically install required software dependencies, and improve software deployment reducing maintenance efforts and hospital IT staff [57]. Thus, our CPMs will be packaged using a Docker container, which reduces deployment and maintenance efforts per clinical site.

Results

We have received initial funding for NephroCAGE in February 2021. Data owners from all clinical transplant centers have successfully received ethics approval for participating in the project in 2022. The process of exploration of clinical transplant database for variable extraction and harmonization has started at all centers in 2022. Therefore, we have developed software

XSL•FO
RenderX

tools to facilitate the extraction, cleansing, and harmonization of relevant transplant data.

For the harmonization of data, we have defined the NephroCAGE data dictionary (DD) together with all clinical partners. The DD covers all attributes per data element, for example, data type, valid data ranges, and harmonized measurement unit. We have 2 types of attributes in the NephroCAGE DD: numerical and categorical. For numerical attributes, we have defined harmonized measurement units, for example, creatinine in µmol/L, age in years, and weight in kg. For categorical data, we have defined all valid categories per attribute, for example, $sex_{recipient} \in \{♀, ♂\}$. Some attributes correspond to numerical or categorial attributes depending on the way it was measured. For example, proteinuria can be stored as numerical attribute with the unit mg/day if it was acquired through a 24-hour urine collection or as categorical attribute using the set {+,++,+++} (+=low, ++=medium, +++=high) if it was acquired using a dipstick quick test.

As of August 2023, a total of 8120 patient records have been retrieved by all clinical partners for use in the NephroCAGE data set as depicted in Table 1. We will calculate the molecular epitope matching score for donors and recipients and extend our data set by it to gain insights in formation of donor-specific antibody formation and impact on the clinical outcome. Subsequently, we will use the NephroCAGE data set to train and validate CPMs for selected posttransplant clinical end points. Locally pretrained CPMs will be retrained and validated by clinical sites through the use of the NephroCAGE FLI. We will focus on ensemble methods to aggregate models trained on individual clinical sites. Setting up the NephroCAGE FLI runtime at each clinical site requires compliance with data compliance regulations of pertaining individual clinical sites and geographies. Our NephroCAGE FLI will facilitate the development of CPMs, enable continuous training at each site without the need for pooling sensitive transplant data in a central database or data warehouse.

Discussion

Findings on Using Sensitive Health Data for Development of CPMs

Transplant data used to form the NephroCAGE data set—as any patient data—are very sensitive and requires dedicated protection measures. However, the accessibility of such data is crucial to enable training of CPMs with high prognostic value. Running a multinational project requiring access to data from different geographic jurisdictions is complex, for example, due to compliance with individual data protection regulations and variety of data formats and semantic meaning. The NephroCAGE consortium develops the privacy-preserving NephroCAGE FLI to comply with the regulations of Canada and Germany. Furthermore, the NephroCAGE data set is unique in its size, details, and longitudinal completeness. As a result, we believe that the NephroCAGE data set can also serve future research as a profound foundation. For example, we plan to use the NephroCAGE data set to analyze the impact of demographics and health care systems on the posttransplant outcomes in Germany and Canada.

The complexity of transplant data stems from its multiple attributes originating from different sources. It contains longitudinal data about clinical events typically occurring years or decades after transplantation and comorbidities related to the underlying disease, for example, creatinine from laboratories and hospitalization data from HISs. Data extraction and harmonization across partners is one of the most challenging parts of our project, because each center has its individual IT infrastructure to store transplant data. Due to our federated setup, we do not make use of a central data warehouse. Therefore, harmonizing transplant data before developing CPMs is more crucial than in a traditional data warehouse setup. Thus, we will perform specific data preprocessing activities, for example, harmonizing categorical variables with the same name and units and checking numerical variables for outliers.

We will work together with nephrologists and clinical experts to identify clinical end points of interest as basis for CPM development. We will start to investigate the applicability of tree-based models and artificial neural networks as ML methods based on our literature review, because tree-based methods perform better on imbalanced tabular data than neural networks. Furthermore, tree-based methods show better explainability by providing explicit feature importance. Finally, an imbalance of data in kidney transplantation might lead to over-fitting for the majority classes. Consequently, we will apply resampling methods to reduce this effect [58-60].

Genomic data for the HLA compatibility algorithm are among the most sensitive transplant data. Therefore, we aim to implement an anonymization client so that the HLA is not susceptible to various privacy threats. Today, only 5 genetic loci from HLA-A, -B, and -DR are used by Eurotransplant's graft allocation algorithm despite a total of 11 clinically relevant HLA loci being associated with immunologic risk [15]. Molecular matching, such as PIRCHE, has been shown to provide additional value to serologic HLA matching in assessing risk of developing donor-specific HLA antibodies, thus having the potential to improve long-term transplant outcomes. Furthermore, donor-specific antibodies are a major factor for rejection that deteriorate organ function and result in graft loss. Although we will use the NephroCAGE FLI to share CPMs between partners, still concerns remain about the privacy of patient data in the case of backtracking the ML model coefficient into individual patient outcomes. Therefore, we will incorporate only deidentified data as basis for CPM training, that is, anonymization of sensitive attributes such as follow-up visit dates, surgery date, and birth date.

Furthermore, the prediction results of CPMs alone are not sufficient to fully explore the reasons. Therefore, we will add additional information to the results, which will enable clinicians to perform informed decision-making, for example, most important features used by the model or details about the specific subtree the individual is assigned to. Thus, clinicians will be enabled to assess the provided prediction and also provide feedback about their final decision, which might be different from the prediction. Thus, we trust that clinicians can incorporate additional insights provided by CPMs into their decision-making process, but still remain the final and human decision maker responsible for clinical treatment decision.

XSL•FO
RenderX

Limitations

We use observational retrospective data over different time periods and different centers. For example, the majority of transplant data contributed to the NephroCAGE data set is provided by 1 center as outlined in Table 1. Furthermore, transplant data from individual centers was collected across different time periods, thus they might differ due to advances in medical practice. This limits data integration from all centers, including preprocessing and modeling of the data in a similar fashion. Different times and eras of transplantation may infer time bias in the model. Different center practices and demographics may be challenging to interpret and might influence the prediction of CPMs. Therefore, CPMs will show the differential importance of features on the desired clinical outcome. However, clinically actionable features must be determined as certain features cannot be changed, for example, the donor's age. For some clinically relevant factors, interventions must be found, and randomized controlled trials must be established to find appropriate therapy. By diminishing worse outcomes, training and improvement of the CPM may change over time, resulting in inferior model performance, thus deteriorating identifying patients at risk. All the hospitals represent independent cohort in our federated learning setup and hence a particular attention needs to be given in the order of learning to be done on these data set [61].

Conclusions

We have introduced the overall goals of our German-Canadian NephroCAGE consortium, addressing multiple challenges in implementing latest federated learning methods to enable privacy-preserving training of CPMs using real-world transplant data from transplant centers in Germany and Canada. We have highlighted the need to perform data harmonization and develop automated data extraction pipelines per transplant center to ensure reproducibility and scalability of the developed CPMs. Our NephroCAGE FLI will be used for privacy-preserved training and exchange of CPMs, which incorporate data from various hospitals. By including molecular epitope matching into our CPM, we aim to gain insights on donor and recipient HLA-matching beyond the current standard of care. The goal of our CPMs is to support clinicians by identifying severe posttransplant risks as early as possible for individual transplant patients. We aim to develop a clinical demonstrator, which will be used for evaluation of CPMs in a clinical setting. The CPM needs to be verified in randomized clinical studies and evaluated to assess factors that can be used for treatment and modification to improve outcomes. This will especially be achieved if more transplant centers join the consortium and share their transplant data via the NephroCAGE FLI.

Abstract

Background: Veterans Affairs Farming and Recovery Mental Health Services (VA FARMS) is an innovative pilot program to provide supportive resources for veterans with interests in agricultural vocations. Implemented at 10 pilot sites, VA FARMS will provide mental health services and resources for veterans while supporting training in gardening and agriculture. As each pilot site project has unique goals, outreach strategies, and implementation efforts based on the local environment and veteran population, evaluating the pilot program provides a unique challenge for evaluators. This paper describes the protocol to evaluate VA FARMS, which was specifically designed to enable site variation by providing both site-specific and cross-site understanding of site implementation processes and outcomes.

Objective: The objectives of this paper are to (1) describe the protocol used for evaluating VA FARMS, as an innovative Department of Veterans Affairs (VA) agriculturally based, mental health, and employment pilot program serving veterans at 10 pilot sites across the Veterans Health Administration enterprise; and (2) provide guidance to other evaluators assessing innovative programs.

Methods: This evaluation uses the context, inputs, process, product (CIPP) model, which evaluates a program's content and implementation to identify strengths and areas for improvement. Data collection will use a concurrent mixed methods approach. Quantitative data collection will involve quarterly program surveys, as well as three individual veteran participant surveys administered upon the veteran's entrance and exit of the pilot program and 3 months postexit. Quantitative data will include baseline descriptive statistics and follow-up statistics on veteran health care utilization, health care status, and agriculture employment status. Qualitative data collection will include participant observation at each pilot site, and interviews with participants, staff, and community stakeholders. Qualitative data will provide insights about pilot program implementation processes, veterans' experiences, and short-term participation outcomes.

Results: Evaluation efforts began in December 2018 and are ongoing. Between October 2018 and September 2020, 494 veterans had enrolled in VA FARMS and 1326 veterans were reached through program activities such as demonstrations, informational presentations, and town-hall discussions. A total of 1623 community members and 655 VA employees were similarly reached by VA FARMS programming during that time. Data were collected between October 2018 and September 2020 in the form of 336 veteran surveys, 30 veteran interviews, 27 staff interviews, and 11 community partner interviews. Data analysis is expected to be completed by October 2022.

Conclusions: This evaluation protocol will provide guidance to other evaluators assessing innovative programs. In its application to the VA FARMS pilot, the evaluation aims to add to existing literature on nature-based therapies and the rehabilitation outcomes

XSL•FO
RenderX

of agricultural training programs for veterans. Results will provide programmatic insights on the implementation of pilot programs, along with needed improvements and modifications for the future expansion of VA FARMS and other veteran-focused agricultural programs.

Introduction

Background

In a health care organization as large and complex as the Veterans Health Administration (VHA), successful innovations are a strategic priority [1]. Health care service innovation and continuous quality improvement help meet the diverse needs of the over 9 million veterans who receive care from VHA's 1293 health care facilities. The VHA's primary goal is to deliver greater care and treatment choices "by improving experiences and outcomes" for veterans [2]. Rigorous evaluation ensures innovations are both fiscally responsible and support the public's interest. Evaluative analysis is the foundation for data-driven decisions about the ultimate value of a practice [3]. Evaluating innovation is challenging because processes are new, and typical evaluation approaches are summative and emphasize averages, metrics, and short-term program outcomes [4]. This paper describes the protocol for evaluating an innovative VA agriculturally based mental health and employment pilot program, which serves veterans at 10 pilot project sites across the VHA enterprise.

Pilot Program

VHA's Office of Rural Health (ORH) was established by US Congress in 2006 with a mission to improve health outcomes and increase access to care for the 2.7 million rural veterans enrolled in VHA care [4]. Given ORH's mission, Senate Report (SR) 115-130 directed US $2,000,000 of funding to ORH to implement the Veterans Affairs Farming and Recovery Mental Health Services (VA FARMS) pilot program. In the spring of 2018, ORH partnered with VHA's Office of Care Management and Social Work, Office of Mental Health and Suicide Prevention's Therapeutic and Supported Employment section, Nutrition and Food Services, and Office of Community Engagement to develop a request for applications (RFA) that met the requirements outlined in SR 115-130. The RFA was open to VHA facilities and encouraged each applicant to partner with an existing community organization engaged in agricultural training. Guidelines for implementation were purposely broad so that each pilot site could tailor projects to meet the unique needs of their local population and the structure of their site. The RFA received 23 applications. Representatives from each partner office reviewed all applications with a standard set of criteria that examined feasibility, probability for success, and compliance with the congressional mandate. Ten applicants were chosen to participate in the pilot program (see Figure 1) [5]. Each VA FARMS pilot site project is unique in its design, goals and desired outcomes, duration, target veteran population, and programming. In general, pilot projects offer educational programming using a variety of modalities. These include virtual and in-person education, and some combination of classroom and hands-on project–based learning. Some pilot site projects include internships or other forms of direct job placement.

XSL•FO
RenderX

Figure 1. Map of funded pilot sites.

The goal of the VA FARMS pilot program is to provide supportive resources to veterans who desire agricultural-based treatment activities, specifically targeted to veterans diagnosed with posttraumatic stress disorder (PTSD) to complement evidence-based standard care approaches. Due to high rates of PTSD and suicide among veterans of all service eras [6], the VHA has prioritized the implementation of programs that connect veterans to critical mental health services and resources. The VHA also recognizes that there are many other social determinants of veteran health, such as economic stability and education. For this reason, programs that address multiple social determinants of health are of great value [7-9].

Nature-Based Innovation for Veterans With PTSD and Mental Health Needs

The VA FARMS pilot program combines the benefits of nature-based therapies (NBTs) for veterans experiencing PTSD and other mental health issues with opportunities for vocational rehabilitation and training. This is in line with the Department of Veteran Affairs (VA)'s prioritization of the diagnosis and treatment of PTSD in veterans and their efforts to improve access to VA benefits to treat PTSD symptoms [10-12]. VA FARMS uses agritherapy, "an approach that incorporates mental health care and services with agricultural vocational training to support veterans' behavioral and mental health needs" [13]. This is a novel approach that can positively influence community reintegration for veterans, especially those who face physical and psychological health issues, substance abuse, and unemployment [14].

Facilitation of community reintegration (CR) is part of the mission of the VA [2]. Veteran community reintegration refers to a military service member's transition from active duty to participation in life outside of the military [15]. Key components of CR are (1) employment or other productive activities, (2) independent living, and (3) social relationships [15]. A substantial proportion of veterans report difficulties with CR following discharge from military service [16]. These difficulties are associated with poor social and family relationships, unemployment, financial strain, homelessness, and poor physical and mental health [17].

VHA's commitment to veteran-centered care has improved veteran access to complementary and integrative health approaches [18]. One such example is NBT, which is an umbrella term for therapeutic approaches that incorporate nature as a key element of the therapeutic process [19]. These approaches can include outdoor programs, therapeutic landscapes, healing gardens, adventure-based counseling, and outdoor-based therapeutic recreation, as representative examples [11,20-23]. There are increasing numbers and types of outdoor programs that specifically offer different therapeutic opportunities for veterans to be immersed in natural environments [21]. Some veterans with PTSD symptoms seek to complement standard psychotherapy and medication treatments with NBTs [20,21,24-27]. For example, community gardens and other green spaces are recognized as safe, therapeutic community spaces [28,29]; they support reintegration by encouraging veterans to interact and socialize with other veterans and civilian community members while engaging in a personally and physically satisfying activity [11,30].

NBTs are not new treatment options for veterans. Historically, they were used to treat "shell shock," war-related stress, traumatic stress, and PTSD among veterans returning from

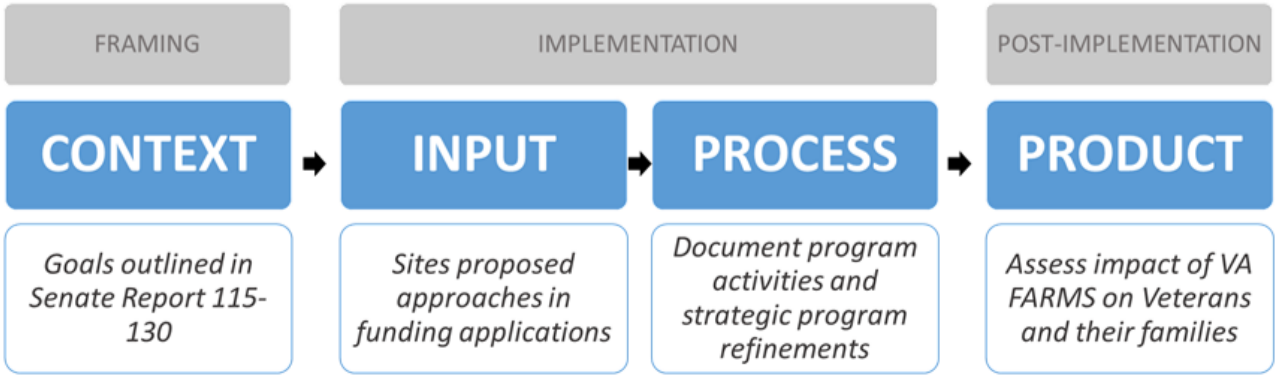
XSL•FO
RenderX

combat [14,31,32]. Although these NBTs are not considered standard care, there is some evidence that they are beneficial for the treatment of PTSD; however, much of this literature lacks measurement tools, precise descriptions of the therapeutic approach used, and clear distinctions between outdoor activities and NBT [23].

Evaluation of the VA FARMS Pilot Program

Evaluating the VA FARMS pilot program will be challenging, in part because of its novelty. The rollout will be purposefully broad, allowing each pilot site's goals, outreach, and implementation to differ based on the local environment and the unique needs of their veteran population. While mandated to provide training in agricultural vocations and access to behavioral health care services by licensed providers, each VA FARMS pilot site project is unique in its design and tailored to provide agricultural opportunities that meet local veteran needs. The evaluation protocol described herein will evaluate VA FARMS as a mechanism that supports tailored approaches to agricultural vocational training. The protocol allows for a site-specific and cross-site understanding of pilot project design and implementation processes. Programmatic data will provide a broad understanding of administrative logistics, promising practices, and modifications that may be needed to improve VA FARMS models. The protocol includes an assessment of the feasibility of measuring individual participant outcomes over time. By describing the protocol, this paper aims to provide guidance to other evaluators who are assessing innovative programs.

Study Objectives



The specific objectives of this evaluation are to: (1) identify barriers and strategies to implement sustainable ORH-funded agritherapy pilot site projects; (2) identify best practices that can be used to inform future VA agritherapy programing; (3) describe barriers, benefits, and personal experiences of veterans who participated in VA FARMS programming; and (4) assess pilot program implementation processes, barriers, facilitators, strategies, and outcomes for providing mental health care referrals and developing pathways toward employment in the agricultural sector.

Conceptual Framework

The context, inputs, process, product (CIPP) model [33] is well-suited to guide the evaluation of VA FARMS because it has been successfully used to evaluate training and educational programs [34] and innovations in dynamic real-world settings [35,36]. According to Stufflebeam and Shinkfield [35], the most important purpose of evaluation is not to "prove" but to "improve." The CIPP model systematically evaluates a program's content and implementation to identify strengths and areas for improvement. It enhances program effectiveness and supports program planning efforts [34]. Thus, this model is applicable to both formative and summative evaluations as it emphasizes "learning by doing" and promotes continuous program improvement [36].

The VA FARMS's goals (*context*) were outlined in the congressional legislation. The pilot sites proposed unique approaches (*input*) in their funding applications to ORH. For example, they outlined budget and staffing needs, partnerships, and implementation strategies. The evaluation will record each pilot site program model and the degree to which this approach helped them achieve their goals; however, the primary focus will be to assess pilot program *processes* and *products* to suggest optimal models and promising practices. The process evaluation will document pilot program activities and strategic refinements. The product evaluation will assess the impact of participating in VA FARMS on veterans. Figure 2 schematically describes application of the CIPP framework in the VA FARMS evaluation.

Figure 2. Scheme of application of the context, inputs, process, product (CIPP) framework to evaluation of the Veterans Affairs Farming and Recovery Mental Health Services (VA FARMS) pilot program.

Methods

Data Collection Procedures, Participants, and Recruitment

This 3-year evaluation will use a concurrent mixed methods approach to collect process and product data [37]. VA FARMS processes will be evaluated by collecting data about pilot program activities, implementation barriers, and modifications. These data will be collected through (1) quarterly surveys of project directors; (2) planned monthly *project status* conference calls between staff at individual pilot sites, ORH program management, and the evaluation team; (3) participant observation of activities at planned yearly site visits; and (4) *program implementation interviews* with VA FARMS pilot site staff and community stakeholders.

XSL•FO
RenderX

Products of VA FARMS will be evaluated by assessing the individual impact of participating in the pilot site projects. These data will be collected through (1) Individual *veteran participant surveys* administered by each pilot site at baseline (within 2 weeks of initial VA FARMS programming exposure), at exit (when a VA FARMS veteran participant ends their training activities), and at 3 months after the exit survey; and (2) *veteran voice interviews* with veteran participants who completed an *individual veteran participant survey* at baseline and/or exit. Interviews will be collected via telephone in years 2 and 3 of the pilot. The activities of data collection and the associated timeline are summarized in Table 1.

Table 1. Evaluation activities, methods, and timeline.

Method	Timeline	Participants	Procedure	Analysis	CIPP[a] outcome
Project status conference calls	Years 1, 2, and 3	Program coordinators at all pilot sites	Collected monthly in a 1-hour meeting via teleconferencing technology	Content analysis of meeting minutes	Process evaluation
Individual veteran participant survey: baseline, exit, 3 months postexit	Years 1, 2, and 3	Veteran participants at all pilot sites	Collected on a rolling basis, distributed by pilot sites in paper-based or online format	Descriptive statistics: RMANOVA[b], paired *t*-tests/ Wilcoxon signed-rank tests	Product evaluation
Quarterly program surveys	Years 1, 2, and 3	Program coordinators at all pilot sites	Collected every 3 months; administered online	Descriptive statistics	Process evaluation
Participant observation	Years 1, 2, and 3	Participants, staff, and stakeholders	Conducted yearly at annual site visits in person	Content analysis of field notes	Process evaluation
Implementation interviews	Years 1, 2, and 3	Year 1: Pilot site staff and community stakeholders; year 2: pilot site staff; year 3: pilot site staff and community stakeholders	Collected yearly in a 1-hour semistructured interview	Noticing, collecting, and thinking (NCT) analysis	Process evaluation
Veteran voice interviews	Years 1, 2, and 3	Veteran participants at all pilot sites	Conducted yearly in 30-minute semistructured interviews in person and via telephone	NCT analysis	Product evaluation

[a]CIPP: context, inputs, process, product.

[b]RMANOVA: repeated-measures analysis of variance.

Data Collection Procedures

Individual Veteran Surveys

Individual veteran participant surveys (see Multimedia Appendix 1) will be offered in two formats: paper-based and web-based. Completed paper-based hard copies will either be submitted to the evaluation team via United States Postal Service or scanned and sent via encrypted email. Surveys submitted via the online platform Qualtrics [38] will be accessible only to evaluation staff and stored on a secure drive. Each individual veteran participant survey includes a 16-item demographic questionnaire and the following validated measures: (1) Military to Civilian Questionnaire (M2CQ) [39], a validated measure of veteran community reintegration; (2) PTSD Checklist–Military Version (PCL-M) [40], a validated PTSD self-report questionnaire that assesses 20 Diagnostic and Statistical Manual of Mental Disorders (DSM)-5 symptoms of PTSD; (3) Patient-Reported Outcomes Measurement Information System (PROMIS) Global Health (10) SF: Quality of Life [41], a validated self-report measure that assesses overall physical health, mental health, social health, pain, fatigue, and overall perceived quality of life; and (4) Work and Meaning Inventory (WAMI) [42], a validated self-report measure that assesses the personal meaning people draw from the work they perform, as well as how work broadens life purpose and contributes to the greater good.

Individual veteran participant surveys that are administered at exit and 3 months postexit will also include a 20-item satisfaction survey.

Quarterly Program Surveys

Throughout the pilot period, quarterly program data will be reported to ORH electronically. Awardee sites will report the number of veteran participants recruited, attrition, completion, number of referrals for mental health services, number of participants who gained employment in agriculture, type and amount of service use/referrals made, and number and type of outreach events (see Multimedia Appendix 2). The evaluation team will rely on site-reported numbers of referrals as we are not able to access participant medical records.

Participant Observation and Field Notes

Evaluators will attend annual site visits lasting approximately 2.5 days. Site visits will include participant observation of classes, demonstrations, and field activities. This method will allow evaluators to participate in VA FARMS activities and observe the day-to-day operations from both a programmatic and veteran participant perspective. A field notes template (see

XSL•FO
RenderX

Multimedia Appendix 3) will capture evaluator impressions during site visits, and a debrief worksheet (see Multimedia Appendix 3) will allow evaluators to write a formal postvisit report.

Interviews With VA FARMS Staff, Community Stakeholders, and Participants

Interview guides will be developed iteratively based on pilot program goals and site-specific context, as well as evaluation survey results and conversations with VA FARMS program staff and ORH partners during monthly project status update calls. All interview guides will be based on 30-minute semistructured interviews. In Year 1, *implementation interviews* (See Multimedia Appendix 4) will be conducted in person during annual site visits with VA FARMS pilot program staff and community stakeholders. Interviews with pilot site staff will focus on start-up and implementation processes, including facilitators and barriers. Interviews with community stakeholders will document how community partnerships impacted program goals and veteran service provision. Also in year 1, evaluators will conduct in-person *veteran voice interviews* during annual site visits. Interviews will focus on veterans' experiences and short-term participation outcomes (eg, service access, goal attainment, satisfaction).

In year 2, *implementation interviews* with VA FARMS pilot site staff will focus on VA FARMS program modifications and lessons learned that were driven by implementation needs and barriers. *Veteran voice interviews* (see Multimedia Appendix 5) will be conducted via telephone to capture the lived experiences, meaning, and intermediate outcomes (eg, new knowledge, increased skills, service access, goal attainment, satisfaction) of veterans who participated in a VA FARMS pilot program in year 1.

In year 3, final *implementation interviews* will be conducted with VA FARMS staff, administrative leadership at facilities hosting pilot sites, and community stakeholders to holistically describe barriers and facilitators to program implementation, changes to VA FARMS programming, outcomes of community partnerships, and long-term sustainability prospects. *Veteran voice interviews* will be conducted via telephone to capture the lived experiences, meaning, and long-term outcomes of participating in VA FARMS (eg, changes in attitudes or values, modified behavior, perceived improved condition).

Participant Recruitment

Evaluation participants will be recruited from each of the 10 local VA FARMS pilot project sites. Pilot project site directors will be required to provide quarterly pilot program data as a condition of funding. All other evaluation activities will be voluntary. A convenience sample of pilot project staff, partners, and veteran participants of VA FARMS pilot projects will be invited to take part in *implementation interviews*. Participants will be recruited based on exit survey data where veterans will indicate a willingness to participate in an interview discussing their experiences in the VA FARMS pilot program at each site. In years 2 and 3, *veteran voice interview* participants will be recruited based on exit survey data where veterans will indicate a willingness to participate in an interview discussing their experiences in the VA FARMS pilot program at each site.

Data Analysis

Quantitative Data Analysis

Descriptive statistics will be provided for all quantitative measures, which will include frequencies and percentages for categorical variables, as well as means, medians, standard deviations, and ranges for continuous variables. For variables measured over multiple time points, statistics will be provided both cumulatively and per time point (ie, quarterly or annually). Where appropriate, paired *t*-tests (ie, comparing change at two time points), Wilcoxon signed-rank tests (ie, nonparametric test to compare change at two time points when data are not normally distributed), or repeated-measures analysis of variance (RMANOVA) will be used to compare changes in continuous outcomes over multiple measurement time points.

To understand implementation processes (ie, pilot program activities and strategic refinements), quarterly pilot program surveys will be analyzed using descriptive statistics, and information will be presented both per quarter and cumulatively. In addition, data about veteran enrollments, outreach activities, and community partnerships will be collected to describe the number of participants who receive VA and non-VA health care and resource referrals, and the number of participants who became employed in agriculture.

To understand implementation products (ie, the impact of VA FARMS on veterans and their families), baseline descriptive statistics will be provided for veteran demographics, previous experience with gardening or agriculture, health care utilization, and PTSD and associated factors. Demographics will include gender, age, race/ethnicity, education, baseline employment and student status, military service branch, military service era, and service-connected disability rating. Previous experience with gardening or agriculture will be quantified in months. Health care utilization will include frequency of primary care visits, specialist visits, other provider visits, and hospital stays. Factors associated with PTSD will include reintegration, global physical health, and global mental health (encompassing pain, fatigue, depression, and overall quality of life).

In addition to baseline descriptive statistics, follow-up statistics on participant outcomes will be obtained from self-reports and validated measures (M2CQ, PROMIS, PCL-M). Veterans will report on health care utilization, PTSD, and PTSD-related symptoms. It is important to note that the selected measures are not diagnostic but allow veterans to self-report the presence of the 20 DSM-5 symptoms of PTSD. Descriptive statistics will be provided for scores at pilot program exit and at 3 months postexit. Additionally, RMANOVA, paired *t*-tests, or Wilcoxon signed-rank tests—depending on the data distribution and satisfaction of analysis assumptions such as normality and sphericity—will be performed to compare baseline to exit scores and to compare exit scores to 3 months postexit scores. Participants will also be asked about their agriculture employment status.

XSL•FO
RenderX

Qualitative Data Analysis

Monthly Project Status Updates and Field Notes

Note-taking templates will be created to structure notes from project status update calls and observations from site visits. Project status call templates will include sections to record information about reported implementation activities, successes, and challenges. Field note templates (see Multimedia Appendix 3) will include sections to record information about observed program activities, reflections, emerging questions and analyses, and future actions.

Data will be analyzed using a matrix analysis process [43]. Notes will be summarized and added to individual rows of a Microsoft Excel spreadsheet. Evaluators will read each summary and identify important concepts. These concepts will be summarized with a single word or short phrase called a "code." Each Microsoft Excel column header will be labeled with a qualitative code. Summaries will be coded by typing a "1" in the cells that join rows (summaries) and columns (qualitative codes) to indicate that a piece of text is meaningfully connected to a specific concept. Evaluators will compare coding structures, discuss discrepancies, and reach consensus about the essential meaning of the data.

Interviews With VA FARMS Staff, Stakeholders, and Participants

Semistructured interviews with VA FARMS staff, community stakeholders, and veteran participants will be conducted primarily over the phone, except during site visits where interviews will be conducted in person. In both cases, two experienced qualitative evaluation team members will conduct the interviews in tandem, one as the primary facilitator and the other as the notetaker and timekeeper. Detailed notes and an overall summary of the interview will be completed using the interview summary template. This template will be used as a first-level analysis document that will be integrated into the principal analysis effort using ATLAS.ti v8.0 [44].

Data collection and analysis will occur concurrently allowing for insights from data analysis to iteratively guide subsequent data collection (eg, modification of interview questions). The detailed note summaries will be uploaded into ATLAS.ti v8.0. Interview data will be analyzed using the noticing, collecting, and thinking (NCT) analysis model [45]. As defined, the NCT consists of three basic components: noticing, collecting, and thinking about interesting things in the data. The NCT model will use coding structures, writing memos, process mapping, and diagramming to describe, categorize, and connect the data. This process will help to determine common themes, patterns, and inconsistencies related to the participants' experiences, perceptions, and opinions. The qualitative team will systematically develop a code book (ie, operationalize codes and thematic categories) by meeting routinely to review ongoing coding results, resolve coding issues that arise, and discuss the development of thematic coding categories. Hyperlinks may be used to compare sections of text that occur in different interviews. Advanced search techniques including Boolean, code co-occurrence, and cross-tabulation searches will be used to sort and compare important pieces of text by VA FARMS staff, community stakeholders, and veteran participants.

Ethical Considerations

This evaluation has been determined by the local VA Research and Development Service at the James A Haley Veterans' Hospital to be a quality improvement project and will thus not be subject to the Institutional Review Board review for research [46]. Given this assessment, no written informed consent will be required. However, all participants, including veterans, VA FARMS staff, administrative leadership, and community stakeholders, will be verbally assured of confidentiality and will complete required VA verbal and written consent for use of photographs and audio recordings (VA Form 10-3203).

Privacy and Security

Interviews will be audio-recorded with the permission of each participant, including veterans, VA FARMS staff, administrative leadership, and community stakeholders. All data will be kept in a secured folder behind the VHA firewall. The folder will only be accessible to members of the evaluation team. After interviews have been summarized, audio recordings will be deleted.

Ensuring Inclusion and Accessibility

Interview guides and recruitment invitations will be drafted at a sixth-grade reading level using "plain language" principles for clear communication [47]. These materials will also be drafted in Spanish for participants at the Puerto Rico pilot site. Veterans with hearing impairment will be interviewed via email using tailored methods [48,49].

Expert Advisory Board

An advisory board of subject matter experts (SMEs) will assist the evaluation team in quarterly meetings as well as on an as-needed basis. Advisory board participants will include SMEs in farm safety, PTSD, veteran farming programs, and disability and farming issues. They will assist with instrument development, face validity, pilot testing, and technical and agricultural issues that may arise during the evaluation, along with data collection and interpretation questions. Additionally, they will be available for general technical and programmatic issues that may arise for awardee sites. They will not see any data, and any information provided will be in aggregate or deidentified form.

Results

In July 2018, a total of 10 sites were awarded with funding to implement their proposed pilot projects [5] and were subsequently enrolled in evaluation efforts starting in December 2018. Data analysis will be ongoing to fulfill quarterly and annual reporting. Overall findings are expected to be submitted for publication by October 2022. As of the end of September 2020, some data had been collected and analyzed (Tables 2 and 3).

XSL•FO

Table 2. Implementation outcomes in 2019 and 2020.

Evaluation period	Number of veterans enrolled[a]	Number of veterans reached[b]	Number of communities reached[c]	Number of VA[d] employees reached[e]
October 2018 to September 2019	229	1326	1623	655
October 2019 to September 2020	265	2341	1696	1816
Total	494	3667	3319	2435

[a]Total number of unique individual veterans enrolled in the VA FARMS pilot program in a fiscal year. These are veterans who had never been enrolled in the VA FARMS pilot program previously.

[b]Total number of veterans reached by the VA FARMS pilot program in a fiscal year. This number includes veterans who are not enrolled in VA FARMS but participated in pilot program activities such as demonstrations, informational presentations, and town-hall discussions.

[c]Total number of community members reached by the VA FARMS pilot program in a fiscal year. This includes face-to-face contact with people who are not enrolled in VA FARMS through demonstrations, informational presentations, town-hall discussions, etc.

[d]VA: Department of Veteran Affairs.

[e]Total number of VA employees reached by the VA FARMS pilot program in a fiscal year. This includes face-to-face contact with VA employees through demonstrations, presentations, grand rounds, etc.

Table 3. Data collection activities and outcomes October 2019 to September 2021.

Data collection activities	October 2018 to September 2019, n	October 2019 to September 2020, n	Total, N
Project status updates	114	32	146
Baseline surveys	191	59	250
Exit surveys	36	34	70
3-month follow-up surveys	7	11	18
Quarterly program surveys	36	36	72
Site visits	8	0	8
Pilot site staff interviews	17	10	27
Pilot site community partner interviews	11	0	11
Veteran voice interviews	15	15	30

Discussion

Projected Significance

Agricultural programs have been found to provide physical and behavioral health benefits to veterans who are struggling to transition from military to civilian life. European studies on the impact of horticulture and agriculture on the health and well-being of veterans and service members have found positive benefits for veteran participants with PTSD, including feeling relaxed, secure, and safe; having a sense of purpose; a decrease in PTSD symptoms; and learning new skills [50-52]. In the United States, findings on the benefits associated with farming and horticulture on veterans and service members are sparse, and primarily come from studies and evaluations of regional programs and populations that are veteran-focused. For example, an evaluation of a veteran-oriented community agricultural initiative in western Washington found that participation in the program contributed to improved mental, physical, and emotional health; increased vocational skills, community connectedness, interpersonal communication, a sense of satisfaction, and a sense of belonging; and helped decrease stigma surrounding veteran status [53-56]. A recent pilot horticultural therapy intervention showed significant improvements in reported stress, depressed mood, pain, and loneliness, and a decline in suicidal ideation in high-risk veterans [57]. Overall, findings from the United States are similar to those found in European studies, including promotion of the formation of trusted interpersonal relationships and community connectedness [30,31,56]; improved vocational skills [30,31,55,58]; improvement in pain, self-efficacy, and quality of life [58]; and better nutritional quality of diet [59].

Despite a long history of farming as therapy for veterans [11,14,52,60] and positive coverage in the news media [13,61], there is limited scientific evidence supporting the specific use of agritherapy for mental health and vocational rehabilitation in this population. For this reason, rigorous evaluation of the VA FARMS pilot program processes and products will be critical for understanding the benefits, barriers, and outcomes of implementing innovative programs within the VA system of care. This mixed methods evaluation protocol is designed to inform on diverse VA FARMS pilot projects with site-specific contexts for a rich understanding of program context and local definitions of successful reintegration for veterans. This will be critical given the many contextual factors known to influence CR in veterans [62-65]. Both the funding mechanism and evaluation design will allow for multiple models of VA FARMS to be implemented and is uniquely situated, as the VA is deeply aware of the multifaceted, heterogeneous needs of veterans

XSL•FO
RenderX

[63,66,67]. Ideally, this will allow for multiple promising practices and programs to emerge, which can act as models for other VAs to choose from and tailor as they implement for their veteran communities. For example, pilot programs such as VA FARMS that follow an ecological approach provide opportunities for veterans to practice CR, increase self-efficacy, increase social support, coordinate with trusted community members or organizations, and meet in nonstigmatizing community locations have been found to facilitate veteran CR and program participation [62,68]. Many of the VA FARMS pilot site projects will include some or all of these elements and will be assessed through this multisite evaluation.

Notably, there are no validated quantitative measures that capture CR or rehabilitation outcomes of agricultural training programs in the civilian or veteran population [23]. The need for research focusing on CR outcome measures in rehabilitation-related studies and the study of CR outcomes was proposed by a VA Rehabilitation Research and Development Work Group on Community Reintegration [15,69]. This evaluation will also help to address identified gaps in the NBT literature, notably a lack of measurement tools and poor descriptions of the therapeutic approach used [23]. In this evaluation, PTSD and associated factors such as reintegration, global physical health, and global mental health (encompassing pain, fatigue, depression, and overall quality of life) will be measured at baseline, exit, and 3 months postexit using validated scales. These data, along with self-report of health care utilization (frequency of primary care visits, specialist visits, other provider visits, hospital stays) and agriculture employment status, will provide a basis for comparing participant outcomes from the individual pilot site projects and VA FARMS as a whole. In addition, individual pilot site project activities, including therapeutic approaches, will be clearly described and categorized through quarterly reporting as well as observation during site visits.

Conclusions

This 3-year evaluation will employ a concurrent mixed methods approach and a CIPP model to collect process and product data. The evaluation will allow for a site-specific and cross-project understanding of project designs and implementation processes, as well as an assessment of the feasibility of measuring individual participant outcomes over time. Results of this evaluation will contribute rigorous evaluation findings of veteran agritherapy programs to the literature, an area that is notably sparse. Additionally, this evaluation will address the lack of measurement tools and poor descriptions of the therapeutic approach used in the NBT literature [23]. Programmatic insights will include a broad understanding of administration impacts, needed improvements, and modifications for expansion of VA FARMS models. Additionally, since this evaluation protocol will be designed to provide a rich understanding of contexts and local pilot site definitions of successful veteran reintegration, promising practices that emerge will be able to be applied to not only the implementation of VA FARMS models but also may be extended to other veteran-focused agricultural programs with consideration of CR and PTSD.

Acknowledgments

We would like to acknowledge the work and input of Janice Garland, MPH; Kiersten Downs, PhD; Xinping Wang, PhD; Diane Cowper-Ripley, PhD; Karyn Johnstone, MPH; Pamela Lee, PhD; and Thomas Klobucar, PhD. This material is based upon work supported by the Department of Veterans Affairs and Veterans Health Administration Office of Rural Health. The funding source had no role in the study design; in the collection, analysis, or interpretation of the data; in the writing of the manuscript; or in the decision to submit the paper for publication. The views expressed in this paper are those of the authors and do not necessarily reflect the views, position, or policy of the Department of Veterans Affairs or the United States Government.

Data Availability

The data sets generated during and/or analyzed during the current study are not publicly available due to veteran confidentiality but are available from the corresponding author on reasonable request.

Abstract

Background: In competency-based medical education (CBME), "Assessment for learning" or "Formative Assessment" (FA) plays a key role in augmenting student learning. FAs help students to measure their progress over time, enabling them to proactively improve their performance in summative assessments. FAs also encourage students to learn in a way where they address their knowledge gaps and gaps in their conceptualization of the subject matter. The effectiveness of an FA, as a learning and development instrument, relies on the degree of student involvement in the corresponding educational intervention's design and implementation. The extent of students' engagement in FA can be evaluated by appraising their perception regarding the educational intervention itself.

Objective: This proof-of-concept study aims to develop a systemic understanding of a Formative Assessment as an Instructional Tool (FAIS) implemented in a biochemistry course in the Basic Medical Sciences component of an undergraduate entry, CBME.

Methods: The educational intervention in question is an FAIS, which is implemented in a biochemistry course in the first semester of a 6-year bachelor of medicine, bachelor of surgery program. When developing the FAIS, each area of knowledge, skills, and attitudes were considered. Assessment formats are developed per Miller's learning pyramid. This multiphase study is meant to rely on a convergent mixed methods design, where qualitative and quantitative data are independently collected and analyzed. Thereafter, the outputs of analyses are systematically merged using joint display analysis process. Qualitative data are collected through a focus group session that captures the students' perception toward the FAIS. Data collection, integral to this focus group session, is exploratory. The inductive qualitative data analysis follows Braun and Clarke's 6-step framework. The quantitative component of this study revolves around investigating the effect of the FAIS on the course's summative assessment. The summative assessment performance of the 71 students, enrolled in the FAIS cohort, will be compared to that of the students in the non-FAIS cohort. The total duration of the proposed multiphase research study is 6 months.

Results: This proposed multiphase study is expected to showcase, from a systemic perspective, the effectiveness of the respective educational intervention. It will shed light on the participating students' attitudes in relation to the usefulness of FA in achieving competency goals and in fostering self-directed learning. The proposed study could also uncover the hypothesized association between the FA intervention and enhanced performance in summative assessments.

Conclusions: Our findings will generate evidence regarding the application of FAs, which can be leveraged by other medical educators in contexts similar to those under investigation.

Introduction

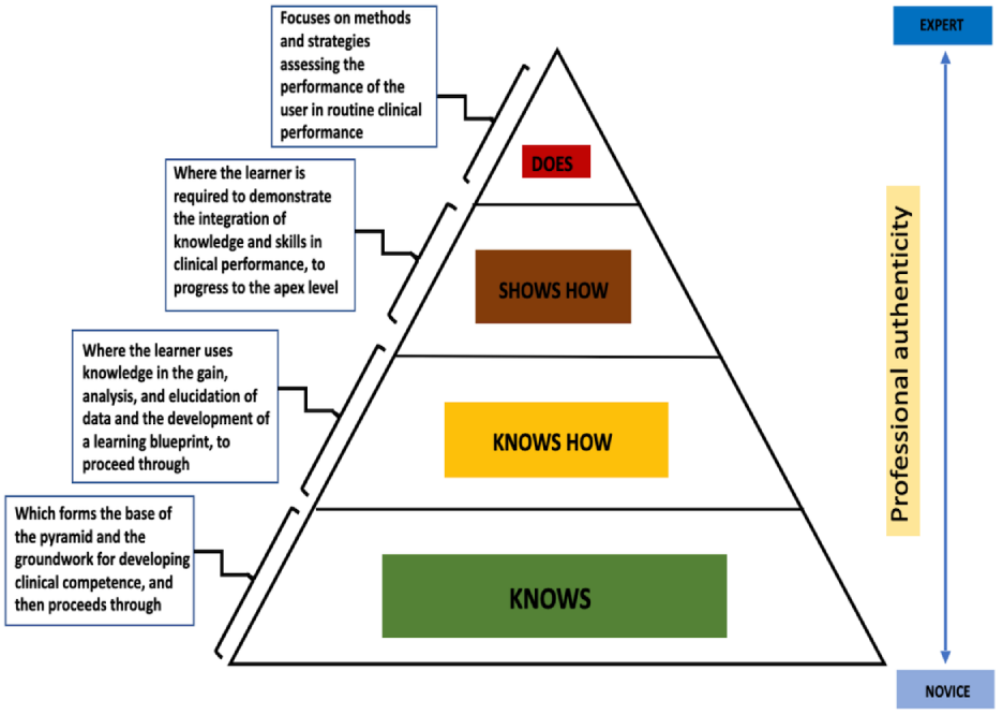
Background

A pivotal challenge in implementing competency-based medical education (CBME) is the consequential assessment of competence. The transfer to CBME has raised awareness of the confines and limitations of existing assessment methods [1]. It has also highlighted the need to develop approaches to assess the competencies expected of today's physicians in an era portrayed by increasing interdependence and collaboration among health care professionals, the recognition that patients' safety is everyone's responsibility, and an expectation of pellucidity and accountability.

In designing an assessment program, the intention is to articulate its purpose. Assessment has been shown to influence students' excellence and allocation of their efforts. While experts might differ with regard to when and how the effects of assessment are exerted, the existence of such a relationship is irrefutable [2]. The influence of assessments on students' learning, often referred to as the "educational impact" of the assessment, "testing effect," "consequential validity," "test-enhanced learning," "backwash," "washback," and "testing phenomenon," is an imperative element of the effectiveness of an assessment system [3]. Two fundamental and essentially different rationales are "assessment of learning" and "assessment for learning." "Assessment of learning" or "Summative Assessment" evaluates a student's learning progress and archetypally provides concrete grades or other objective measures [4]. The intended purpose of summative assessments is to measure the students' achievement to make decisions about promotion or progression, direct what and how students learn, and motivate students to learn [5].

"Assessment for learning" or "Formative Assessment" (FA) is used to bolster the learning process. It focuses on providing the student with feedback on their performance to improve their skills [6], knowledge, and learning behavior. FAs focus on specific content, topics, and skills, and can be conducted as frequently as needed.

FAs also serve the purpose of measuring students' progress over time, which can assist the students to incessantly improve and support students in focusing their learning efforts on gaps in knowledge and their conceptualization of the subject matter. The key objectives of FAs are to inform the students of required knowledge for the future, identify student's lag in performance, assist with timely performance improvement, and provide feedback to teachers about how best to assist and facilitate student learning. Miller [7] identified 4 levels of learning, conceptualized as a pyramid as shown in Figure 1. Beginning at the base, the learner "knows," which forms the base of the pyramid and the groundwork for developing clinical competence, and then proceeds through "knows how," where the learner uses knowledge in the gain, analysis, and elucidation of data and the development of a learning blueprint, to proceed through "shows how," where the learner is required to demonstrate the integration of knowledge and skills in clinical performance, to progress to the apex level "does," which focuses on methods and strategies to assess the performance of the user in routine clinical performance.



The assessment strategies tied to each level inform and contribute to learning as well as assessment, provided that formative feedback is given. At the "does" level, assessment becomes part of the authentic context in which one works and learns; learning provides deeper meaning for the trainee and builds a substrate for the cognitive processes of clinical decision-making [8].

Key to the effectiveness of an FA as a learning and development instrument is the degree of student involvement in the design and implementation of the FA used to train them. The extent of students' engagement in FA can be effectively evaluated by appraising the students' perception regarding the educational intervention itself.

Five specific features are essential to secure a sufficient level of student involvement: (1) congruence (ie, the tasks of an FA must reflect the instructional content), (2) authenticity (ie, the tasks of an FA should be related to students' backgrounds and study contexts), (3) consultation (ie, students should have a say in how their answers are evaluated and based on which criteria), (4) transparency (ie, no "mystery items"; the wording of the items must clearly address the targeted content), and (5) accommodation (ie, all students should have the same chance to complete the items of a FA).

XSL•FO

Figure 1. Miller's pyramid of learning [7].

Objective of the Proposed Study

The overall objective of the multiphase proof-of-concept study proposed in this protocol is to develop a systemic understanding of the effectiveness of a Formative Assessment as an Instructional Tool (FAIS) implemented in a biochemistry course in the Basic Medical Sciences component of an undergraduate entry, competency-based medical curriculum at the Mohammed Bin Rashid University (MBRU) of Medicine and Health Sciences, Dubai, the United Arab Emirates.

Methods

Study Context

The CBME at MBRU comprises 3 phases. Each phase of the curriculum includes integrated courses and builds on the preceding one, such that the curriculum is "spiral." The students purposefully repeat subjects, where with each successive encounter, concepts build upon those acquired in the previous round. The medical school, in which the proposed multiphase study will be conducted, caters to a student population from more than 19 different countries and from 20 different high school curricula. Approximately 75% of the students are female [9].

Research Team

CBME requires medical educators to reimagine almost every aspect of undergraduate medical training, including curriculum delivery and assessments. Therefore, the proposed multiphase study is meant to be conducted through a reliable student-faculty partnership, which is expected to facilitate the entailed processes. This includes involving students as coinvestigators, where they are considered partners in the entailed decision-making processes, through their active engagement in collaborative meetings. The 3 student researchers who are involved in the proposed multiphase study include MG, IF, and AA, who are drawn from across the spectrum of the respective medical curriculum. Further, as the proposed study forms a part of a process whereby MBRU engages in continuing self-evaluation to measure achievements and outcomes as they relate to the institution's preset goals (ie, effectiveness of MBRU as an institution in disseminating medical and health sciences education), a member of the strategy and institutional excellence (SIE) team (ie, the entity handling the MBRU Quality Assurance and Institutional Effectiveness portfolio), FO, is part of the team as a co–principal investigator. She is a senior specialist in the SIE unit with expertise in research design and quantitative and qualitative data analyses. Her research interest is focused on means of nurturing health professionals to equip them with competences complementary to basic and clinical medical sciences and how this affects the health professionals' clinical performance and, in turn, outcomes of care. The global aspect of this study is overseen by YB. His research expertise in medical education is primarily focused on epistemology, ethnography, delineation of strategies for integration, and contextualization of basic sciences in the medical curriculum to inform clinical practice, change-management models, and Pierre Bourdieu's multifaceted concept of habitus with the aim to understand and transform how groups with diverse clinical proficiency work together to improve patient outcomes. The involvement of a multidisciplinary student-partnered team is, therefore, meant to raise the reliability of the proposed research project and its findings.

The Educational Intervention Under Investigation

The FAIS was implemented in a biochemistry course in the first semester of a 6-year bachelor of medicine, bachelor of surgery program. The reason the FAIS was implemented in this course is because one of the key aims of this course is to develop explicit associations among basic research, medical

XSL•FO
RenderX

understanding, and the patients' perspectives. When developing the FAIS, each area of knowledge, skills, and attitudes was considered. Assessment formats were developed in alignment with the Miller's learning pyramid (Figure 1) [7]. The "student knows" and "student knows how" were assessed with multiple-choice questions and long cases. "Student shows" was assessed with laboratory examinations and objective structured practical examinations. "Student does" assessed the students' competences of analysis of biochemical data. The assessments used to assess "student knows," "student knows how," and "student shows" were standardized assessments. "Student does" level assessments were unstandardized.

Research Design

The multiphase study, proposed in this protocol, is meant to rely on a convergent mixed methods design [10], where the qualitative and quantitative data are independently collected and analyzed. Following that, the output of analysis is systematically merged using joint display analysis process [11,12]. Integration of the output of analyses, as such, is expected to raise the reliability of the study findings, enabling the generation of a holistic understanding of the subject matter. The study comprises 4 phases: data collection, data analyses, information integration, and knowledge generation (Table 1).

Table 1. Outline of the design of the proposed proof-of-concept study.

Phase 1: data collection	Phase 2: data analyses	Phase 3: information integration	Phase 4: knowledge generation
Qualitative: focus group session	Braun and Clarke's [13] 6-step framework	Joint display analysis to generate meta-inferences	Interpretation of study findings
Quantitative: students' performance in the summative assessment	ANOVA with a *P* value of ≤.05	Joint display analysis to generate meta-inferences	Interpretation of study findings

Ethical Considerations

Since the proposed study entails "no more than minimal risk" on human participants, and all the data are already collected as part of institutional research functions and handled by the SIE team at MBRU (which adhere, by virtue of design, to the ethical principles of autonomy, justice, and beneficence), an exempt review will suffice. Progressing with the analyses, reflected upon in this protocol (namely qualitative and quantitative analyses and joint display analysis), is contingent upon the exempt review clearance of the institutional review board of MBRU.

Evaluation of Students' Perceptions

The qualitative component of the study, as illustrated in Table 1, revolves around carrying out a focus group session [14-16] composed of 7-10 randomly selected students from the cohort of 71 students who were exposed to the FAIS. One of the study investigators, who is experienced in socio-behavioral research and was not involved in planning or implementing the FAIS, facilitated the focus group session based on a preset focus group protocol designed for this study (Multimedia Appendix 1). Prior to conducting this focus group session, the protocol underwent face and content validation. The students' participation in this focus group session was completely voluntary, and each participant was required to provide verbal consent prior to the commencement of the session. The data collection, integral to this component of the study, was exploratory, where the participants were invited to externalize their thoughts in relation to their individualized experiences with the FAIS.

Student investigators attended the focus group session in order to ensure flow of the entailed discussions and to take notes and arrange for the recording of the session. The inductive qualitative data analysis will follow Braun and Clarke's [13] 6-step framework recently endorsed in health professionals' education research [17].

Evaluation of the Impact of the FAIS on Students' Performance in Summative Assessments

The quantitative component of the study, as illustrated in Table 1, revolves around the investigation of the effect of the FAIS on the students' performance in the summative assessment. As such, the performance in the summative assessment of the 71 students enrolled in the cohort that was exposed to the FAIS will be compared to that of the students enrolled in a cohort that was not exposed to the FAIS. ANOVA will be performed with the scores of the summative assessments of all students enrolled in both cohorts. A *P* value of ≤.05 will be considered the level of significance.

Joint Display Analysis

The output of analyses of the qualitative and quantitative components of this study (ie, first level of inferences), as illustrated in Table 1, will be integrated using the iterative joint display analysis process [11,12], which enables the development of a macrolevel understanding of the subject matter.

Study Plan

The total duration of the proposed study is 6 months. The key milestones and time line are shown in Table 2.

XSL•FO
RenderX

Table 2. Plan of the proposed multiphase study.

Milestones	Month 1	Month 2	Month 3	Month 4	Month 5	Month 6
Planning for the formative assessment intervention	✓[a]					
Developing and validating the focus group protocol	✓					
Implementing the formative assessment intervention		✓	✓	✓		
Recruiting study Participants				✓		
Conducting the focus group session					✓	
Analyzing data (qualitative and quantitative, and joint display analysis process)					✓	
Reporting on generated information					✓	
Preparing for knowledge sharing						✓

[a]✓: indicates completion of the task at the set deadline.

Results

The mixed methods study proposed in this protocol is expected to generate a systemic understanding of the effectiveness of the respective FAIS educational intervention. This involves exploring the students' perceptions regarding the FAIS, along with investigating the intervention's effectiveness in enhancing the participating students' performance in the corresponding summative assessment. It will shed light on the participating students' attitudes in relation to the use of FA in achieving competency goals and in fostering self-directed learning. It could also uncover the hypothesized association between the FA intervention and enhanced performance in summative assessments.

Discussion

Anticipated Findings

A systemic understanding of the effectiveness of the FAIS in enhancing academic performance and enabling self-directed learning will be developed through the proof-of-concept study proposed in this protocol. The multistage inductive qualitative analysis is expected to generate a conceptual framework that describes the educational intervention from the viewpoint of the learners. The respective framework is expected to highlight the students' reactions and the perceived effects of the FAIS (short- and long-term) and opportunities for improvement. The quantitative component is meant to investigate the association between the FAIS and academic performance (in the summative assessment). The joint display analysis will reveal the lessons learned from the firsthand implementation of the FAIS in the context of the study, and the factors (ie, enablers) that need to be taken into account to maximize the value of such an educational intervention to all involved parties.

Within the context of the study, our findings will shed light on opportunities to maximize the value of the educational intervention, especially in relation to engaging and empowering the students and fostering self-directed learning. The perception of the students of the experience will be factored into the design of upcoming rounds of the FAIS, which is expected to raise the reliability of such interventions [18]. Additionally, if the outcomes are favorable, the long-term goal is to implement the designed and improved FA intervention across all courses in the program under investigation, for which we will strategize a change management approach using Mento's change management model [19].

Self-directed learning has gained widespread recognition [20]. Medical educators have been experimenting with differing techniques to foster self-directed learning and in turn lifelong learning habits [18,21,22]. The study proposed in this protocol is likely to prove that the FAIS is effective in enhancing academic performance through fostering self-directed learning [23,24]. It is expected to enable learners to develop self-regulatory strategies by promoting cognition (ie, learning) and meta-cognition (ie, learning to learn) [25]. Hence, critical and higher-order thinking, along with integration of disciplinary knowledge, are likely to be improved [26]. This will enhance the students' preparedness for summative assessment. It will be interesting to explore the students' perceptions of the learning experience, since it is believed that active student engagement and learner agency can only be ensured when the learners (actually) perceive the benefits of the educational intervention. The proposed study is meant to suggest evidence-driven ways to make the true value of the educational intervention prominent to the learners.

Limitations

The proposed study is characterized by certain limitations. The mixed methods research design, systematically integrating qualitative with quantitative data, enables the generation of thorough insights into the subject matter [27]. Yet, given that the FAIS is implemented in a single biochemistry course in the Basic Medical Sciences component of an undergraduate entry, competency-based medical curriculum at MBRU, the generalizability of the findings is limited. The context of the study is described in detail to enable the transferability of the findings to contexts similar to those under investigation. Also, the study design, especially how the quantitative component is structured, enables investigations of potential associations. Yet, it does not allow for the uncovering of causalities. It would be worthwhile for future studies to take longitudinal approaches that actually reveal the intricacies of the relationship of FAs and academic performance and other desired skills (eg,

XSL•FO
RenderX

self-directed learning and academic resilience) [12], which may turn out to play a moderating (or even mediating) role.

Conclusions

The findings of the proposed study constitute evidence in relation to the application of FAs, which can be leveraged by other medical educators in contexts similar to those under investigation.

Abstract

Background: COVID-19 was characterized by the World Health Organization (WHO) as a pandemic in 2020. Papua New Guinea (PNG) has remained on high alert ever since, and its National Control Centre continues to coordinate national preparedness and response measures, guided by its Emergency Preparedness and Response Plan for COVID-19. As part of the WHO and the Global Alliance for Vaccines and Immunization's COVID-19 Vaccines Global Access (COVAX) program, PNG received several shipments of COVID-19 vaccine doses. A nationwide vaccine rollout for COVID-19 was initiated in PNG in May 2021. Despite the availability of vaccines and the capacity of health systems to vaccinate frontline workers and community members, including high-risk groups, there are still critical issues related to vaccine safety, confidence, and acceptance to ensure the effectiveness of the COVID-19 vaccination campaign. Evidence from studies on COVID-19 vaccine acceptance and demand in low- and middle-income countries (LMICs) suggests that sociocultural characteristics of the community and the behaviors of different vaccine stakeholders, including vaccine recipients, vaccine providers, and policymakers, determine the effectiveness of vaccination interventions or strategies.

Objective: This study will examine sociocultural determinants of anticipated acceptance of the COVID-19 vaccine in urban and rural areas of different regions in PNG and health care providers' views on vaccine acceptance.

Methods: The study design uses a mixed methods approach in PNG's coastal and highlands regions. The first research activity will use a qualitative methodology with an epistemological foundation based on constructivism. This design elicits and listens to community members' accounts of ways culture is a rich resource that provides meaning to the COVID-19 pandemic; the design also measures adherence to *niupela pasin* ("new normal" in Tok Pidgin) and vaccination acceptance. The second activity will be a cross-sectional survey to assess the distribution of features of vaccine acceptance, priorities, and practices. The third activity will be in-depth interviews of health care providers actively involved in either COVID-19 clinical management or public health–related pandemic control activities.

Results: The project proposal has been reviewed and approved by the Medical Research Advisory Committee of Papua New Guinea. Qualitative data collection started in December 2022, and the survey will begin in May 2023. The findings will be disseminated to the participating communities later this year, followed by publication.

Conclusions: The proposed research on community views and experiences concerning sociocultural and behavioral features of acceptance of the vaccine will provide a better understanding of communication and education needs for vaccine action for COVID-19 control in PNG and other LMICs. The research also considers the influence of health care providers' and policy makers' roles in the awareness and use of the COVID-19 vaccine.

Introduction

Background

COVID-19 affected almost every country in the Pacific region, including Papua New Guinea (PNG). As of August 2022, a total of 45,133 confirmed COVID-19 cases were reported in PNG, resulting in 668 deaths [1]. However, these numbers may be an underestimate caused by nonoperational information systems in rural areas. Globally, as a pandemic preventive strategy, countries have been using nonpharmaceutical interventions (NPIs), such as enforced use of face masks, hand sanitization, physical distancing, travel restrictions, avoidance of large gatherings, school closures, and partial or complete lockdowns. [2]. The health department in PNG has introduced the *niupela pasin* ("new normal" in Tok Pidgin) policy, referring to the changes in behavior and habits that individuals and communities need to adopt to prevent the spread of the virus [3]. Despite these NPIs and policies, there have been increased new cases and deaths each day throughout the world.

COVID-19 Vaccines

Vaccines are the most reliable and effective public health intervention to prevent many infectious diseases [4,5]. Other interventions, like developing practical diagnostic tools and therapeutic drugs, also help clinical management and reduce mortality and morbidity. Therefore, developing and producing safe and effective vaccines remains one of the essential tools for ending the COVID-19 pandemic, along with NPIs [6]. In collaboration with global research institutions, the World Health Organization (WHO) and other global agencies accelerated the development process of COVID-19 vaccines while maintaining the highest standards of safety [7]. The WHO emergency use listing approved several vaccines developed on different platforms. The COVID-19 Vaccines Global Access (COVAX) program is a groundbreaking collaboration between the WHO, the United Nations Children's Fund (UNICEF), the Global Alliance for Vaccines and Immunization (GAVI), and the Coalition for Epidemic Preparedness Innovations (CEPI) to accelerate the development and production of vaccines and equitable access to them for every nation in the world [8]. So far, the COVAX program has provided 71 million vaccine doses to 125 participating countries [9]. Many countries have initiated vaccine rollouts at a national level since 2021. However, with equitable access to and availability of COVID-19 vaccines, the issue of vaccine acceptance and uptake among different high-risk groups, including frontline health workers and the general population, remains critical.

Research on COVID-19 Vaccine Acceptance

Although vaccines are generally well-received, the fast-tracking of COVID-19 vaccine development procedures and the use of new platforms, such as RNA-based vaccines, has created some doubts about vaccine safety and reduced confidence. Vaccine confidence can be defined as the trust and willingness of individuals and communities to accept and use vaccines, and it is important to measure vaccine confidence to identify and address community concerns about vaccination [10]. In general, vaccine hesitancy undermines vaccine acceptance and demand. The WHO's Strategic Advisory Group of Experts (SAGE) on immunization defined vaccine hesitancy as a delay in acceptance or refusal of vaccination despite the availability of vaccination services [11,12]. It is crucial to assess the determinants of vaccine acceptance among vaccine recipients to deal with vaccine hesitancy.

Almost all countries in the world prioritized frontline workers for COVID-19 vaccination. However, research suggests that health care workers' anticipated COVID-19 vaccine acceptance rates vary from low to high [13-15]. A global survey based on 13,426 participants from 19 countries showed that global acceptance of COVID-19 vaccines ranges between 54.8% in Russia to 88.6% in China [16]. In a narrative review of 15 studies, frequently given reasons for refusing the COVID-19 vaccine were related to the fast-tracked vaccine development and vaccine safety and effectiveness [17]. Nevertheless, the WHO has stated that vaccine safety was not compromised by fast-tracking development [7]. With careful evidence-based communication strategies, it is possible to convey the safety of COVID-19 vaccines to the general population.

Public Health Priority of COVID-19 Vaccines in PNG

PNG is the largest country in the Pacific region. The health system of PNG has been struggling for decades to provide universal access to quality services [18]. Nevertheless, PNG has remained on high alert ever since COVID-19 was characterized by the WHO as a pandemic in 2020, and its National Control Centre (NCC) continues to coordinate national preparedness and response measures guided by its Emergency Preparedness and Response Plan for COVID-19 [19]. As in many low- and middle-countries (LMICs), even PNG, vaccination is the only way of protecting frontline workers and community members during the COVID-19 pandemic. As part of the COVAX program, 588,000 COVID vaccine doses were allocated for PNG. The National Department of Health initiated a nationwide vaccine rollout for COVID-19 on May 4, 2021 [20]. So far, more than 348,938 doses have been administered in 22 provinces of PNG [1].

Rationale for This Research

Despite the availability of vaccines and the capacity of health systems to vaccinate frontline health care workers and community members, issues related to vaccine safety, confidence, and acceptance remain critical for the effectiveness of the COVID-19 vaccination campaign. Evidence from studies on differing vaccine acceptance in LMICs suggests that

XSL•FO
RenderX

sociocultural factors in the community and the behaviors of different vaccine stakeholders, including vaccine recipients, vaccine providers, and policy makers, determine the effectiveness of vaccination interventions or strategies. So far, no literature exists on determinants of COVID-19 vaccine acceptance in the PNG context.

Understanding the local context is critical for an effective vaccination program at the community level. The proposed research on community views and experiences concerning sociocultural and behavioral features of anticipated vaccine acceptance will enable a better understanding of communication and education needs for vaccine action for COVID-19 control in PNG and other LMICs. Our pilot study, which explored views on COVID-19 vaccines among students (n=90) with different cultural backgrounds at the Faculty of Medicine and Health Sciences of Divine Word University, indicated 50% tentative acceptance and highlighted the role of the media in determining vaccine acceptance.

Objectives

This study will examine sociocultural determinants of anticipated acceptance of the COVID-19 vaccine in urban and rural areas of different regions in PNG. The following are the specific study objectives: (1) understand community members' accounts of experiences, meaning, and behavior concerning the COVID-19 pandemic, as well as their awareness of and adherence to *niupela pasin* and their perceptions of vaccines based on Melanesian culture, and (2) assess the role of health care providers in determining COVID-19 vaccine acceptance in the coastal and highlands regions, considering their awareness, acceptance and personal use, and vaccine recommendation practices.

Methods

Study Design

The research project will use a mixed methods design. The first research component will use a qualitative methodology with an epistemological foundation that is based on constructivism and embraces meaningful reality as it is socially constructed [21]. This design elicits and listens to community members' accounts of ways culture is a rich source of meaning in the COVID-19 pandemic, their adherence to *niupela pasin*, and their vaccination acceptance. In the context of health, adherence to the new normal is an indicator of the behavior of communities toward their health and is important for understanding these communities. This design will proceed with individual, in-depth, semistructured interviews with community members, community opinion leaders, and church leaders.

The second component, a cross-sectional survey, will use data collected from ethnographic key informant interviews to develop an instrument with open-ended and closed questions. The survey design adapts the WHO immunization and vaccine-related implementation research advisory committee's vaccine stakeholder framework to assess the awareness, priorities, and practices of community members. This design includes an integrated quantitative and qualitative methods approach, and the data collected will indicate the distribution of key features of vaccine acceptance and demand [22].

The third component, semistructured interviews with health care providers actively involved in either COVID-19 clinical management or public health–related pandemic control activities, will determine vaccine acceptance factors. This component will focus on assessing health care providers' views on personal vaccine acceptance and their role in facilitating community vaccination.

Study Sites

This study will proceed in urban and rural areas in the coastal and highlands regions of PNG. Most of the PNG population lives in rural areas (85%), and the economy is primarily agricultural. We selected the Momase region as the coastal region in our study. The Momase region is composed of 4 constitutional provinces with a population over 1.8 million (2011 census). Madang is one of the provinces in this region; it has a population of 493,906 (2011 census). The study will be conducted in urban and rural villages in Madang district.

The Highlands region is the most densely populated region of PNG, with 23% of the total PNG population (2011 census). This region is composed of 7 provinces. The Eastern Highlands province is in the central highland's cordillera and has a population of 579,825 (2011 census). Goroka is the capital of this province. The study will be conducted in Goroka and in rural villages of the Lufa district. These study sites are culturally and linguistically diverse. Tok Pidgin is the lingua franca.

Study Groups and Sampling

Community Members

The criteria for including community members in interviews and the cultural epidemiological survey are being aged between 18 to 65 years and being cognitively able and willing to participate. The study will be conducted in either English or Tok Pidgin and participants should be able to communicate in either of these languages.

In-depth Interviews

A purposive sampling strategy will be used for recruiting participants for in-depth interviews. The sample will be distributed equally among male and female participants (ie, a 50% gender distribution). Community members are key stakeholders in adhering to *niupela pasin* and providing meaning to vaccine acceptance and demand. Starting with exploring and understanding their views is therefore critical.

A collaborating team of research assistants at each study site will initially meet local communities in urban and rural sites to establish rapport. Community opinion leaders and leaders of formal and informal community groups will be contacted, and we will explain the purpose and anticipated value of the study. Further, we will request their participation and assistance to facilitate community participation. Engaging these urban and rural opinion leaders and enlisting their cooperation will facilitate the planning and implementation of in-depth interviews. We will interview church leaders from the selected study sites.

XSL•FO
RenderX

The team of research assistants will go from house to house in parts of the selected study area to identify potential participants and achieve the desired sample compositions of urban and rural and male and female participants. The team will explain the purpose of the visit, solicit potential participants' willingness to participate in the study, and, if they agree, obtain their informed consent (one-to-one) in confidence and with due attention to privacy. A total of 48 in-depth interviews will be conducted (12 community opinion leaders, 24 community members, and 12 church leaders). All interviews will be audio-recorded. The duration of each interview will be approximately 30 to 45 minutes.

Vaccine Acceptance Survey

A random sampling strategy will be used to select the participants for this survey. We plan to use either the voters' list or household listings to randomize the sample at an individual level or use village maps to randomize households to select the eligible participants. This will be achieved in collaboration with the provincial health authority (PHA). However, randomization depends on the availability of these resources. Otherwise, a convenience sample will be selected from the urban and rural areas of the selected study sites, stratified by gender (with a 50% distribution) and age group (18-40 years and 41-65 years). Trained research assistants working in 2 teams will conduct the survey, one interviewing and the other responsible for maintaining the data records. Approximately 360 interviews will be conducted (180 in each of the two regions. We calculated the sample size at a 5% margin of error with a 95% confidence level and a 50% response distribution.

Health Care Providers

Health care providers involved in either COVID-19 clinical management or public health–related pandemic control activities in the selected study sites will be interviewed. We will identify key informant health care providers during earlier stages of the study based on respondent-provided information that identifies health care professionals engaged in relevant activities.

This sample will be selected purposively, and a question guide will guide the in-depth interview. The rationale for using in-depth interviews is to allow health care professionals to share their experiences and views privately without having another person in the room. A total of 16 interviews will be conducted with clinicians, health extension officers, nurses, midwives, and community health workers in health facilities (government and church-based), including provincial hospitals and health centers of urban and rural study areas.

Data Management and Analysis Plan

The study instruments were pilot-tested during training workshops for validity and feasibility. The interview guides for community members and health care workers were developed after consulting experts in the field and the literature. They were pilot-tested with potential participants for rigor and credibility. For the quantitative survey, we adapted an instrument developed by one of the authors for a vaccine acceptance study in India. After completing the qualitative component, we will further develop this questionnaire to ensure feasibility in the study context. This instrument will be tested for content and face validity. All the interview guides and initial questionnaires were developed in English and translated into Tok Pidgin. All instruments were then back translated to English for accuracy.

Data Collection

In-depth interviews will be audio-recorded, and notes will be taken by the field investigators and research assistants. Qualitative data from in-depth interviews will be transcribed verbatim, translated into English, and imported into MAXQDA (version 2020; VERBI Software) for analysis.

The data collection and management of cultural epidemiology will be done using the Open Data Kit (ODK) tool (GetODK). Data will be collected digitally on an Android tablet using the ODK Collect application. Later, the data will be uploaded to a cloud server. From there, the data set will be downloaded as an Excel (Microsoft Corp) spreadsheet.

Data Security

All interviews will be recorded for documentation. The information recorded is confidential. Data sheets, audio records, and transcripts will have unique identifier codes. They will not bear the participant's name. Soft copies (ie, audio records and transcripts) will be stored electronically on password-protected external hard disks or drives. Hard copies (ie, data sheets) will be stored under lock and key at the faculty office. Informed consent forms will bear participants' names and signatures. Therefore, they will be kept under lock and key separately from data sheets, audio records, and transcripts. They will be accessible through only the principal investigator or coinvestigators, with lists linking unique identifier codes to names. Data sheets, audio records, transcripts, and informed consent forms will be destroyed (by incineration or digital erasure) 3 years after study completion.

Analysis Plan

The primary goal of the study is to clarify descriptive, comparative, and analytic accounts of explanatory models of COVID-19 and how they explain awareness, acceptance, and use of vaccines. Comparative analysis will focus on questions of gender and rural-urban features of the COVID-19 pandemic and determinants of anticipated acceptance or refusal of COVID-19 vaccines.

Qualitative Analysis

The in-depth interviews of community members will provide their views on the risk of contracting the virus, behavior to prevent the virus, experience and meaning of COVID-19, and their perception of COVID-19 vaccination. The interviews with health care workers will provide their views about COVID-19 vaccine priorities and practices and their recommendations for promoting the rollout of vaccination. All these in-depth interviews will be transcribed verbatim, verified against the audio tapes, and translated into English. The English transcripts will then be imported into MAXQDA software for managing the data. Thematic analysis will be used as an inductive and deductive process. Analysis involves familiarization with the data, generation of codes, and discovery of initial themes. Themes will be refined through an interactive process, and a

XSL•FO
RenderX

coding framework will be developed that reflects the core themes [23]. A team of research assistants with author ES will develop codes using an inductive approach, allowing themes to emerge from the data. A coding framework will be used to categorize codes and identify meaningful and potential themes. We will perform peer debriefing regularly to discuss the emerging themes and interpretations, ensuring the rigor of the analysis.

Quantitative Analysis

The epidemiological survey will be conducted on tablets with ODK software. All interviews will be uploaded electronically to Google Spreadsheets (Google Inc). The final data set will be downloaded as Excel spreadsheets. STATA/SE (version 16.1; Stata Corp) will be used for statistical analyses. A descriptive analysis will be conducted to summarize the important results. The sociocultural and demographic characteristics of the participants will be summarized. Illness-related questions, such as perceived causes, distress patterns, and help-seeking behaviors, will be presented and compared between different gender and age groups across study areas. The explanatory variables in this study will be social and cultural features of illness experience, meaning and behavior, and questions of awareness and use of the COVID-19 vaccines for prevention. Inferential analysis using regression models will assess the determinants of COVID-19 vaccine acceptance. Narratives of statistically significant factors will be reviewed to better understand their importance.

Ethical Approval

The study has been approved by the Medical Research Advisory Committee of PNG (MRAC#22.19), the Medical Research Committee of Madang PHA (MAPHAREC 06.22), and the Research and Ethics Committee of Eastern Highlands Province PHA. All participants will provide written informed consent in either English or Tok Pidgin before participating in the study. In the case of illiterate participants, verbal informed consent will be obtained in the presence of a family member or relative. The purpose, procedure, and potential risks of the study will be explained to the participants, and they will be informed that they can withdraw from the study at any time without consequences.

Results

The project proposal has been reviewed and approved by the Medical Research Advisory Committee of PNG. The permissions required from the provincial health authority to conduct data collection in the selected provinces have been obtained. The research team has recruited participants for in-depth interviews, including key informants in the communities and health facilities. The qualitative data collection started in December 2022, and the preliminary analysis of these data is underway. The insights from the in-depth interviews will be used to further refine the survey instrument by adapting it to the local context. We plan to pretest the survey instrument for validity and proceed with the survey in May 2023. The findings from the interviews and the survey will be disseminated to the participating communities and key stakeholders in a professional dissemination meeting, followed by publication.

Discussion

Expected Outcomes

This study's experiences and findings will contribute to the effective planning and implementation of the COVID-19 vaccine program in PNG. Furthermore, our findings and approach to health social science vaccine research will have implications and potential applications elsewhere for strategic planning of effective action for other vaccines. The following are anticipated specific contributions of the study: (1) identify priorities and approaches for community action based on Melanesian culture to contribute to health system preparedness for control of pandemics; (2) understand the awareness and acceptance of vaccines for COVID-19, indicating the potential value of COVID-19 vaccines in PNG; (3) clarify current views of clinicians and other health professionals concerning their enthusiasm or reluctance to promote vaccine action to control COVID-19; (4) develop and clarify the value of an approach to studying vaccine acceptance in local settings so that planning may consider the relevance of cultural features of health and illness on anticipated and actual vaccine acceptance; (5) clarify features and determinants of COVID-19 vaccine acceptance that can guide policy to ensure that efficacious vaccines are also effective in the context of actual public health action (findings should guide strategic planning to address knowledge gaps and misunderstandings about the benefits and risks of COVID-19 vaccines); and (6) contribute to the National Research Agenda of PNG to strengthen the operation and delivery of the health system and services.

Potential Impact on Participants

It is possible that participating in the study may influence participants' views on COVID-19 vaccines. For example, exposure to information about the COVID-19 vaccine or discussions about vaccine hesitancy during data collection may lead participants to change their attitudes or beliefs about the vaccine. To mitigate any unintended consequences and ensure the ethical conduct of the study, we will maintain (1) informed consent, (2) accuracy of information, (3) voluntary participation, and (4) confidentiality. First, all participants will be provided with detailed information about the study and its purpose and will be asked to provide informed consent before participating. This will ensure that participants fully understand the nature of the study and the potential impact it may have on their views. Second, all participants will be provided with accurate and unbiased information about the COVID-19 vaccine, both before and after participating in the study. This will help to ensure that participants have access to the information they need to make informed decisions about the vaccine. Third, participation in the study will be completely voluntary, and participants will be free to withdraw from the study at any time without penalty. This will help to minimize any potential for coercion or undue influence on participants. Fourth, all data collected during the study will be kept confidential and participants' identities will be protected. This will help to ensure that participants feel comfortable sharing their views and that their privacy is respected.

XSL•FO
RenderX

By taking these steps, we hope to minimize any unintended consequences of the study design on participants' views on COVID-19 vaccine acceptance and ensure that the study is conducted ethically and with the informed consent of participants.

Limitations

The proposed study design does not include any provinces from the Southern or Islands regions of PNG. We recognize that the generalizability of our study findings will be limited to the Highlands and Coastal regions. However, the Southern and Islands regions can also be categorized as coastal areas. In addition, this study might be subject to social desirability bias. In general, participants will provide responses that they believe are socially acceptable, rather than responding truthfully. To address this potential bias, open-ended questions and follow-up probes will be used to encourage participants to provide detailed and honest responses. However, some participants may still be hesitant to disclose certain information. In addition, the study will be limited by the potential impact of stigma on recruitment and participation. Participants might be hesitant to participate or disclose certain information due to concerns about stigma or judgment. Efforts will be made to address these concerns, including providing a safe and confidential environment for participation, but the impact of stigma on the findings will be considered when interpreting the results.

Acknowledgments

The authors would like to acknowledge Moses Laman, the deputy director of the Papua New Guinea Institute of Medical Research, for supporting development of this study protocol. The study is funded by the Papua New Guinea Science and Technology Secretariat of the Government of Papua New Guinea (grant 07/2021). The funder had no role in study design, data collection or analysis, publication decisions, or manuscript preparation. The study protocol was peer reviewed by the funding body before the grant was provided.

Data Availability

The data sets generated and/or analyzed during this study will be available in subsequent papers.

Authors' Contributions

JGG and ES are responsible for the study design. JGG and CM will be responsible for the quantitative data collection and analysis. ES will be responsible for qualitative data collection and analysis. All authors contributed equally to the writing and critical review of the protocol for important intellectual content. The final manuscript was read and approved by all authors.

Conflicts of Interest

None declared.

Abstract

Background: Antimicrobial resistance (AMR) has emerged as a major global public health challenge due to the overuse and misuse of antibiotics for humans and animals. Hospitals are among the major users of antibiotics, thereby having a large contribution to AMR.

Objective: The aim of this study is to determine the prevalence of antibiotic-resistant pathogenic bacteria and the level of antibiotic residues in the hospital effluents in Selangor, Malaysia.

Methods: A cross-sectional study will be performed in the state of Selangor, Malaysia. Tertiary hospitals will be identified based on the inclusion and exclusion criteria. The methods are divided into three phases: sample collection, microbiological analysis, and chemical analysis. Microbiological analyses will include the isolation of bacteria from hospital effluents by culturing on selective media. Antibiotic sensitivity testing will be performed on the isolated bacteria against ceftriaxone, ciprofloxacin, meropenem, vancomycin, colistin, and piperacillin/tazobactam. The identification of bacteria will be confirmed using 16S RNA polymerase chain reaction (PCR) and multiplex PCR will be performed to detect resistance genes (*ermB*, *mecA*, bla_{NDM-L}, bla_{CTX-M}, bla_{OXA-48}, bla_{SHV}, *VanA*, *VanB*, *VanC1*, *mcr-1*, *mcr-2*, *mcr-3*, *Intl1*, *Intl2*, and *qnrA*). Finally, the level of antibiotic residues will be measured using ultrahigh-performance liquid chromatography.

Results: The expected outcomes will be the prevalence of antibiotic-resistant *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* (ESKAPE) bacterial species from the hospital effluents, the occurrence of antibiotic resistance genes (ARGs) from the isolated ESKAPE bacteria, and the level of antibiotic residues that may be detected from the effluent. Sampling has been conducted in three hospitals. Data analysis from one hospital showed that as of July 2022, 80% (8/10) of *E. faecium* isolates were resistant to vancomycin and 10% (1/10) were resistant to ciprofloxacin. Further analysis will be conducted to determine if the isolates harbor any ARGs and effluent samples

XSL•FO
RenderX

are being analyzed to detect antibiotic residues. Sampling activities will be resumed after being suspended due to the COVID-19 pandemic and are scheduled to end by December 2022.

Conclusions: This study will provide the first baseline information to elucidate the current status of AMR of highly pathogenic bacteria present in hospital effluents in Malaysia.

Introduction

Background

Antibiotics have been the most crucial medications for the treatment of infections since the 1940s. However, some bacteria have developed resistance to practically all of the widely accessible antibiotics, which makes them capable of causing serious illness, resulting in a significant public health issue. Due to the selective pressure caused by the overuse of antibiotics, antibiotic-resistant bacteria (ARB) have developed and spread among human and animal populations worldwide [1].

The overuse and abuse of antibiotics have contributed to the global epidemic of antimicrobial resistance (AMR). Environmental contamination with antibiotic residues and resistant microorganisms and genes due to human activity has been demonstrated in pharmaceutical plants and may be a leading driver of the spread of ARB. Insufficient wastewater management by bulk drug manufacturing facilities has led to unprecedented levels of contamination of water resources with antimicrobial pharmaceuticals, which seems to be associated with the selection and dissemination of carbapenemase-producing pathogens [2]. In India, the concentration of the most abundant drug, ciprofloxacin (up to 31,000 µg/L), was reported to exceed the toxicity level by over 1000-fold [3].

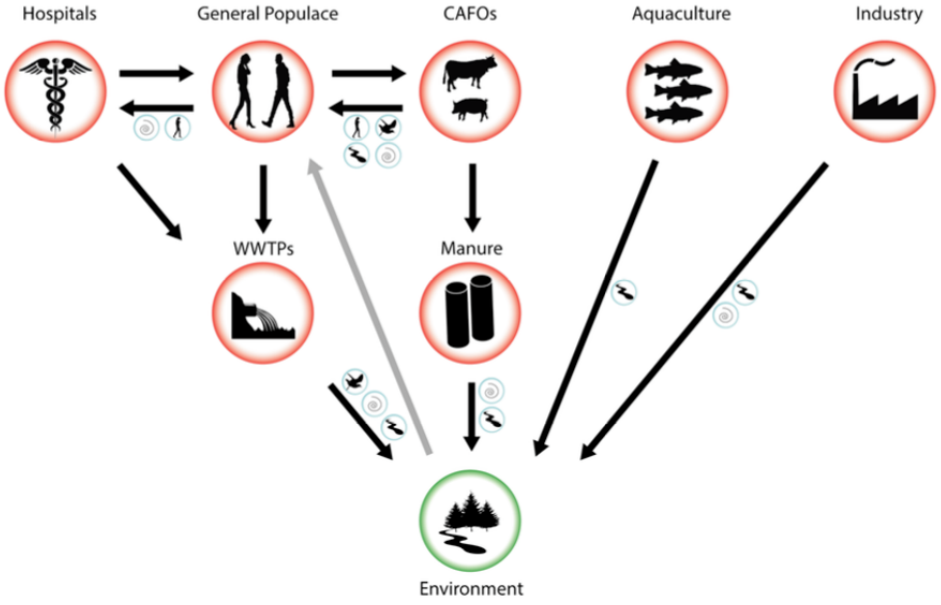
Several hospital-acquired outbreaks caused by gram-negative bacteria such as *Acinetobacter baumannii* and *Pseudomonas aeruginosa* have been associated with contaminated water distribution systems [4-6]. The presence of *Escherichia coli* has been used as an indicator of fecal contamination in drinking water. Multidrug-resistant *E. coli* have been isolated from food sources [7] and urinary samples [8], as well as from hospital and municipal effluents [9]. However, the relationship between environmentally driven and clinically acquired resistant bacteria remains unclear; therefore, it is important to determine whether this effect is either strictly environmental or clinical.

The hospital setting has been the focus of AMR as one of the primary sources owing to the high usage of a wide range of antibiotics and the spread of antibiotic resistance genes (ARGs) that may be transferred by the ARB released into the environment from hospital effluents [10]. Some antibiotic-resistant pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA), carbapenem-resistant Enterobacteriaceae (CRE), and vancomycin-resistant enterococci (VRE) may pose significant risks to human health [11-13]. Ignorance that these possible effluent sources such as hospitals, including ARB or ARGs from clinical sources, can be dispersed and even thrive in the environment is likely to accelerate the development of multiple antibiotic–resistant bacteria.

Although antibiotics remain effective at treating many bacterial infections, some strains are extremely difficult to treat, and therapeutic options are becoming increasingly scarce. The term “ESKAPE” encompasses six such pathogens with growing multidrug resistance and virulence: *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *A. baumannii*, *P. aeruginosa*, and *Enterobacter* species [14]. ESKAPE pathogens are responsible for most nosocomial infections and are capable of resisting the biocidal action of antimicrobial agents. This phenomenon is caused by bacterial evolution; thus, AMR has increasingly become a problem with rapid rates of development and spread, and we are lacking new drugs to challenge these new superbugs.

The World Health Organization (WHO) has called for coordinated actions to minimize the emergence and spread of AMR by providing technical assistance for countries to develop national health action plans and urging more research and development on AMR [15]. In Malaysia, the collaborative effort between the Ministry of Health and the Ministry of Agriculture and Agro-based Industry resulted in the Malaysian Action Plan on Antimicrobial Resistance (MyAP-AMR) 2017-2021. The MyAP-AMR details plans to minimize AMR in both health care practices and agricultural sectors, including increasing awareness of antimicrobials, appropriate usage of antibiotics in clinical settings, and pollution influenced by the direct use of antibiotics in poultry farms [16].

The Bacteriology Unit, Infectious Diseases Research Centre in the Institute for Medical Research has performed profiling of antibiotic resistance from a poultry farm and clinical samples in Malaysia. Some published studies also reported the presence of pharmaceutical residues from surface water in Malaysia. Al-Odaini et al [17] documented the presence of human pharmaceutical products—including antidiabetic, antihypertensive, and hypolipidemic agents; β2-adrenergic receptor agonists; antihistamines; analgesics; and sex hormones—in river water and sewage effluents, although no antibiotics were measured. Praveena et al [18] reported the presence of pharmaceutical residues, including antibiotics, in three rivers in Selangor, Malaysia. The researchers detected ciprofloxacin in all samples, which was the most common pollutant in the rivers. Recently, Bong et al [19] found that



XSL•FO
RenderX

multiple antibiotic-resistant phenotypes of *E. coli*, harboring the *tet* and *sul* resistance genes, were more prevalent in wastewater effluents than in the river waters. A concerted effort has been carried out to address the issue of AMR in clinical settings and the misuse of antibiotics in the current practice of poultry farming and pharmaceutical manufacturing industries. However, Malaysia lacks research on environmental aspects that may contribute to AMR, particularly the possibility of ARB and ARGs that may be released from hospitals into the environment through various modes. Moreover, no study has investigated whether antibiotic residues present in the hospital effluent contribute to the AMR problem in Malaysia. Since hospitals are the major users of antibiotics, it is important to determine the status of the effluent water from our hospitals that is released into the environment. However, to date, there has been no monitoring of the antibiotic residues under wastewater management in Malaysia. Therefore, this proposed study represents a first step to fill this gap to better address the AMR issues in Malaysia.

Dissemination of Antibiotic Resistance

Antibiotics can enter the environment through several different routes. Antibiotics and their metabolites are released from hospitals with urine and feces from patients as hospital wastewater effluent [20]. Similarly, antibiotics are released into the wastewater treatment system from people taking antibiotics in their homes [21]. Antibiotics are also used therapeutically or as growth promoters in livestock and poultry in Malaysia. Antibiotics and their metabolites will spread through animal excrement and end up in fields and groundwater, or in the case of antibiotic use in fish farms directly into the aquatic environment [22] (Figure 1). Regardless of the routes for antibiotics disseminating in the environment, it is also likely that resistant bacteria follow the same routes of dispersal [23]. This results in an environment where antibiotics, ARGs, resistant bacteria, and the environmental bacterial flora are mixed. However, the environment is likely becoming a resistance hotspot where ARGs can proliferate and undergo a process of evolution to result in the development of new resistant strains. Pathogens can acquire an ARG from the environmental gene pool by either conjugation, transformation, or transduction. The most important genetic elements capable of being transferred by conjugation are plasmids and integrative conjugative elements, which may carry ARGs and potential virulence genes.

Figure 1. Schematic flow of antibiotic-resistant bacteria (ARB) and antibiotic resistance genes (ARGs) from hotspots of evolution and transmission (red circles) to the environment (green circle). Blue circles indicate possible vectors that may aid transmission between specific environments, including air, surface waters, humans, and other animal vectors. Black arrows indicate known flows of ARB and ARGs. The grey arrow indicates a possible transmission route from a contaminated environment back to the general populace. CAFO: concentrated animal feeding operation; WWTP: wastewater treatment plant (reproduced from Kraemer et al [22], which is published under Creative Commons Attribution 4.0 International License [24]).

Scale of the Problem

A total of 88 pathogen-drug combinations were used to quantify the worldwide burden of drug-resistant diseases in 2019. This resulted in an estimated 495 million fatalities, of which 127 million deaths were directly attributed to drug resistance [25]. By 2050, it is estimated that approximately 10 million lives will be at risk annually as a consequence of the rise in drug-resistant infections [26].

Furthermore, antibiotic resistance is a substantial economic burden worldwide. In 2006, approximately 50,000 Americans died due to two common hospital-acquired infections (HAIs), namely pneumonia and sepsis, costing approximately US $8 billion [27]. In Europe, the levels of antibiotic resistance are varied. The common causes of infections are used as indicators to focus on AMR in *S. aureus*, specifically against methicillin (ie, MRSA) as a common cause of severe infections in health facilities and the community. MRSA is among the resistant pathogens that are widely recognized to pose an urgent or serious threat to human health. CRE such as *K. pneumoniae and E. coli* are also recognized as major causes of HAIs, including pneumonia. The WHO has listed MRSA as a high-priority (priority 2) pathogen for research and development

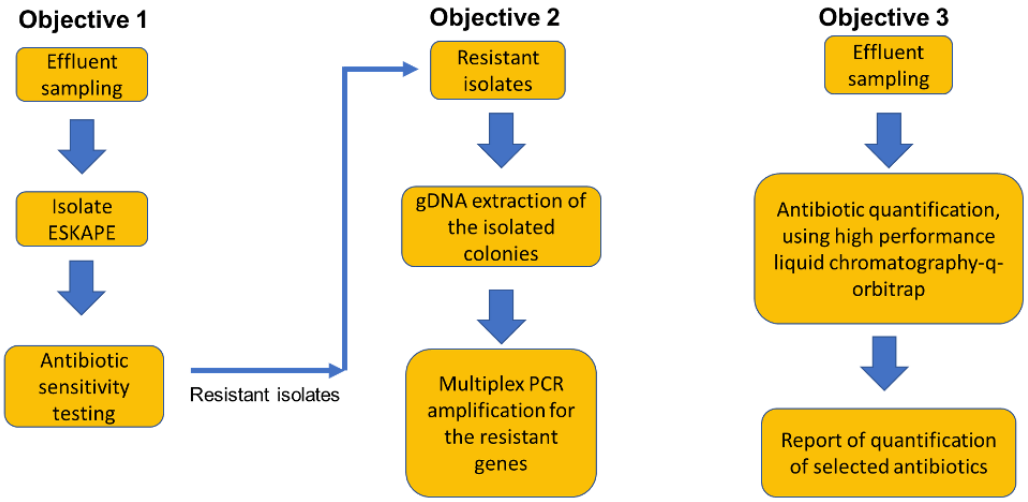
XSL•FO
RenderX

of new antibiotics, while CRE have been listed as critically important (priority 1) [28].

In Asia, India has been documented as one of the largest burdens of drug-resistant pathogens worldwide, including the highest burden of multidrug-resistant tuberculosis, along with alarmingly high resistance rates among gram-negative and gram-positive bacteria even to newer antimicrobials such as carbapenems and faropenem since its introduction in 2010 [29]. Regional studies in India reported high AMR among pathogens such as *Salmonella typhi*, *Shigella*, *Pseudomonas*, and *Acinetobacter* [30].

In Thailand, approximately 88,000 infections were attributed to AMR, resulting in at least 3.24 million additional days in the hospital and 38,000 deaths [31]. The Global Antimicrobial Resistance Surveillance System (GLASS) launched by the WHO was implemented in Siriraj Hospital in Bangkok, reporting that in-hospital mortality was significantly higher in patients with antibiotic-resistant bacteremia than in patients with antibiotic nonresistant bacteremia (40.5% vs 28.5%, $P<.001$) [32]. The same study concluded that patients with antibiotic-resistant bacteremia utilized more resources than those with antibiotic nonresistant bacteremia [32].

MRSA emerged in Singapore in the 1970s [33], rapidly becoming endemic in local health care facilities, with 35.3% of all *S. aureus* isolates reported to be methicillin-resistant in 2006 [34]. In another study, the prevalence of MRSA was found to be significantly higher in intermediate (29.9%) and long-term (20.4%) care facilities than in acute-care hospitals (11.8%) [35], and the organism has also been sporadically reported in the community as well as in local retail food and animals [36-38].



Nonetheless, there are limited studies examining the role of hospital effluents in contributing to the development of drug-resistant pathogens in the environment. Hospitals are the major users of antibiotics and may become one of the major contributors to AMR in the environment. Furthermore, the levels of antibiotic resistance in hospital effluents may be different from those of other water environments such as homes or agriculture. Therefore, the general aim of this study is to determine the prevalence of antibiotic-resistant pathogenic bacteria and the level of antibiotic residues in hospital effluents in Selangor, Malaysia. This study will also be determining the prevalence of ARB (specifically ESKAPE) present in the effluents of hospitals with an individual sewage treatment system, the occurrence of ARGs among ESKAPE bacteria, and the residual concentrations of antibiotics based on their usage at the selected hospitals. The findings from this study will provide important scientific evidence relevant to stakeholders that can help to reduce or interrupt the spread of AMR from clinical settings into the environment.

Methods

Study Design

A cross-sectional study will be performed at preidentified hospitals with three specific objectives as depicted in the workflow diagram in Figure 2. Objective 1 is to obtain resistant isolates of ESKAPE bacteria from the hospital effluent and to perform antibiotic susceptibility testing (AST). Objective 2 is to extract the genomic DNA of the resistant isolates from objective 1 to identify the isolates and the ARGs present in the isolates. Objective 3 is to quantify the level of targeted antibiotic residues from the hospital effluent samples. The targeted antibiotics that will be quantified are ceftriaxone, ciprofloxacin, meropenem, vancomycin, colistin, piperacillin, and tazobactam, which are the most highly used antibiotics in the hospital setting. The outcome of activities in objective 1 and 2 will provide estimates of the prevalence of the ARB in the hospital effluent, while the outcome of objective 3 will determine the level of antibiotic residues in the hospital effluent to address the overall aim of this study.

Figure 2. Summary of the workflow for this study. ESKAPE: Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa, Enterobacteriaceae; gDNA: genomic DNA; PCR: polymerase chain reaction.

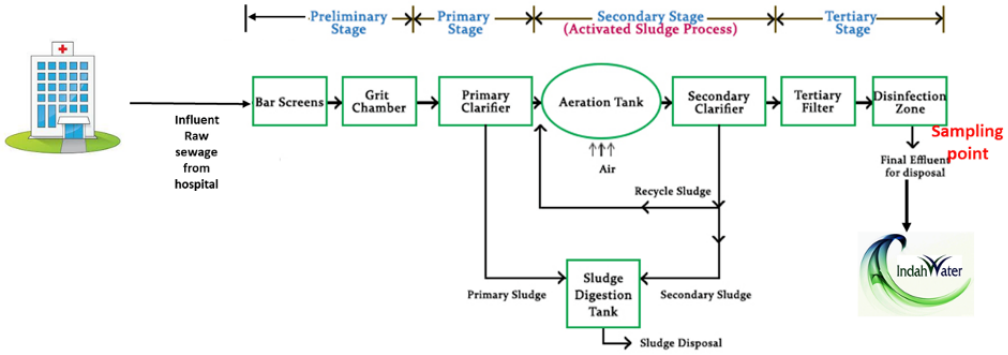
Selection of Study Area

We will identify all the tertiary hospitals in Selangor, one of the states in Malaysia, prior to effluent sample collection, based on the following inclusion and exclusion criteria.

Hospitals with individual sewage treatment plants will be included. An individual sewage treatment plant is a system whereby the sewage from the hospital is the only source that enters the sewage treatment plant, as depicted in Figure 3. Hospitals with nonindividual sewage treatment plants will be excluded. A nonindividual sewage treatment plant is defined as a communal sewage treatment plant whereby the sewage entering the sewage treatment plant is coming from various sources such as housing, farming, and manufacturing industries, as illustrated in Figure 4.

Figure 3. The sampling point for the effluent sample to be collected is at the final effluent for the disposal outlet, as depicted in the diagram. This is the outlet after the treatment before entering the river system that is going to be treated by the Indah Water Treatment Plant to be used as a clean water source for the public.



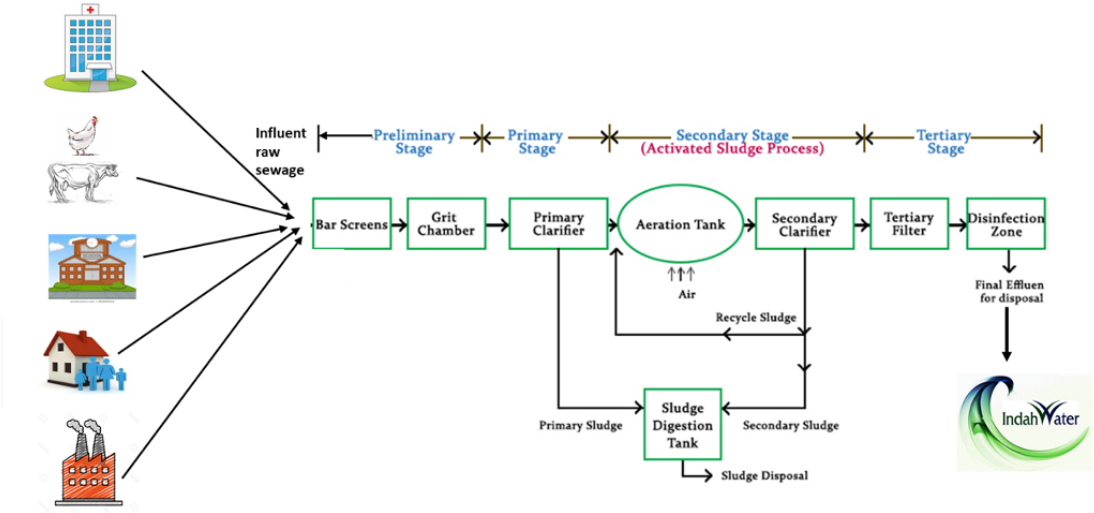


Figure 4. The waste from multiple human activities such as farming, domestic, school, factory, and hospital activities is concentrated into same sewage treatment plant before release to the river to be treated by Indah Water Treatment Plant as a clean water source for the public.

Sample Size Calculation

Calculation of sample size is based on the prevalence using the following formula [39]: $N=Z^2p(1-p)/d^2$, where N is the sample size, Z is the statistic for a level of confidence, and p is the expected prevalence or proportion (considering a total proportion of 100%, if 20% then p=0.2), and d is precision. For this study in proportion of 100%, if 5%, d=0.05. Considering a conventional 95% CI as the level of confidence, the Z value is 1.96. The sample size was determined from prevalence estimates of previous studies of ESKAPE isolates from the hospital or wastewater treatment plant with the 95% CIs, as shown in Table 1. This calculation served as the guidance for the number of plates to be used to isolate the targeted ESKAPE bacteria.

XSL•FO
RenderX

Table 1. Prevalence of antibiotic-resistant bacteria from related studies.

Study and bacterial species	Prevalence, %	Sample size (number of plates to isolate ESKAPE[a] bacteria)
Haller et al [40]		
Pseudomonas spp.	28.2	312
Klebsiella spp.	28.2	312
Enterobacter spp.	18.3	230
Citrobacter spp.	11.3	155
Hrenovic et al [41]: *Acinetobacter baumannii*	57.0	377
Thompson et al [42]: methicillin-resistant *Staphylococcus aureus*	81.0	237
Varela et al [43]		
Enterococcus spp. on vancomycin	0.7	11
Enterococcus spp. on ciprofloxacin	3.4	54
Karimi et al [44]		
Enterococcus faecium	6.03	88
Enterococcus faecalis	0.63	10

[a]ESKAPE: *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter.*

Sample Collection and Preparation

In total, two bottles of effluent water will be collected. Samples for objective 1 and objective 2 will be collected in a 1-L sterile screw-capped Schott Duran (Germany) amber bottle. In addition, samples for antibiotics quantification (objective 3) will be collected in a 1-L high-density polyethylene (Kris Plastic Industries, Malaysia) sample bottle. All samples will be kept in an ice-packed cooler box maintained at 4°C and transported back to the Environmental Microbiology Laboratory, Institute for Medical Research, for immediate processing. The samples will be collected at the final effluent disposal point of the sewage treatment system before reaching the Indah Water Treatment Plant Malaysia (Figure 3).

Microbiological Analysis

Isolation of ESKAPE ARB

Ten-fold serial dilutions for each water sample will be prepared in 50-mL sterile saline solution and 10 mL of the sample will be filtered through sterile 0.45-µm pore size cellulose acetate filters (Sartorious Singapore Pte Ltd) in triplicate (Figure 5). The filter will be then placed onto the selective media to isolate ESKAPE pathogens. The selective media to be used in this process of isolation are listed in Table 2. Identification of the ESKAPE bacteria will be carried out using the 16S RNA polymerase chain reaction (PCR) technique with a universal primer pair (forward, CCT ACG GGA GGC AGC AG; reverse, ATT ACC GCG GCT GCT GG) under the following condition: polymerase activation at 94°C for 2 minutes, denaturation at 94°C for 5 seconds, annealing at 60°C for 10 seconds, extension at 72°C for 20 seconds, and holding at 4°C.

The positive colonies will be subjected to AST using the disk diffusion method (Kirby Bauer) referring to the Clinical Laboratory Standards Institute (CLSI) guidelines. The antibiotics that will be used for AST are ceftriaxone (30 µg), ciprofloxacin (5 µg), meropenem (10 µg), vancomycin (30 µg), colistin (10 µg), and piperacillin/tazobactam (110 µg). For the bacteria that are not available in CLSI guidelines, measurement will refer to European Committee of Antimicrobial Susceptibility Testing (EUCAST) guidelines. The minimal inhibitory concentration of colistin will be determined using a liquid broth dilution test as recommended by EUCAST with cation-adjusted Mueller-Hinton broth (NutriSelect Plus, Germany), because the disk diffusion method is not reliable for this antibiotic since its large molecular size results in poor diffusion into the agar medium, leading to inaccurate results with a high error rate and poor reproducibility [45].

RenderX

Figure 5. The number of plates to be used to isolate ESKAPE (Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acitenobacter baumannii, Pseudomonas aeruginosa, and Enterobacter) pathogens from the hospital effluent based on the calculated sample size. See Table 2 for the selective media used for each species.

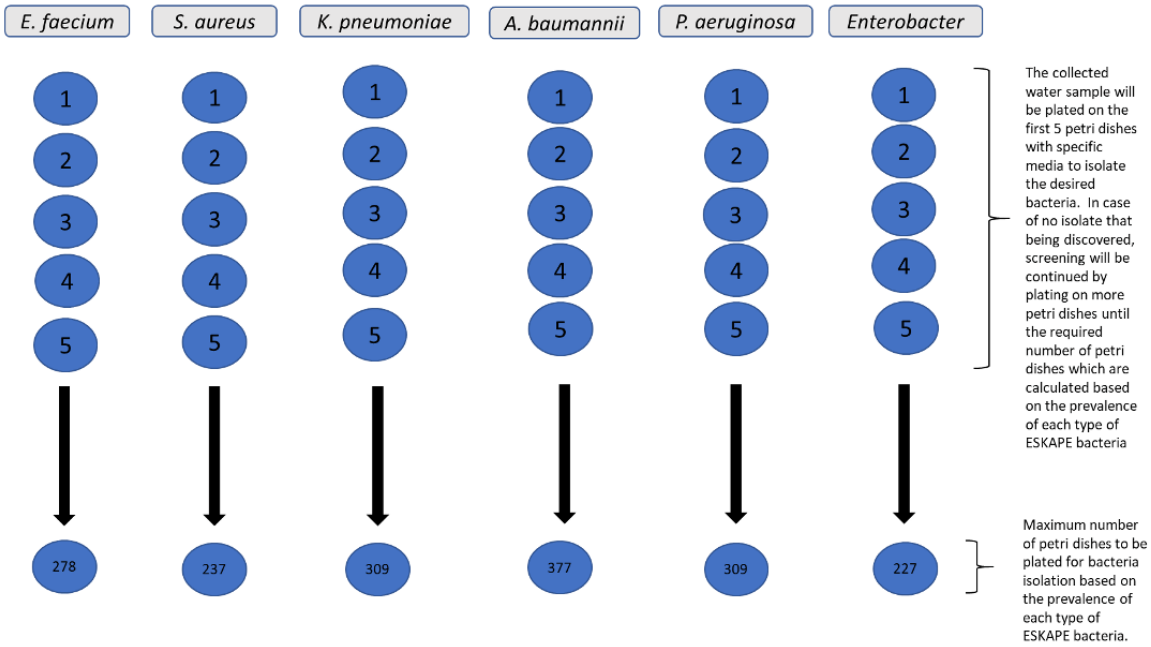

Table 2. Selective media and the incubation condition to isolate pathogens from the effluent samples.

Selective organism	Medium	Incubation condition
Enterococcus faecium	Chromogenic *E. faecium* Agar (Himedia, India)	37°C, aerobic, 24-48 hours
Staphylococcus aureus	Mannitol Salt Agar (BD, Germany)	37°C, aerobic, 24-48 hours
Klebsiella pneumoniae	Eosin Methylene Blue Agar Modified (HHT) (BD-BBL, USA)	37°C, aerobic, 24-48 hours
Acinetobacter baumannii	Chromagar Acinetobacter (CHROMagar, Paris France)	37 °C, aerobic, 24-48 hours
Pseudomonas aeruginosa	Cetrimide Agar (Neogen USA)	37°C, aerobic, 24-48 hours
Enterobacter	MacConkey II Agar (BD-BBL, USA)	37°C, aerobic, 24 hours

Detection of ARGs Among ESKAPE Isolates

Each colony found to be resistant to any of the tested antibiotics will be cultured and inoculated in tryptone soy broth medium (CM0129, Oxoid). The culture will be incubated at 37°C for 18-24 hours. The genomic DNA will be extracted using the PureGene Bacteria Kit (Qiagen, Germany) following the manufacturer's instructions. The concentration of the extracted DNA will be measured using a Multiskan SkyHigh microplate spectrophotometer (Thermo Scientific) before multiplex PCR amplification. Primers were selected to amplify the targeted ARGs based on published findings [46-56] (see Multimedia Appendix 1). The extracted DNA will be amplified using multiplex PCR following the single-template PCR method. The PCR conditions will be optimized according to published methods. The size of the amplified products will be confirmed by 3% agarose gel (NextGene) electrophoresis at 90 V for 90 minutes. The PCR products will be sent to an outsourcing service for Sanger sequencing. The sequencing results will be analyzed using the Basic Local Alignment Search Tool nucleotide (BLASTn) tool in the National Center for Biotechnology Information database to identify the correct amplified relevant genes.

Chemical Analysis

Quantification of the Concentrations of Selected Antibiotics

An ultrahigh-performance liquid chromatography (UHPLC) system will be used to quantify the levels of antibiotics from all samples following the method reported by Kim et al [57]. Samples will be collected and treated by preconcentration using a nitrogen evaporator. The samples will then be cleaned by an automated solid-phase extraction system. The analysis will be performed using Q-exactive liquid chromatography-mass spectrometry. External standards of antibiotics will include ceftriaxone, ciprofloxacin, meropenem, vancomycin, colistin, piperacillin, and tazobactam. The internal standards will be ciprofloxacin-d8 (molecular weight: 339.38) and piperacillin-d5 (molecular weight: 522.59). The analytical column will be Waters Xbridge C18 Column (50 mm × 2.1 mm, 2.5 µm inner diameter) run at 35°C. Two types of solvents will be used: 0.1% formic acid (solvent A) in water and 100% acetonitrile (solvent B). The solvent gradients with a flow rate of 0.2 mL/min for this experiment are shown in Table 3.

XSL•FO
RenderX

Table 3. Solvent gradients with a flow rate of 0.2 mL/min.

Time (minutes)	Solvent A (0.1% formic acid), %	Solvent B (100% acetonitrile), %
0.0	98	2
4.9	35	65
13.5	2	98
21.0	2	98
21.5	98	2
26.0	98	2

Data Analysis

The prevalence of ARB will be calculated using the following formula:

> Prevalence (%)=(number of resistant isolates/number of resistant isolates + number of susceptible isolates) × 100

To detect ARGs carried by ESKAPE bacteria, nucleotide results from the sequencing will be checked using Chromas, a DNA sequencing software to view and edit the chromatograms (traces) from automated Sanger sequencers. The edited chromatograms from the sequencing results will be sent to the BLASTn database to confirm the amplified genes.

The concentration of the antibiotic residues quantified using UHPLC will be compared to the antibiotic usage in the hospitals.

Ethics Considerations

No primary data will be collected and thus no ethical approval is required. The study protocol was approved by the Medical Research and Ethical Committee, Ministry of Health Malaysia. This study is also registered under the National Medical Research Registry (NMRR-19-3637-51680) Malaysia.

Results

The primary outcome measure for this study is the prevalence of resistant ESKAPE bacteria isolated from antibiotic-selective media. The bacteria will be identified by 16S RNA PCR to determine species. The secondary outcome of this study is the occurrence of ARGs that may be discovered from the resistant ESKAPE bacteria isolates as the likely cause of the resistance toward the antibiotics (Table 2). The multiplex PCR method will be applied to screen the ARGs present. As of July 2022, effluent sampling has been conducted in three hospitals and analysis of samples is ongoing to determine the level of antibiotic residues. ESKAPE bacteria were isolated and AST is ongoing to determine the resistant isolates. Some preliminary findings for *E. faecium* from Hospital A showed that 80% (8/10) were resistant to vancomycin and 20% (2/10) were susceptible, whereas only 10% (1/10) were resistant, 60% (6/10) had intermediate resistance, and 30% (3/10) were susceptible to ciprofloxacin. Moreover, 100% (10/10) of *E. faecium* isolates from Hospital B were resistant toward vancomycin but susceptible toward ciprofloxacin. Resistant isolates will be processed for further screening of ARGs using PCR. Effluent sampling activities were suspended for a few months due to the COVID-19 pandemic, which caused a delay in the downstream analysis. The findings of the study will be disseminated through peer-reviewed journals and scientific conferences.

Discussion

VRE represent an issue of both medical and public health importance, as these bacteria are commonly associated with multidrug-resistant infections and persistent colonization in patients [58]. From our early findings, the prevalence of vancomycin-resistant *E. faecium* from two hospitals was more than 80%, which was higher than the prevalence of 11% reported in a study performed in the Czech Republic on isolates collected from Military Hospital Olomouc and University Hospital Olomouc [59].

The outcomes of this study will fill the gap of important information for clinical practitioners to determine whether the hospitals in Malaysia are main contributors to the AMR problem in the country. This study will provide baseline information on the prevalence of antibiotic resistance from hospital effluents in Malaysia to assist in hospital wastewater management and improve antibiotic stewardship in Malaysia.

This study will have an impact on the improvement of hospital sewage treatment because the data will provide information to the Engineering Service Division of the Ministry of Health that reflects the efficiency of the current sewage treatment in Ministry of Health hospitals. This should facilitate the hospital's sewage manager in the Engineering Service Division in effective service improvement.

Moreover, the findings from this study will help in the optimization of antimicrobial stewardship programs by recommending strategies for infectious disease physicians and pharmacists in their prospective audit and feedback of antimicrobial prescriptions to clinicians, formulary restriction, education, and guidelines. Antimicrobial stewardship programs are aiming to optimize antimicrobial selection, dosing, route, and duration of therapy to maximize a clinical cure or prevention of infection, while limiting unintended consequences such as the emergence of resistance, adverse drug events, and extra costs.

Ultimately, this study will contribute to the improvement in public health. The improvement in the hospital sewage system will eventually lead to controlling antibiotics pollution in the environment by reducing the spread of clinically driven ARB and ARGs into the environment. This will in turn reduce the unnecessary demand for stronger antibiotics or even failure to treat many types of resistant infections.

Abstract

Background: The COVID-19 pandemic undermined gains in reducing maternal and perinatal mortality in South Africa. The Mphatlalatsane Initiative is a health system intervention to reduce mortality and morbidity in women and newborns to desired levels.

Objective: Our evaluation aims to determine the effect of various exposures, including the COVID-19 pandemic, and a system-level, complex, patient-centered quality improvement (QI) intervention (the Mphatlalatsane Initiative) on maternal and neonatal health services at 21 selected South African facilities. The objectives are to determine whether Mphatlalatsane reduces the institutional maternal mortality ratio, neonatal mortality rate, and stillbirth rate (objective 1) and improves patients' experiences (objective 2) and quality of care (objective 3). Objective 4 assesses the contextual and implementation process factors, including the COVID-19 pandemic, that shape Mphatlalatsane uptake and variation.

Methods: This study is an implementation science type 2 hybrid effectiveness, controlled before-and-after design with quantitative and qualitative components. The Mphatlalatsane intervention commenced at the end of 2019. For objective 1, intervention and control facility-level data from the District Health Information System are compared for changes in institutional maternal and neonatal mortality and stillbirth rates and associations with QI, the COVID-19 pandemic, and both. This first analysis includes data from 18 facilities, regardless of their allocation to intervention or comparison, to obtain a general idea of the effect of the COVID-19 pandemic. For objectives 2 to 3, data collectors abstract data from maternal and neonatal records, interview participants, and conduct neonatal facility assessments. For objective 4, interviews, program documentation, surveys, and observations are used to assess how contextual factors at the macro-, meso-, and microlevels explain variation in intervention uptake and outcome. The intervention dose is measured at the microlevel only in the intervention facilities. The study assesses the Mphatlalatsane Initiative from 2020 to 2022.

XSL•FO
RenderX

Results: From preliminary analysis, across the 3 provinces, maternal and neonatal deaths increased during the COVID-19 pandemic, whereas stillbirths remained unchanged. Maternal satisfaction with quality of care was >90%. The COVID-19 pandemic severely disrupted the QI teams functioning. However, the QI teams regained their pre–COVID-19 momentum by adapting the QI model, with advisers providing mentoring and support. Variation in adoption at the mesolevel was related to stable and motivated leadership (particularly at the facility level), poor integration into routine processes, and buy-in from senior district managers who were affected by competing priorities. Varying referral and specialist outreach systems, staff availability and development, and service delivery infrastructure are plausible factors in variable outcomes.

Conclusions: Few evaluations rigorously evaluated the effect of health system interventions on improving health services and outcomes. Results will inform the scaling up of successful intervention components and strategies to mitigate the effects of the COVID-19 pandemic or similar emerging epidemics on maternal and neonatal mortality.

Introduction

Background

The emergence of COVID-19 caused by SARS-CoV-2 in 2020 had a detrimental effect on maternal and infant health gains. Pregnant and breastfeeding women are at a high risk for COVID-19–related morbidity and mortality [1,2]. Given the high number of pre–COVID-19 medically complicated pregnancies in low- and middle-income countries, the pandemic substantially increased the risks to pregnant and breastfeeding women and their infants [3] and undermined gains made in reducing maternal and perinatal mortality [4].

South Africa invested in improving sexual, reproductive, maternal, and neonatal health (SRMNH) services but did not reach the Millennium Development Goals targets for maternal and child health by the end of 2015. Aligned with the United Nations Sustainable Development Goals (SDG) of reducing maternal mortality to <70 per 100,000 live births and neonatal mortality to 12 deaths per 1000 live births [5], South Africa aims to reduce the institutional maternal mortality ratio (iMMR), neonatal mortality, and stillbirths by 50% by 2030 [6]. In 2019, the iMMR of 120 per 100,000 live births was well above the SDG target [6]. Moreover, although the institutional neonatal mortality rate (12 per 1000 live births in 2021) meets the SDG, almost 50% of neonatal deaths are avoidable (2021) [6]. This is despite the substantial reduction in iMMR since 2011, attributable to South Africa's antiretroviral treatment program, which increased access to lifelong maternal antiretroviral treatment at higher CD4 cell counts [7].

National policies and strategies for SRMNH have been in place but lack a cohesive quality improvement (QI) strategy. These challenges have been exacerbated by the COVID-19 pandemic, which has complicated access to health care and delivery of maternal and perinatal interventions [4]. Furthermore, despite the strengths of South Africa's existing maternal, perinatal, and child mortality audits, the availability of real-time data to address frontline challenges is undermined by outdated software and fragmented systems with inherent data quality issues and data gaps. These data gaps became more apparent as the pandemic necessitated rapid access to real-time maternal and perinatal data on COVID-19.

Optimal health care provides quality services that are effective and safe while also being timely, equitable, integrated, and efficient [8], with a focus on people-centered care as an essential component [9]. Quality of care is defined as the extent to which health services can increase the probability of desired health outcomes [10].

QI interventions in low- and middle-income countries have improved access to care, skilled delivery, and viral load monitoring. In a South African stepped-wedge randomized controlled trial, a continuous QI intervention resulted in a notable rise in viral load monitoring (relative risk [RR] 1.38, 95% CI 1.21-1.57; *P*<.001) [11]. However, there was no improvement in repeat HIV testing (RR 1.00, 95% CI 0.88-1.13; *P*=.96). In Ethiopia, there was a favorable effect on health workers' adherence to safe childbirth practices immediately after birth (β=8.22, 95% CI 5.15-11.29) [12]. In Ghana, a QI intervention to reduce waiting time for emergency obstetric care and hand hygiene in the neonatal intensive care unit (ICU) improved hand hygiene compliance by 93%. Moreover, the percentage of mothers needing emergency cesarean surgery with unacceptable waiting times decreased by 4 times, and 93% of the sickest mothers were correctly identified [13].

Conversely, in 2 randomized controlled trials conducted at the primary care level in Nigeria and Malawi, continuous QI was ineffective [14,15]. The researchers rigorously measured continuous QI in terms of impact on neonatal and perinatal mortality rates in the Malawi study [14] and 6-month postpartum retention in the Nigerian study [15]. However, these end points do not reflect the QI activities that occurred in the primary care centers. The variability of these end points is likely related to elements outside the remit of the QI, such as emergency care availability, road infrastructure, and mothers' educational attainment.

In 2017, the Mphatlalatsane Initiative was launched to provide a national unified response to improve the quality and equity of SRMNH care at the cusp of the National Health Insurance reform, using the Institute for Health Improvement QI methodology [16]. The final output is anticipated to be a proven

XSL•FO
RenderX

and replicable model of catalytic health systems and clinical interventions to reduce unintended pregnancies and maternal and newborn deaths. These can be tested for sustainability and scaled up to emulate achievements across the rest of the country.

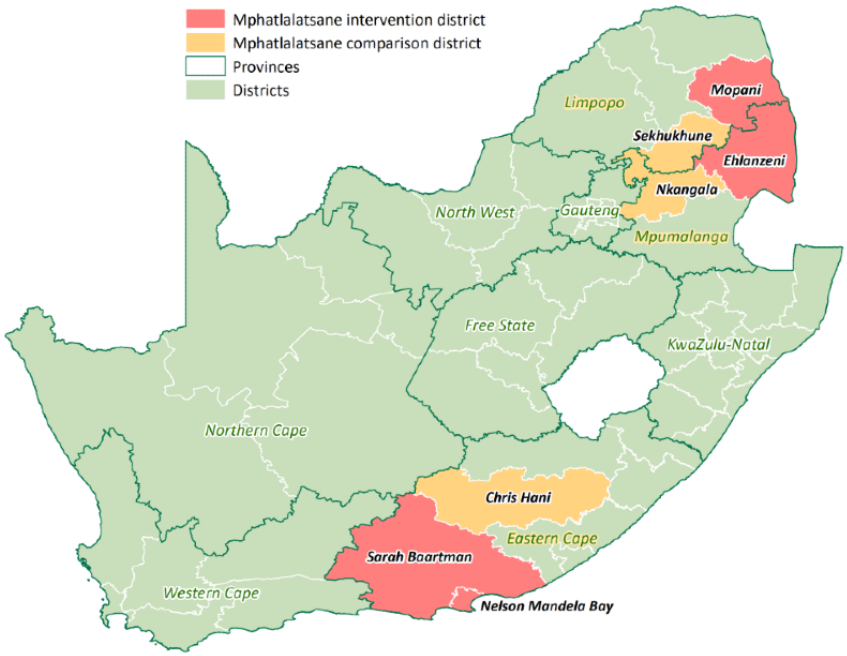
In this study, we report the protocol for the evaluation of the Mphatlalatsane Initiative. The initial aim of the protocol was to determine if a complex area–based QI initiative would reduce iMMR, neonatal mortality, and stillbirth rate by 50% in 5 years. Given the emergence of COVID-19 in March 2020 in South Africa with concomitant increased public health measures and national level-5 lockdown [17], the Mphatlalatsane Initiative was adapted to provide the much-needed support for maternal and perinatal care during the pandemic. The evaluation protocol was reframed to account for these adaptations and to determine the effect of the Mphatlalatsane Initiative on maternal and perinatal health care and outcomes, implementation processes, and health care system functioning during the pandemic from 2019 to 2022.

Study Aims and Objectives

The evaluation primarily aims to measure the effectiveness of the Mphatlalatsane Initiative on iMMR, neonatal mortality rate, and stillbirth rate (objective 1). We also assess whether patients' experiences of care (objective 2) and quality of maternal (objective 3a) and neonatal care (objective 3b) were affected by the pandemic. Objective 4a explores the macrolevel (regional and national) and mesolevel (subdistrict and district) factors, and objective 4b explores the microlevel (facility) process and contextual factors, including the COVID-19 pandemic, to explain variations in QI uptake and program outcomes and implications for scale-up. Partner interviews (objective 4a) commenced in early 2020, and data collection for objective 4b began in May 2021.

Outcome Measures

The primary end points are (1) iMMR, (2) neonatal mortality rate, and (3) stillbirth rate. The secondary end points include patient experiences of health care quality and facility processes during the antenatal and postpartum periods (objective 2) and the quality of maternal (objective 3a) and neonatal care (objective 3b). The study also explores *macro-*, *meso-*, *and microlevel contexts* and implementation processes for improved quality and outcomes of maternal and neonatal health (MNH). Additional details on the secondary outcomes are provided in Multimedia Appendix 1.



Methods

Study Setting

The evaluation is underway in 4 intervention and 3 nonoverlapping comparison districts across 3 provinces: the Eastern Cape, Limpopo, and Mpumalanga. All catchment areas are in 1 district, except for the Eastern Cape intervention catchment area, which spans across 2 districts.

The catchment area is subdivided into a wedge with 2 arms within each wedge. Each wedge has a district hospital at the apex. The hospital is linked to a regional hospital, 2 community health care centers, and 2 primary health care clinics in each arm. The intervention study districts in the Eastern Cape, Limpopo, and Mpumalanga are highlighted in red in Figure 1. The comparison facilities and the intervention facilities are in different districts to avoid contamination, and the former will not have the same apex district hospital as the intervention site. The comparison districts (Figure 1 in yellow) are not evaluated for objective 4.

RenderX

Study Design

We are conducting a mixed methods implementation science type 2 hybrid effectiveness design to study the intervention effect (objectives 1-3) and implementation (objective 4) during the COVID-19 pandemic. Given that the intervention facilities were preselected, the quantitative component will be implemented as a quasi-experimental controlled before-and-after study (nonrandomized assignment of the intervention and comparison groups) to measure the effect of a QI intervention implemented during the COVID-19 pandemic on maternal and neonatal outcomes. Data on the iMMR, neonatal mortality rate, and stillbirth rate will be analyzed from 2019 to 2021, including the time before and during the COVID-19 pandemic in South Africa (objective 1). Study data on maternal experiences of care (objective 2) and maternal and neonatal quality of care (objectives 3a and 3b) were collected between 2021 and 2022. Objective 4 data collection commenced in early 2020 and ended in August 2022.

Eligibility Criteria and Recruitment of Facilities

Overview

The intervention facilities were purposively identified by the National Department of Health (NDOH) as sites with MNH service performance and capacity below the national average in South Africa. In addition, the selected intervention sites reflect the clinical and referral pathways and represent both urban and rural settings. For objectives 2 and 3, the comparison districts were purposively selected to match the intervention districts in as many respects as possible, including iMMR, stillbirth rate, neonatal mortality rate, sociodemographic characteristics, service organization, and setting (rural, urban, and periurban), and to provide the NDOH standard of care. In total, 3 facilities (2 district hospitals and 1 regional hospital) in the comparison district were selected and matched to the intervention district based on the total number of births. Data collection for objectives 2 and 3 is conducted in 18 hospitals (15 district- and 3 regional-level hospitals). Objective 4b is being conducted in 15 hospitals, purposively selected from the 21 intervention facilities.

Participant Inclusion Criteria for Maternal Interview Shortly After Delivery (Objective 2) and Data Abstraction From Maternity Records (Objective 3)

To assess patient experiences of care and determine the quality of maternal care, participants who are aged ≥18 years, has a pregnancy diagnosis, who accessed care within the participating health facilities during their pregnancy, or who are within 1 week post partum are eligible. Research assistants will screen for eligibility using specified inclusion criteria. All women meeting any of the following criteria will be eligible: (1) pregnant women at ≥36 weeks gestation without any complications, (2) pregnant women at ≥36 weeks gestation with HIV before pregnancy and on antiretroviral therapy and diagnosed with HIV at first antenatal visit, (3) positive repeat antenatal HIV test following the first negative antenatal HIV test, (4) pregnant women at ≥36 weeks' gestation with eclampsia, (5) pregnant women at ≥36 weeks' gestation with primary postpartum hemorrhage, (6) postpartum women at ≤7 days with a premature baby, (7) postpartum women at ≤7 days with a healthy term baby, and (8) postpartum women at ≤7 days with a baby in the ICU. The medical records of eligible cases will be retrieved for a thorough review at hospital discharge or on transfer to another hospital.

Data collectors will conduct daily visits to maternity wards to recruit maternal participants and determine the antenatal quality of care during the pandemic era. During the daily visit, the admission and maternity registers are screened for participants who meet the study inclusion criteria. Stable women with recent deliveries are approached by an interviewer for recruitment before leaving the facility and are interviewed in a private space to ensure confidentiality or via telephones if on-site interviews are not possible. Women are excluded from participation if they are aged <18 years, delivered at home or on the way to the facility, are acutely ill in the ICU or with life-threatening conditions, or are emotionally distressed. Women whose infants are admitted to the ICU or who experienced a stillbirth or neonatal death will be approached for interview, and if they agree, they will be interviewed at a time that suits the mother.

Participant Inclusion Criteria (Objective 4)

At the macrolevel (provincial and national) and mesolevel (subdistrict and district; objective 4a), the study team will purposively recruit subdistrict, district, and area managers and those specifically responsible for managing maternal and neonatal care services across subdistricts, districts, provinces, and areas. At the microlevel (facility; objective 4b), we include all QI advisers, that is, persons who provide QI expertise and support to participating facilities' health workers who are organized in QI teams as well as the operational managers of the sampled facilities.

Procedures

Conceptual Framework

Our initial hypothesis was that the QI methodology will enhance the quality of MNH care by creating an enabling environment for leadership and governance to flourish, ensuring that clinical processes are delivered safely and reliably. A key component of the QI approach is ensuring respectful care and support for patients. We further hypothesize that optimizing the environment and processes will improve the health care system, leading to improved health outcomes and patient experience of care. Our underlying causal assumptions are that QI will empower macro- and mesolevel management and microlevel health workers to drive and implement change.

Implicit assumptions are staff participation in QI training, a facility QI team that continues QI activities throughout study implementation, and a leader within that team with continuity of participation are integral to its success. At the start of the intervention, the Mphatlalatsane Initiative implemented the Institute for Healthcare Improvement model for improvement as a framework to guide its implementation strategy [10]. The strategy involves the identification of a specific goal for improvement and a plan to measure progress and then commences with change ideas that may lead to improvement over a short duration. As the change ideas are refined and successfully applied, the interventions are broadened to increase

XSL•FO
RenderX

the magnitude of the changes. The Institute for Healthcare Improvement stresses initiating improvement on a small scale and leveraging the obtained knowledge to plan for wider implementation and eventual scale-up. Additional assumptions included that other competing programs or priorities implemented by the NDOH would not be conducted in the intervention catchment areas. However, the COVID-19 pandemic disrupted QI team functioning. The consortium partners prioritized the immediate needs of facilities, which broadened the initial intervention scope (described below under *Intervention Dose* section) of the Mphatlalatsane Initiative.

A framework of mesolevel (district and subdistrict) enabling environments was developed a priori, which included factors of distributed leadership and buy-in, area-based mechanisms of service delivery coordination and review, referral and outreach systems, and the allocation of resources in response to identified needs at the facility level.

Intervention Package

The Mphatlalatsane Initiative initially aimed to improve the quality of maternal and neonatal care in the participating facilities through QI activities. A QI adviser has been appointed in each catchment area to manage and support these teams. We anticipate that these teams will become nodes of "learning practices," with team members pooling their efforts and skills toward solving targeted service problems [18]. We view the respective microlevel health systems, in which the QI teams function, as social systems, with the agency of staff and the relationships, existing and to-be-established, within these systems [19], as key to understanding the teams' performance. The evaluation and intervention teams are independent to minimize bias. The intervention design of in-person support shifted based on facility responses during the COVID-19 pandemic. Initial attempts to use digital platforms to support QI teams were unsuccessful, and QI advisers subsequently supported QI teams through telephonic messages and calls. Other design changes included providing emotional support and guidance and improving the efficiency of supply chain management for infection control and personal protective equipment. Once the acute demands were met, the Mphatlalatsane intervention was revised to mitigate the interruptions in access to routine MNH services.

QI activities comprise the repeated and rapid implementation of Plan-Do-Study-Act (PDSA) cycles [20,21]. The *Plan* refers to problem identification and development of solutions; the *Do* refers to implementation of the solutions; the *Study* refers to the evaluation of effects of the solutions and then *Acting* on the outcome of the evaluation by adopting, adapting, or rejecting the solutions [20,21]. QI teams have been established in each participating facility to engage maternal and neonatal staff in relevant PDSA activities [21,22].

Comparator

Health care providers in the control district facilities continue to provide the NDOH standard of care to antenatal and postnatal attendees as per the policy and guidelines. The usual training for staff involves weekly 1-hour in-service training on current evidence-based guidelines. The usual training does not include a coaching or mentoring component and is not a data-driven process for evaluating the implementation of evidence-based guidelines.

Data Sources

Objective 1

Mortality data from 2017 to 2022 were extracted from the District Health Information System (DHIS; Table 1).

XSL•FO
RenderX

Table 1. Mphatlalatsane data sources.

Objective	Data source	Variable or theme	Level of analysis
1	• DHIS[a]	• Mortality data (maternal, neonatal, and stillbirths) extracted quarterly from 2019 to 2022	District and facility
2	• Participant interview shortly after delivery in regional or district hospitals	• The effect of the QI[b] intervention over time on patients' experience of the quality of antenatal and postnatal health care services from 2021 to 2022	Individual
3a	• Maternal records from regional or district hospitals	• Facility audit of maternal records will be conducted to measure adherence to clinical protocols on normal pregnancy, HIV, eclampsia, and postpartum hemorrhage from 2021 to 2022	Individual
3b	• Structured observation checklists will be interviewer administered in selected facilities based on the Newborn QI Toolkit norms and standards for newborn care, which were developed to collect data in each facility [23]	• Availability of equipment and supplies • Availability of guidelines or policies • Distribution and availability of drugs • Data quality and use • Staffing • Infrastructure	Facility
4a	• Semistructured interviews and FGDs[c] with the QI advisers, operational managers, and management staff	• Stakeholder analysis: coordination processes, nature and quality of social networks, decision-making processes, formal and informal communication, and collaboration between key actors. We will set up monthly individually open-ended debriefing meetings with the QI advisers, and they will reflect on their work and engagement with the QI teams. We will also review program documentation, including the documentation that the QI teams will generate during the PDSA[d] cycles. We will also conduct other program meetings at the macro- and mesolevels.	National, provincial, district and subdistrict
4b	• Interviews and FDGs with QI teams • QI team surveys • QI adviser debriefings • Program documentation	• QI advisers, teams, and facility managers: setting up, management structures, systems of communication, translation of their PDSA cycles into everyday practices, climate for QI activities, relational dynamics in the teams, ownership of change, resource use, experiences, and perceptions of implementation changes over time, perceived benefits, and challenges of the QI work in their facilities. • QI team outcomes: packaging learning practices for scale-up and identify the "leverage points" for change. [c]FGD: focus group discussion.

[d]PDSA: Plan-Do-Study-Act.

Objective 2

In-person or telephonic interviews were conducted with pregnant women shortly after delivery to measure participants' subjective experiences of care. The survey used a 5-point Likert scale based on a prior study of maternal patient satisfaction with services in Tanzania [24]. Data collectors administered paper-based surveys at the midline, which were then captured using REDCap (Research Electronic Data Capture; Vanderbilt University) software.

Objective 3a

Data collectors took photographs or abstracted data from maternal records, which were then entered into the REDCap database. Facility audit of maternal records were conducted by an experienced nurse to measure adherence to the guidelines and implementation of care. Data were collected at a single time point within 1 week of delivery.

Objective 3b

Interview-administered structured observation checklists were completed in all selected facilities based on the Newborn QI Toolkit [23] norms and standards for newborn care.

Data were also collected using a series of checklists to determine the quality of record keeping for the newborns. Staff members in the neonatal unit were requested to provide the clinical records of a sample of newborns with the following conditions: (1) low birth weight, (2) infection, and (3) asphyxia. A review of these records was conducted to determine the quality of record keeping. Data collection for objective 3 was at the end line (approximately June 2022 to August 2022).

XSL•FO
RenderX

Objective 4a

Semistructured interviews and focus group discussions (FGDs) were conducted with the QI advisers, QI teams, operational managers, and management staff at the subdistrict, district, and provincial levels.

Objective 4b

The data collection comprised (1) interviews and FGDs with the QI team leaders and members, (2) digital surveys to leaders and teams to assess their performance, (3) regular debriefings with the advisers, and (4) a review of program documentation. The debriefings and documentation reviews commenced in February 2020, and the interviews, FGDs, and surveys began in May 2021. As of November 2022, we conducted 32 interviews with leaders and 51 interviews or FGDs with team members.

Sample Size

Objective 1

Using the number of deliveries and maternal and perinatal deaths in 9 regional and district facilities in the chosen intervention catchment areas (the Eastern Cape, Limpopo, and Mpumalanga) between 2018 and April 2019, rates were found to be 115.4 maternal deaths per 100,000 live births, 14.4 neonatal deaths per 1000 live births, and 22.5 stillbirth births per 1000 facility births. For this study, an intraclass correlation estimator from a random intercept logistic regression model was used. Using the average facility size (based on deliveries in the intervention catchment areas during the baseline period), the variance inflation factor was estimated at 1.0, 1.4, and 1.3 for the maternal mortality ratio, neonatal mortality rate, and stillbirth rate, respectively. To test the hypothesis that there was no improvement against a 50% increase in the baseline, with 80% power at a 5% two-sided significance level, the number of live births would be 40,524 and 4512 for testing maternal and neonatal mortality rates and 2666 for stillbirth rates. We will observe at least 41,000 deliveries pooled across the 3 catchment areas over a 3-year period to have minimum power for all outcome comparisons. The same would accrue in the control facilities.

Objective 2 and 3a

Literature on patient satisfaction in South Africa is scarce; in other studies, patient satisfaction varies from <50% to as high as 75% [25]. The impact of the intervention on patient satisfaction may likely be less compared with that before the COVID-19 era because of disruptions in service delivery. For the 18 facilities in the intervention arm and 18 facilities in the control arm, at a power of 80%, and an expected increase in patient satisfaction from 50% to 60%, given an intraclass correlation coefficient of 0.06, the number of pregnant women required is 102, with a total sample size of 1529 per arm in the pre- and postintervention periods.

Objective 3b

The study team will evaluate 18 facilities (3 in each of the intervention and control catchment areas).

Objective 4

Sampling at the meso- and macrolevels will be linked to the microlevel sampling. The subdistricts and districts where facilities have been selected and their respective area levels will be included in the evaluation at the macro- and mesolevels. At minimum, 2 subdistricts, 2 districts, and 3 areas (total 7 “units” of assessment) will be selected, although additional units could be added if primary health care clinics, community health care centers, and district hospitals are not all from the same subdistrict. We anticipate approximately 90 and 120 interviews or FGDs, respectively, for the macro-, meso-, and microlevel interviews or FGDs over the 18 months of data collection. At the microlevel, we sampled QI teams across the 3 catchment areas, as follows:

Objective 4b facilities (Table 2) were sampled based on readiness assessment scores from the NDOH (this was done before the start of the intervention to assess the state of maternal and neonatal care in the intervention facilities) and input from the QI advisers and represent the range of facility types; MNH care packages; and urban, semiurban, and rural areas.

Table 2. Type of objective 4b facilities sampled in Eastern Cape, Limpopo, and Mpumalanga from 2020 to 2022 (N=15).

	Eastern Cape (n=4), n (%)	Limpopo (n=5), n (%)	Mpumalanga (n=6), n (%)
Regional hospital (n=3)	1 (7)	1 (7)	1 (7)
District hospital (n=4)	1 (7)	1 (7)	2 (13)
Community health care center (n=5)	1 (7)	2 (13)	2 (13)
Primary health care clinic (n=3)	1 (7)	1 (7)	1 (7)

Intervention Dose

The intervention dose, defined as the “quality and quantity of an intervention and participation” [26], may be necessary to determine the barriers or enablers of the Mphatlalatsane Initiative. However, measuring the intervention dose is complex and requires substantial data collection to quantify the various intervention dose dimensions. Moreover, there are currently no accepted methods for measuring this dose. McHugh et al [26] outlines 8 dimensions of intervention dose that may affect whether or not a QI initiative succeeds. In the Mphatlalatsane Initiative, the measurement of the intervention dose is further complicated by the COVID-19 pandemic. The implementation of the Mphatlalatsane Initiative was ongoing for approximately 6 months when the first case of COVID-19 was diagnosed in South Africa in March 2020 [27]. Following the national state of the disaster and level-5 lockdown, the Mphatlalatsane Initiative was redefined to provide support to the intervention

XSL•FO
RenderX

sites. This support took the form of a web-based platform, telephonic meetings, and in-person QI adviser support when lockdown restrictions eased. However, the use of the web-based platform to provide support was unsuccessful owing to issues with internet connectivity, the lack of equipment, and user competence. As such, the Mphatlalatsane Initiative implementation may have varied at the micro-, meso-, and macrolevels. To determine the Mphatlalatsane intervention dose at the microlevel, a scoring system is in development based on prior work [26]. The first 2 domains, exposure and intensity, relate to the QI adviser. *Exposure* is the number of interactions between the adviser and the QI team; *intensity* is the nature of the interaction between QI advisers and QI teams, for instance, face-to-face support to the team in reviewing their change ideas and offering technical advice during the support visit (high intensity) or a mobile call from the adviser to find out when the team will send their QI documentation (low intensity). The remaining 4 domains relate to the adopted change idea. Quantity is the number of adopted (ie, change ideas with quantifiable evidence that it improves care) change ideas; *reach* is the number of facility workers involved; *duration* is the implementation period in months; *scope* is the 5 Mphatlalatsane outcomes that have been targeted for the change ideas in terms of leadership, clinical care, health systems, patients' experience of care, and patients' health. For the period from September 2019 to December 31, 2021, retrospective data are collected by QI advisers for 4 domains: quantity, reach, duration, and scope (Multimedia Appendix 2). For the period from January 1 to December 31, 2022, all domains will be extracted from the adviser's routine reports (Multimedia Appendix 2). The scoring of each domain and assessment of the intervention dose are evolving and will be finalized once the data have been collected. It is envisaged that 2 members of the evaluation team will independently score each domain, and disagreements will be resolved by a third member.

Statistical Analysis

Objective 1

The institution maternal and perinatal mortality indicators will be calculated using DHIS data. Trend in iMMR, neonatal mortality rate, and stillbirth rates (with SE bars) during the pre- and postintervention periods will be disaggregated by intervention arms. RR and 95% CI will be calculated along with data on confounding variables, such as antenatal care coverage before 20 weeks, delivery at health facility access by tar road, deliveries of female participants aged <19 years, and deliveries of female participants aged ≥19 years (derived from total deliveries and deliveries of female participants aged <19 years). The trends in mortality and stillbirths will be compared before the COVID-19 pandemic (January 2019-March 2020) and during the COVID-19 pandemic (April 2020-March 2021) and in the context of the COVID-19 waves. The baseline period (2017-2018) will also be provided. Observed numbers and rates will be determined monthly and quarterly across all 9 provinces in the country and overall. To compare the Mphatlalatsane Initiative intervention and control arm trends in mortality, an interrupted time series regression model using Poisson regression model with Newey-West SEs to account for autocorrelation and possible heteroskedasticity will be used.

Objective 2

This study will use quantitative descriptive analyses and exploratory factor analysis to examine associations between sociodemographic characteristics, childbirth characteristics, and maternal participants' experience of health care quality and the health care facility during the antenatal to postpartum period.

Objective 3a and 3b

Quantitative data analysis will be conducted on demographic data as well as specific management elements offered to participants with hypertension in pregnancy and primary postpartum hemorrhage based on predetermined criteria [28]. Patients with normal pregnancies will be scored against the NDOH clinic checklist for booking and follow-up of patients without HIV [29]. A study nurse will allocate the score based on antenatal and intrapartum data abstracted from maternity records. The scoring system will be as follows: for any variable that is fully met, 1 unit will be awarded; if partially met, half of a unit will be awarded; whereas if absent, 0 will be awarded. If a patient is managed for more than one of the specific complications, each entity will be assessed separately. The criteria scores for each patient will be individualized. The level of care for each complication will then be assessed as follows:

$$\textit{Care score/Criteria score} \times 100 \quad \textbf{(1)}$$

and is similar to a prior study evaluating QI in neonatal services in KwaZulu-Natal, South Africa [30].

Objective 4

Assuming that attitudes will be complex, grounded theory will be used during this research to keep an open view. Instead of beginning with hypotheses about attitudes, a theory will be developed during the data collection. The interviews and FGDs will be analyzed with qualitative data analysis by using coding, concepts, and categories to develop a theory. The interviews and FDGs will be recorded and transcribed using Microsoft Word (Microsoft Corp). First, a South African Medical Research Council (SAMRC) and a University of Western Cape (UWC) staff member will read through all texts, look for patterns, and assign codes for these patterns. These codes will be assigned to all texts using a qualitative data analysis software program, Atlast.ti (version 8; ATLAS.ti Scientific Software Development GmbH). The SAMRC and UWC staff will then jointly describe these codes and develop categories from combinations of codes and triangulation of concurrent quantitative and qualitative data and then develop hypotheses based on relationships between these concepts, which will form the theoretical framework. The survey data will be imported into Excel, and descriptive analysis techniques will be used to analyze the data.

All quantitative data will be entered into an electronic format and stored in a web-based interface. The quantitative questionnaires will be analyzed using Stata (version 16; StataCorp) [31].

Ethics Approval

Overview

This study has been approved by the SAMRC Human Research Ethics Committee (EC019-11/2019). The proposal for objective

XSL•FO
RenderX

4 was approved by the UWC Biomedical Research Ethics Committee (BM19/10/16). All participants sign written informed consent or provide verbal consent when the participant is illiterate, with an independent witness present to confirm that the relevant information was understood by the participant.

Objectives 1 to 3

We inform all patients and staff about the evaluation and elicit written informed consent before all interviews, photographs, and data abstraction from the maternity registers and maternity records. Data are deidentified before photographs are taken, and the interview takes approximately 30 minutes with participant confidentiality maintained. Survey administration entails minimal risks to patients and health staff. The results are anonymous and kept confidential. Although participants may decline the interview, we obtained permission from the NDOH to access and analyze data from the DHIS from the relevant catchment areas of the Eastern Cape, Limpopo, and Mpumalanga. We also have approval from the National and Provincial Department of Health to access routine records and photograph maternity case records.

Objective 4

Recruitment of Participants: Interviews, FGDs, and Observations

Written informed consents are obtained from all the individuals who participate in the interviews, FGDs, and observations. A detailed explanation of the purpose and nature of the study is provided to all the participants verbally and in writing with the information sheet in English. For the digital survey, participants receive the same study information as for the other data collection components and provide a digital signature to prove their consent.

Voluntary participation and the right to withdraw from the study at any point is emphasized during this explanation. Participants can consider their participation and ask questions before signing the informed consent form. Data collection occurs at a time and place that is convenient for the participants to ensure that health care delivery is not disrupted. Although anonymity cannot be guaranteed in FGDs, participants are requested to treat the information discussed as confidential. Participants who complete the surveys using personal devices are reimbursed with a data voucher. The NDOH requested that the interview and FGD participants not be reimbursed, given that they participate in working hours.

Accessing Facility Service Data Used by the QI Teams

Permission to access these data has been obtained from the NDOH and the respective Provincial Departments of Health.

Results

Institutional Live Births, Maternal Deaths, Neonatal Deaths, and Stillbirths

Data from the DHIS in the Eastern Cape, Limpopo, and Mpumalanga revealed 1,093,372 live births during the pre–COVID-19 period from March 2019 to March 2020 versus 1,037,528 during the COVID-19 pandemic (April 2020-March 2021). There were 1024 maternal deaths reported from March 2019 to March 2020 versus 1315 maternal deaths during the COVID-19 pandemic. There was a small decline in neonatal deaths from 13,095 during the pre–COVID-19 period to 13,026 deaths during the COVID-19 pandemic. The number of stillbirths also decreased from 22,030 during the pre–COVID-19 period to 20,891 during the COVID-19 pandemic.

Maternal Satisfaction With Care

From October 27, 2021, to July 8, 2022, there were 3934 completed maternal interviews across 18 hospitals. In the maternal interviews, participants were largely satisfied with their antepartum care (3556/3841, 92.58%). Approximately 5.88% (226/3841) of the participants self-reported complicated deliveries.

Microlevel Contexts and Implementation Processes

In the preliminary analysis, although the COVID-19 pandemic severely disrupted the functioning of the QI teams, the pre–COVID-19 momentum was regained, with advisers providing mentoring and support and teams adapting the QI model.

Mesolevel (Subdistrict and District) Enabling Environments

Variation in adoption was related to stable and motivated leadership (particularly at the facility level) and buy-in from senior district managers (affected by competing priorities and a lack of integration into routine processes). Referral and specialist outreach systems, staff availability and development, and service delivery infrastructure also varied, which are plausible factors in variable outcomes.

Discussion

Overview

In our preliminary results, the routine mortality data on maternal and neonatal deaths and stillbirths reflected a mixed picture regarding maternal and perinatal care in South Africa before and during the COVID-19 pandemic. Across the intervention and control facilities, the participants were satisfied with the antepartum and intrapartum care received.

The increase in institutional maternal and neonatal deaths from the Eastern Cape, Limpopo, and Mpumalanga is consistent with prior evidence from Pattinson et al [4] and Pillay et al [32], who note that increased maternal and neonatal mortality was a direct effect of COVID-19–related deaths in pregnant women and an indirect effect of poor access to health services during the pandemic. This study reports on 3 provinces where the Mphatlalatsane Initiative was implemented versus the national reports from Pattinson et al [4] and Pillay et al [32]. Stillbirth rate appeared to remain relatively unchanged during the COVID-19 pandemic in these provinces. The major data limitation is the reliance on a single data source, the DHIS. Further analyses will stratify the catchment areas according to intervention and control facilities. The preliminary objective 4b data point to important contextual and implementation process differences across districts; for instance, a travel embargo in 1 district restricted the district management support

XSL•FO
RenderX

visits to the intervention facilities, which have been reported by other districts to be an important motivation for QI teams. We are also observing differences between facilities in the same district, for example, some leaders are more motivated to implement the intervention than others. Unpacking the contextual and implementation processes that are shaping the QI intervention may facilitate the understanding of the Mphatlalatsane Initiative outcomes.

Globally, health systems have faced unprecedented strain and uncertainty during the COVID-19 pandemic [33]. Policy makers and health care providers made rapid shifts in all aspects of the health system to mitigate the COVID-19 risk [33] and accommodated the growing COVID-19–related morbidity and mortality. These changes included performing remote patient consultations [34]; repurposing wards and hospitals for COVID-19 [34]; and developing innovations, including vaccines [35], to counter the COVID-19 risk.

Several authors have suggested ways in which QI might be applied during the pandemic; for instance, rapid learning collaboratives, which are the most successful interventions when changes are occurring concurrently [36]. QI could enhance the health system, provide a methodology for systematic change, and improve learning [37,38].

When a swift response to changing circumstances is required, rapid learning cycles, such as through the PDSA structure, can enable teams to adapt quickly with minimal risk and interruption to clinical work. Having a mechanism to try, and refine, ideas and ensuring that they are plausible before implementing them can support teams in responding to challenges that have no known solution, as described by Fitzsimons [36].

This evaluation protocol aims to determine the effect of the Mphatlalatsane Initiative on maternal and perinatal health during the COVID-19 pandemic. A key strength of this evaluation is that the study is embedded within the public health system and implemented within routine structures, processes, and data and importantly within available human resources. Moreover, the QI initiative ran for approximately 6 months before the pandemic arose in March 2020 in South Africa. Thus, it is possible to evaluate how various exposures, including the COVID-19 pandemic and the Mphatlalatsane Initiative, affected maternal and perinatal care in the intervention districts. In particular, the evaluation will consider the COVID-19 burden of disease in intervention and control districts and the heterogeneity in maternal and perinatal care during and between COVID-19 waves. As the Mphatlalatsane intervention broadened from the QI methodology to supporting MNH health services during the COVID-19 pandemic [16], we cannot discount the effect of the pandemic when evaluating the causality between the Mphatlalatsane intervention and MNH outcomes. Moreover, the process evaluation will capture the nuanced changes that were occurring as the Mphatlalatsane Initiative was evolving and the iterative way the intervention was delivered with changes responsive to health system requirements (adaptive *function*).

Limitations

This study has some limitations. As mortality data are extracted from the DHIS, which contains summary-level data on maternal and neonatal deaths and stillbirths, we cannot account for missing or incomplete data. A further limitation is that the QI intervention dose was not equally applied across facilities in the chosen districts, as the pandemic interrupted QI training and support structures that were necessary to implement the intervention. Although the evaluation team will strive to measure the intervention dose in a structured manner, the complex manner in which the intervention adapted to the requirements of the health system, particularly during the COVID-19 pandemic, may mean that only a few dimensions of the intervention dose may be captured in the analysis [26]. Moreover, the QI advisers collected intervention dose data both retrospectively and prospectively, which limits interpretation. There were also several Mphatlalatsane staff changes during the implementation period, which further limited the collection of the intervention dose data. Furthermore, data on policy and change at the macro- and mesolevels may not be able to draw narrow causal relationships between the Mphatlalatsane Initiative and outcomes at the facility (micro) level. However, qualitative data from the macro-, meso-, and microlevels may provide a more nuanced picture of the complexity of the Mphatlalatsane Initiative.

The results of the Mphatlalatsane evaluation will inform whether the Mphatlalatsane Initiative in the context of the COVID-19 pandemic is effective at improving maternal and neonatal mortality and stillbirth rate in a resource-limited setting. The results will inform strategies to mitigate the effects of the COVID-19 pandemic or similar emerging epidemics on maternal and neonatal mortality.

Acknowledgments

The authors are grateful to the key implementers responsible for the Mphatlalatsane Initiative for their advice, support, and collaboration on this project: Department of Health Republic of South Africa, University of Pretoria, Clinton Health Access Initiative, University of Limpopo, and the Institute for Healthcare Improvement. The authors also acknowledge the health care staff who should be applauded for their dedication and commitment to maintaining health care services during the COVID-19 pandemic and patients who participated in this evaluation for contributing their knowledge and data to this study. The evaluation was funded by the South African Medical Research Council (SAMRC) and The ELMA Philanthropies Services (U.S.) Inc.

Data Availability

The data sets generated and analyzed during this study are not publicly available because some data are owned by the South African National Department of Health but are available from the corresponding author on reasonable request.

Authors' Contributions

The evaluation team comprise of AG (South African Medical Research Council [SAMRC]) as the principal investigator, with TC (SAMRC) and HS (University of Western Cape [UWC]-SAMRC) as coprincipal investigators and YS (SAMRC), SM (UWC), WO (SAMRC), SM (SAMRC), and NA as coinvestigators. The protocol was jointly written by AG, TC, HS, WO, YS, and SM. AG and TC assumed responsibility for the overall evaluation and conduct of the study objectives 1 to 3 along with YS. HS and SM are responsible for conducting objective 4a. WO assumed responsibility for conducting objective 4b. AG, TC, HS, WO, YS, and SM conceived the study design. TC wrote the first draft of the manuscript. SM and NA performed the statistical analyses. All authors commented on the manuscript and contributed to all subsequent manuscript drafts.

Abstract

Background: Homelessness is a global burden, estimated to impact more than 100 million people worldwide. Individuals and families experiencing homelessness are more likely to have poorer physical and mental health than the general population. Administrative data is being increasingly used in homelessness research.

Objective: The objective of this study is to combine administrative health care data and social housing data to better understand the consequences and predictors associated with being homeless.

Methods: We will be linking health and social care administrative databases from Northern Ireland, United Kingdom. We will conduct descriptive analyses to examine trends in homelessness and investigate risk factors for key outcomes.

Results: The results of our analyses will be shared with stakeholders, reported at conferences and in academic journals, and summarized in policy briefing notes for policymakers.

Conclusions: This study will aim to identify predictors and consequences of homelessness in Northern Ireland using linked housing, health, and social care data. The findings of this study will examine trends and outcomes in this vulnerable population using routinely collected health and social care administrative data.

KEYWORDS

administrative data; data linkage; health care use; homelessness; housing; mortality

Introduction

Overview

Worldwide, it is estimated that more than 100 million people are homeless [1]. Determining an accurate picture of the scale and impact of homelessness is challenging given the diverse definitions of homelessness that are used within and between countries [2-5]. The United Nations Office of the High Commissioner for Human Rights proposed that "experiencing homelessness means not having stable, safe, and adequate housing, nor the means and ability of obtaining it" [6]. The European Typology of Homelessness and Housing Exclusion framework explicitly categorized the different elements of housing insecurity and defined homelessness as "living in a place of habitation (during the reference period) that is below a minimum adequacy standard; and lacking access to adequate housing" [7].

The state of experiencing homelessness results from a complex range of connected factors, including social and economic contexts and policies [8]; cyclical housing markets, during which renters experience rent inflation during the upswing and risk eviction during a downturn; and the availability and quality of housing [9]. Within a society, there are factors that predict which individuals are at greatest risk of becoming homeless. Experiences of physical abuse, foster care experiences, incarceration, suicide attempts, and psychiatric problems, especially drug use problems, have been reported to be associated with an increased risk of becoming homeless in a

XSL•FO
RenderX

systematic review and meta-analysis [10]. Taken together, the allocation of housing can be conceived as a complex queueing process that is stochastic on both the demand side (individuals in need of housing) and the supply side (when housing becomes available [11]).

The state of being homeless is important because people who experience it can be at increased risk of adverse outcomes compared to their peers who do not, especially those experiencing long-term and repeated homelessness [12,13]. Individuals who experience homelessness may have complex health care needs [14-18]. Homeless individuals are at greater risk of death, hospital admission related to substance use, and poor mental and physical health [14-16,19,20].

In the specific context of Northern Ireland, homelessness is a growing health and social issue [20-23], exacerbated by Northern Ireland's history of conflict [24] and the current cost of living crisis [25]. A recent study found that 18 people were observed to be sleeping rough in Northern Ireland's most recent survey in autumn 2020 [26], which was fewer than in previous years, likely due to service changes during the COVID-19 pandemic. The incidence of statutory homelessness in Northern Ireland cannot be easily compared to the rest of the United Kingdom because of the use of different definitions [7,27,28], but the Department for Communities reported 4306 households presenting as homeless between January and March 2021, of which 2717 were accepted as homeless (or threatened with homelessness), in priority need, and unintentionally homeless. The most common reason for homelessness (27%) was "accommodation not reasonable," and for three-quarters of these, the underlying reason was physical health, disability, or mental health [29]. Homelessness among young adults is a growing public health concern in Northern Ireland [30]. Current figures estimate that around 3824 young adults, male and female, aged between 18 and 25 years presented as homeless to the Northern Ireland Housing Executive (NIHE) between 2018 and 2019 [31]. Over the past decade in Northern Ireland, there has been interest in using children's social care data [21,31-33] to better understand the factors associated with young people becoming homeless. Social services may have a duty to accommodate children where they are without parents or if the parents cannot obtain long-term accommodation through a homeless application, for example, due to problems with their immigration status. There is limited information about how frequently children who experienced homelessness had repeated contact with child and family social services over time, through rereferrals, reregistration on the child protection register, and readmission to care rates, and how this is associated with deprivation and other child, family, and case characteristics.

People who experience homelessness are among the most deprived in society, may be underrepresented in government statistics, and are largely omitted from household surveys [23,24,34], making it difficult for researchers and policy makers to identify and address the needs of this vulnerable population group [23]. Administrative linkage data, once linked and appropriately analyzed, can be a useful source of insight to help policymakers with the consequences of homelessness and the policy interventions that might reduce harm and support health and well-being [35-37]. Information about the relationship between homelessness and health is limited in Northern Ireland [21-23,29,38]. Anonymized, linked health and social care (HSC) administrative data sets have considerable potential for measuring outcomes for individuals who are homeless. Linkage of data sets is powerful for conducting large-scale, longitudinal epidemiological research. Studies have also used emergency department (ED) administrative data to track trends and health inequalities and examined outcomes associated with being homelessness [39-41].

Linking homelessness records in Northern Ireland to HSC data sets and analyzing the data with epidemiological and reproducible modern data science methods will create knowledge with practical application in Northern Ireland, which will also be of interest to an international audience [32]. A careful study design is required to measure the effects of homelessness because of potential confounding between risk factors for and consequences of homelessness [42]. We aim to measure the scale of the issue of homelessness and its trends by place and over time, to understand what factors affect the risk of homelessness, and to understand the consequences of homelessness. This protocol describes our analysis plan to achieve this.

Research Aims and Objectives

The aim of this work is to provide information for policy makers, practitioners, and the public about the causes and consequences of homelessness in Northern Ireland using linked health care and administrative data.

To achieve this, we seek to do the following:

1. Measure the incidence, prevalence, and duration of homelessness over time and place, overall, and in subgroup analysis by the reason for homelessness.
2. Describe the characteristics of people who have been homeless, overall and in subgroup analysis by the reason for homelessness, compared to the Northern Ireland population.
3. Investigate the risk factors for becoming homeless, based on personal characteristics, the time period, geographical factors, health-related factors, and social factors (eg, being a looked-after child).
4. Investigate the association between homelessness and health and social outcomes, including physical and mental health, and the use of HSC services.

Methods

Study Design

The primary study design is a retrospective cohort study with nested matched cohort analysis. Homelessness will be defined as individuals registered as homeless with NIHE. Controls will be selected through propensity score matching [43] to the cases based on age, sex, geographical region, year and month of homelessness application, and a propensity score quantile from a multivariable logistic regression model. If assumptions are met, we will conduct a self-controlled case series study [44] as a sensitivity analysis.

XSL•FO
RenderX

Study Population

We will access and analyze national data from Northern Ireland (approximately 1.9 million people). Individuals in Northern Ireland HSC (equivalent to the National Health Services of the rest of the United Kingdom) have a health and care number (H&C number), which is a unique identifier that is used across HSC in Northern Ireland. We will include individuals who were alive, had an H&C number, and had been registered with a general practitioner in Northern Ireland since 2010.

Data Sources

The study will use administrative data obtained from several database sources, including the National Health Authority Information System (NHAIS), Electronic Prescribing Database (EPD), NIHE homelessness applications, patient administration system (PAS), ED information systems, Northern Ireland Maternity Information System (NIMATS), the Social Services Care Administrative and Records Environment (SOSCARE), and Pillar 1 and Pillar 2 COVID-19 data sets. The NHAIS contains information on all patients registered with a primary care physician. Northern Ireland has a universal, tax-financed, free at the point of service health care system with almost 100% population registration. It includes a unique address identifier (unique property reference number; UPRN). A list of temporary accommodations for people experiencing homelessness was compiled from stakeholder organizations and will be used to assign a binary indicator of whether an individual was registered as resident in such accommodation and the date registered to that address. NHAIS receives regular updates on the date and cause of death from the general register's office. International Classification of Diseases, Tenth Revision (ICD-10) codes on death records derive from diagnoses recorded by the certifying the doctor on the death certificate. The PAS data set will be used to collate data relating to admitted patient care delivered by HSC hospitals in Northern Ireland, generated by the PASs within each hospital. These data are held centrally by the HSC Regional Data Warehouse. The SOSCARE data set will be used to collate data regarding information on children registered with social care services, including family support services, children in need services, and the child protection register. The PAS will be used to collate data on general hospital admissions and COVID-19 hospital admissions. The NIMATS data set will contain maternity care data on women and their children. The EPD data set contains detailed information on prescriptions issued in Northern Ireland. The Pillar 1 data sets are extracted from the laboratory information systems in Northern Ireland hospitals on a daily basis into a central repository in the HSC Regional Data Warehouse. It contains details of COVID-19 antigen tests carried out in each of the hospital laboratories, including those processed on behalf of primary care, social care, and community settings. Pillar 2 data processed by NHS Digital and extracted for Northern Ireland residents are sent to the Northern Ireland HSC Regional Data Warehouse. The NIHE data set will contain social housing data for information reasons for applying to be considered homeless, type of accommodation, and previous accommodation and assessment outcome. Table 1 lists the data sets for linkage and potential predictors of homelessness that will be analyzed.

Table 1. Data items or variables and data sources.

Data item	Data set
Patient characteristics and confounders	
Age	NHAIS[a]
Gender	NHAIS
Socioeconomic status	NHAIS
Underlying medical condition	EPD[b]
History of health care use (eg, general practitioner consultations and hospital admissions)	Admissions and discharge data set
Outcomes	
Maternity outcomes	NIMATS[c]
Hospital admission	Admissions and discharge data set
Emergency department	HBS[d]
Prescribed medications	EPD
Type of settlement (eg, private home, care home, or social housing)	NHAIS
Homeless applicant status	NIHE[e]
Homeless presenting reason	NIHE
History with social services	SOSCARE[f]
Cause of death	NHAIS
COVID-19–related death	NHAIS
Laboratory confirmed SARS-CoV-2 infection	Pillar 1 and Pillar 2
Secondary SARS-CoV-2 infection due to household transmission	Pillar 1 and Pillar 2

[a]NHAIS: National Health Authority Information System.

[b]EPD: Electronic Prescribing Database.

[c]NIMATS: Northern Ireland Maternity Information System.

[d]HBS: Honest Broker Service.

[e]NIHE: Northern Ireland Housing Executive.

[f]SOSCARE: Social Services Care Administrative and Records Environment.

Deidentification and Linkage

Linkage will be conducted by the Honest Broker Service (HBS). The personal data transfer to the Business Services Organisation (BSO) will be managed by separating the direct identifiers (name, date of birth, and address) from the rest of the data set at its source in NIHE and sending the 2 parts of the data sets to different teams in BSO for processing. A trusted third-party linkage team will only see the identifiers but never the individual attribute data. The researchers only see the attribute data but not the identifiers. A simple placeholder ID will be used to allow the information to be joined to other data sets without the use of the personal identifiers. The data processing steps are (1) NIHE will transfer a table of direct identifiers only to a "trusted third party" (the Family Practitioner Service; FPS) within the BSO, which is managerially separate and on separate computer networks from the HBS in the BSO. The FPS will aim to match the identifiers in the NIHE and NHAIS data sets (and thus to H&C numbers) using deterministic and fuzzy matching. (2) NIHE will send the main data set without identifiers (but with the placeholder ID) to the HBS. (3) The HBS will prepare all of the other data sets required for the project, assign a pseudonymous study ID to them, and upload the pseudonymized data to the secure research platform. (4) HBS will share with FPS a table (linkage key) that links all H&C numbers in Northern Ireland to the study ID. (5) FPS will join the NIHE identifier list with the matched H&C numbers to the junction table to assign a study ID. (6) Both HBS and FPS will destroy the pseudonymization key. (7) FPS will send a table of the study ID for each individual in the NIHE data set to HBS. (8) HBS will join the study ID from the NIHE to the homelessness data set using the placeholder identifier (eg, row number). The NIHE data set will then have a fully anonymized study ID that can be linked to all the other data sets in the project. HBS will upload the anonymized NIHE data to the secure research platform. The links between the tables will then rely on deterministic linkage. We will use the UPRN, time points, NIMATS, SOSCARE, and information about household size from the NIHE database to create groups of individuals who are associated together as households.

XSL•FO
RenderX

Study Outcomes

For this study, 2 analytic epidemiological studies will be conducted: (1) study 1 will analyze the risk factors for homelessness, while (2) study 2 will examine homelessness as a risk factor for health and health care-related outcomes.

Primary and Secondary Outcomes

In study 1, the primary outcome of interest will be statutory homelessness. For the purpose of propensity score matching, becoming homeless (ie, meeting the NIHE threshold for homeless in the housing data) in the quarterly time period will be dichotomized into a binary variable (true or false). We will explore whether residence in temporary accommodation should be combined in a composite indicator after exploratory data analysis. For the Cox regression analysis (described below), the time from the study start date to the first episode of homelessness in the NIHE data set will be used as the primary outcome. Secondary analyses will be conducted by the established reasons for homelessness.

In study 2, the primary outcome of interest will be death. Secondary outcomes will examine ED attendances, emergency hospital admissions, emergency hospital admissions with COVID-19, and COVID-19 vaccination. All will be measured as time from homelessness onset (of the person who experienced homelessness or their matched pair) to the event.

Statistical Methods

We will commence analysis by conducting descriptive analyses to visually inspect trends in homelessness, trends over time in demand, supply, waiting list size, and waiting times for social housing, and risk factors (hospitalizations and deaths), including by age group, sex, geographical location, and index base year. We will undertake univariable and multivariable logistic regression for the first episode of homelessness. This will be conducted in R using *glm(family = "binominal")*. We will use *glm.predict()* to produce propensity scores for matching. We will use the propensity score to match individuals who have experienced homelessness with controls who have not experienced homelessness. We will match 1:1 on propensity score, age, sex, geographic area, and pregnancy status. Matching will be conducted over quarterly time periods to assign controls who shared characteristics at the time of homelessness. This will be implemented in a loop or apply function in R. Matched variables will not be used as independent variables. We will also undertake 2 alternative analyses to support the primary analysis. First, we will use a Cox proportional hazards model to investigate the hazard ratio of homelessness on the outcomes (censoring at death). Second, if the assumptions can be met, we will conduct a self-controlled case series analysis, which will give an alternative approach to managing confounding, fitting a spline for age.

For study 2, a Cox proportional hazards model will be used, comparing the propensity-matched groups over time to the primary and secondary outcomes producing hazard ratios and 95% CIs.

All tests will be 2-tailed, and a $P<.05$ will be considered statistically significant. All analyses will be carried out using R-Studio. Statistical analysis code will be shared on GitHub alongside publications.

Data Storage and Management

The HBS will carry out the data linkage and offer a secure environment for researchers to access and analyze the pseudonymized individual-level data. The NIHE housing data set will be provided to the BSO family practitioner unit without the H&C number identifier. This unit will undertake deterministic and fuzzy matching according to their normal protocols to assign a H&C number. We will describe in our report the fraction of records that could not be assigned a H&C number. The H&C number will be used to link individuals' data, though it will be replaced with an anonymous study ID in the analysis data set. All data will be securely stored on the HBS systems, and access will be revoked at the end of the project. HBS will archive and later destroy data according to its disposal schedule.

Dissemination and Data Sharing

To enhance reporting transparency, this study will be reported in accordance with the guidelines for the Reporting of Studies Conducted Using Observational Routinely Collected Data (RECORD), which is an extension of the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement. The results from this work will be published as a full-length, peer-reviewed manuscript and presented at participant events and to a representative subgroup of key stakeholders from the homeless sector in Northern Ireland.

Dissemination Plan

Our findings will be presented at national and international conferences and submitted for peer-reviewed publication to inform policy, practice, and research about the causes and consequences of homelessness.

Ethical Considerations

Ethical approval was granted by Queen's University governance and HBS. This study was approved by the National Research Ethics Service (Integrated Research Application System project ID 299887, Research Ethics Committees reference 22/SC/0065). The study was also approved by the HBS governance board (project 073). Data access agreements between the NIHE and the HSC BSO were established to manage the transfer and privacy-preserving deidentification and linkage of data. The research team will not have access to human participant information that can directly identify participants (eg, name, identifier, date of birth, or small geographic-level data). Informed consent was not required for this project. The research team will follow the statistical disclosure policy of the HBS, guided by the statistical disclosure control handbook. All outputs will be checked by the HBS team before being released. The analysis of individual-level data takes place within a safe setting at HBS from which data cannot be removed. Any potentially disclosive findings (eg, cross-tabs with small cell counts that may allow participant identification) will not be permitted to leave the safe setting.

XSL•FO
RenderX

Results

This project is the results of a partnership grant between the Administrative Data Research Northern Ireland (ADR NI), HBS, and NIHE. The transdisciplinary, multi-institutional team brings wide-ranging technical and stakeholder management experience, as well as many years of health prevention and evidence-based public health policy knowledge. The results from this project will aim to identify predictors and consequences of homelessness in Northern Ireland for the first time using linked homelessness, social services, and health administrative data. The results of our analyses will be shared with stakeholders, reported at conferences and in academic journals, and summarized in policy briefing notes for policymakers. As of September 2023, initial data analysis is expected to commence on this project and continue until March 2026.

Discussion

Overview

Our planned study will analyze HSC administrative data to investigate the characteristics, exposures, and outcomes of people who experience homelessness. Research from the United Kingdom [45], Ireland [46], Scotland [47], and Canada [35] has elicited useful policy insights for those contexts at the time points at which they were conducted. Our work will add to the understanding of the relationship between homelessness and health, which is an important contemporary social justice concern [48].

The complex nature of homelessness and its interactions with health require a tailored study design to provide evidence about the direction of causality in associations. For example, ill health could conceivably lead to or result from experiencing homelessness. Our study design introduces a time component that will allow us to understand the order of events and an approach to controlling confounding that will allow us to separate the contribution to homelessness of many interrelated socioeconomic factors. People who reside in temporary accommodations may face challenges around crowding. The impacts of the pandemic on the incidence and prevalence of homelessness remain uncertain at the time of writing [49,50]. However, there is emerging global evidence of higher COVID-19 infection and death rates among individuals who experience homelessness [51-53].

Strengths of this study include the use of a large, whole-population cohort, which should have a relatively low risk of bias. We also have access to a range of routine, whole-population data sources. However, there are limitations to this study. First, our definition of homelessness is restricted to individuals registered as being homeless with the NIHE. This will not detect individuals who were homeless but did not seek housing from NIHE. We will explore the use of residence in temporary accommodations, but at this point in planning, we do not have evidence about the usefulness of this indicator, given that it would require individuals to update their health care registration address. Second, our study will be limited to the Northern Ireland health care context, and results may not be applicable to other settings. There is a risk of bias if individuals experiencing homelessness have a greater risk of health care records not containing their unique identifier.

Conclusion

The findings of this study will be useful for researchers and policymakers seeking to study trends and outcomes associated with being homeless within a Northern Ireland context and will also be applicable to other contexts. Our study will provide evidence that can inform policymakers and highlight the potential societal benefits from the safe use of deidentified administrative data.

Acknowledgments

Funding was provided by the Economic and Social Research Council (award ES/S00744X/1-2021).

Data Availability

The data sets generated during and/or analyzed during this study are not publicly available, due to being controlled by the HSC Regional Business Services Organisation (RBSO/BSO). Data is available from the Honest Broker Service within RBSO/BSO upon request.

Authors' Contributions

EM and DB wrote the manuscript and provided the data for Table 1. All authors reviewed the final manuscript.

Abstract

Background: The increasing prevalence of diabetes is placing important demands on the Chinese health care system. Providing self-management programs to the fast-growing number of people with diabetes presents an urgent need in rural primary care settings in China. Peer support has demonstrated effectiveness in improving self-management for individuals with diabetes in urban communities in China. A priority then becomes developing and evaluating a peer support program in primary care settings in rural communities of China and determining whether it is feasible and acceptable.

Objective: The aims of this study are (1) to evaluate the feasibility and acceptability of a peer support approach to type 2 diabetes self-management in rural primary care settings; (2) to identify enabler and facilitator factors likely to influence the peer support implementation; (3) to provide primary data and evidence for developing a version of the program suitable for a randomized controlled trial in rural primary care settings.

Methods: Three townships will be sampled from 3 different counties of Anhui province as the study setting. Participants will be recruited based on these counties' local primary care health record system. The peer supporters will be recruited from among the participants. The peer support program will be led by peer supporters who have completed 12 hours of training. It will be guided by primary care providers. The program will include biweekly meetings over 3 months with varied peer support contacts between meetings to encourage the implementation of diabetes self-management. Mixed methods will be used for evaluation. Qualitative methods will be used to collect information from health care system professionals, individuals with diabetes, and peer supporters. Quantitative methods will be used to collect baseline data and data at the end of the 3-month intervention regarding psychosocial factors and self-management practices.

Results: The results will include (1) quantitative baseline data that will characterize type 2 diabetes self-management practices of individuals with diabetes; (2) qualitative data that will identify enablers of and barriers to self-management practices for individuals with type 2 diabetes in rural communities; (3) both qualitative and quantitative evaluation data, after the 3-month intervention, to demonstrate the feasibility and acceptability of the peer support approach for individuals with type 2 diabetes.

Conclusions: Our findings will inform the design of a tailored intervention program to improve self-management among individuals with type 2 diabetes in rural primary care settings. If we find that the peer support approach is feasible and acceptable, we will develop a larger randomized controlled trial to evaluate effectiveness in multiple rural settings in the province.

Introduction

Background

Challenges of the Diabetes Situation in China

Diabetes is a growing public health challenge. Diabetes mellitus (DM) imposes a huge economic burden on national health care systems worldwide, including in China. The prevalence of diabetes among adults in China has reached 11.6%, comprising about 114 million people and making China the country with the largest number of individuals with diabetes in the world [1]. The prevalence of diabetes in rural areas increased from 8.2% in 2008 to 10.3% in 2010. Although the prevalence is still lower than in urban areas, the growth rate is higher than in urban areas [2]. Furthermore, two-thirds of Chinese adults with diabetes have complications, and only 20.3% exhibit satisfactory glycemic control [3]. To improve noncommunicable disease prevention and control in diseases including diabetes, the National Basic Public Health Service Program (NBPHSP) was launched as part of China's health care reform initiated in 2009. Subsidized by national and local government budgets, the NBPHSP is mainly implemented by community and township health service centers and health stations in urban areas and village clinics in rural areas [4]. Health management of patients with hypertension and diabetes is an integral and pivotal part of the NBPHSP. However, gaps still exist between guidance on modifiable risk factors and field implementation in primary health care settings. Patients with type 2 diabetes blood glucose and related risk behavior interventions have not been sufficiently studied in primary care settings [5]. Chronic illnesses are largely self-managed, with most of the care becoming the responsibility of patients and their families or others involved in the daily management of their illnesses.

Diabetes Self-Management

Early users of the term *self-management* included Thomas Creer et al [6] in a 1976 book on the rehabilitation of chronically ill children. Creer and colleagues said that "the term of self-management indicated that the patient was an active participant in treatment." Since that time, the term has been widely used, mainly in referring to chronic disease patient education programs. Self-management has been defined as referring to "whether one is engaging in a health promoting activity such as exercise or is living with a chronic disease such as asthma, he or she is responsible for day-to-day management." [7] Prominent approaches emphasize 3 sets of tasks: medical or behavior management, role management, and emotional management [8]. Additionally, 5 core self-management skills are commonly emphasized: problem-solving, decision-making, resource use, forming a patient–health care provider partnership, and taking action [9].

DM is a progressive and chronic condition lasting the remainder of the patient's life. It is widely recognized that self-management is the cornerstone of DM care and has the potential to prevent relevant complications and improve quality of life [10]. Accordingly, the success of the treatment for DM depends on the ability of the individual to successfully sustain effective self-management behaviors that include taking prescribed medications, following diet and exercise regimens, self-monitoring blood glucose, and emotionally coping with the rigors of living with diabetes [8]. The goals of diabetes self-management are to optimize metabolic control, prevent acute and chronic complications, and optimize quality of life while keeping costs acceptable. The management of type 2 DM (T2DM) has traditionally been provided by health care professionals who focus on medication and lifestyle changes that can improve glycemic control.

A meta-analysis of self-management programs in diabetes by Norris and colleagues [11] found that diabetes self-management education provided by health care professionals is effective for improving clinical outcomes and quality of life, at least in the short term, but that these benefits sharply decline only a few months after the intervention ends. Therefore, while essential, education is generally not sufficient for most patients to maintain these behaviors over a lifetime of diabetes. To avoid such declines in benefits, evidence indicates that interventions should include elements of social support from families, engagement of multidisciplinary health care professionals, and support from others with diabetes. It is useful for the person with T2DM to recruit allies in supporting self-management who understand the condition, other people with diabetes who can share experiences and tips, or professionals who encourage a collaborative relationship in which they offer advice and the individual chooses how best to use it based on their knowledge of their own body and condition [12].

Studies show that without sustained support, many adults will not succeed in managing their condition well, leading to worse health outcomes including expensive hospitalizations and avoidable complications [13]. Among all these approaches to ongoing follow-up, peer support for diabetes self-management has been considered a promising strategy to achieve sound long-term outcomes for diabetes patients.

Peer Support for Diabetes Self-Management

Peer support has been formally defined as "the provision of emotional, appraisal, and informational assistance by a created social network member who possesses experiential knowledge of a specific behavioral stressor and similar characteristics as the target population, to address a health-related issue of a potentially or actually stressed focal person" [13]. Peer support may reduce feelings of isolation and loneliness, provide information about access to health services or the benefits of behaviors that positively improve health and well-being, and encourage more positive health practices [14]. Peer support programs have been widely recognized as promising for facilitating self-management behaviors among individuals with T2DM. Evidence demonstrates that the self-management practices of patients with diabetes are influenced by their knowledge, attitude, self-efficacy, and the presence of a supportive interpersonal, community, and policy environment

XSL•FO
RenderX

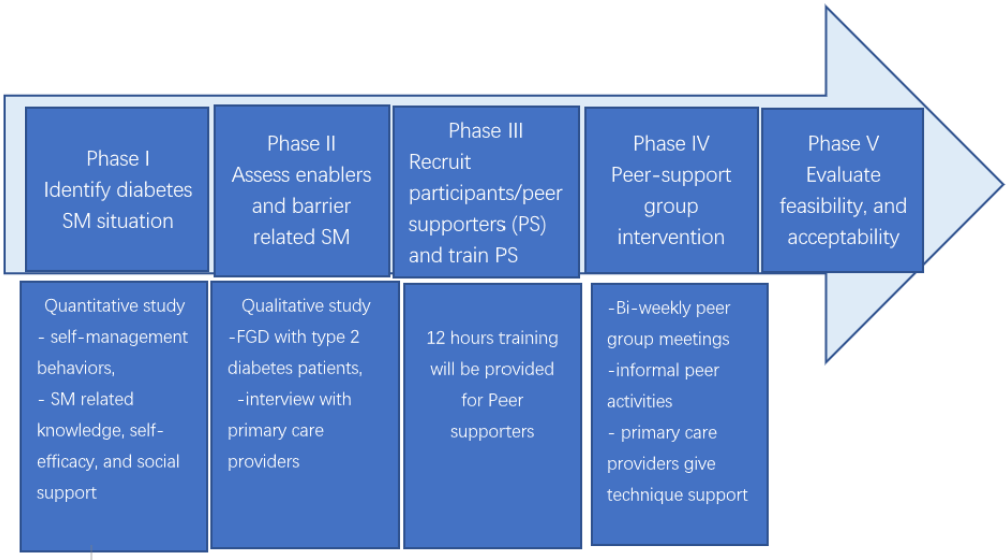
[15]. The peer support approach emphasizes bringing a group of people with the same condition together to share their self-management challenges and address them as a group rather than using a professional leader who may focus purely on education. Peer group sharing and learning increase knowledge, enhance self-efficacy, and change attitudes for self-management practice [16,17].

Diabetes Management in Primary Care Settings in China

Since the 1990s, China has initiated diabetes self-management education programs that have included nurse-based information delivery or clinic counseling targeting inpatients. Literature has shown those programs can improve patients' knowledge and adherence to medication after intensive short-term interventions [18]. However, the beneficial results could not be sustained in the long term because patients lacked self-efficacy, motivation, and ongoing follow-up support [19,20]. Health policy in China has led to diabetes care and management being delivered mainly in local primary care settings. However, it is difficult to provide personalized health management in rural primary-care settings due to the challenges of professional shortages and limited capacity relative to urban settings [21,22]. Moreover, rural populations often live in worse socioeconomic conditions and have lower health literacy. In rural settings, knowledge, adherence to management practices, and blood sugar control are far from meeting national goals [23,24]. Studies have shown, however, that friends, peers, family members, and community lay health workers may all be important supporters of self-management among individuals with diabetes, especially in areas with restricted health resources [25-27]. Additionally, peer support relies on nonhierarchical, reciprocal relationships, which provide a flexible supplement to formal health system services for people with diabetes. In addition, peer support fosters understanding and trust of health care staff among groups who otherwise may be alienated from or have poor access to health care [28,29]. Peer support implemented through primary care is gaining increased interest in urban China [25,30], while few programs exist in rural areas.

Given the needs in rural areas, and the benefits peer support approaches have achieved in urban settings, this project will explore and assess the feasibility and acceptability of peer support approaches in rural areas. We propose to develop community-based peer support for individuals with type 2 diabetes in rural areas in China. In particular, the study is designed to integrate a peer-support approach into local primary care settings. This study outcome will provide valuable information about the effectiveness, acceptability, and feasibility of a program to improve diabetes self-management in rural, resource-limited communities.

Study Purposes



Peer support is a culturally adapted, complex intervention; evaluating such an intervention presents challenges to researchers. This study will pursue the following objectives: (1) to evaluate the feasibility and acceptability of a peer support approach to type 2 diabetes self-management in rural primary care settings; (2) to identify enabler and facilitator factors likely to influence the peer support implementation; (3) to provide primary data and evidence for developing a version of the program suitable for a randomized controlled trial in a rural primary care setting.

Methods

Overview

This project will include formative evaluation to develop and then implement and evaluate a peer support approach to improve diabetes self-management in rural primary care. Figure 1 shows each phase in the study.

Figure 1. Study phases in detail.

Study Setting

This study will be conducted in rural communities in Anhui province. Anhui province is located in eastern China and has about 61 million people. It is divided into 3 geographic areas based on the Huai River and Changjiang River. The 3 areas are north of the Huai River, between the Huai River and Changjiang River, and south of the Changjiang River. These 3 different

XSL•FO
RenderX

areas have different customs, cultures, and dietary habits. Stratified sampling will identify 1 county in each of the northern, southern, and middle regions. One township will be randomly recruited in each county. Within each township, the village that has the largest number of adults with T2DM will be selected based on the electronic management system of the local primary care system. This will result in 3 villages representing 3 areas in Anhui province with high numbers of adults with T2DM.

Participant Recruiting

Study participants will be identified through the Community Chronic Disease Management System (CCDMS), which was established as a national primary care package program in communities in both urban and rural areas. Primary care providers (family doctors and public health physicians) in local primary care settings (township hospitals or village clinics) will contact eligible patients to explain the purpose of the study and details of the program. Since this is an exploratory study with a new intervention approach that has never been tested before in rural Anhui Province, no formal calculation of the sample size will be performed. All patients who are registered in the CCDMS in the sampled study setting (villages) and meet the inclusion criteria will be included if they are willing to participate. An estimated 15 to 20 patients will be recruited in each county, yielding a total sample of 45 to 60 participants. Based on the recommendations of Hertzog [31], a sample of 10 to 40 people is sufficient for a pilot study using a single group to estimate the sample size for a future trial.

Inclusion Criteria

The inclusion criteria are (1) having T2DM and being registered in the electronic CCDMS in the primary care settings (township hospitals and village clinics), (2) declaring voluntary participation in the study program with the signed informed consent form, and (3) having lived in the study village community at least 6 months.

Exclusion Criteria

The exclusion criteria include (1) major psychiatric conditions, (2) serious diabetes complications (eg, blindness) that would impede participation in the program, (3) other serious health conditions (eg, terminal cancer), and (4) current enrollment in other research programs.

Data Collection

Both qualitative and quantitative data will be collected in phases I and II, program development, and phase V, program evaluation. In each phase, there will be 2 stages: first, qualitative data will be collected and analyzed; second, quantitative data will be collected. Here, we describe the general methods of qualitative and quantitative data collection and analysis. The content of these assessments is described in detail in subsequent descriptions of the individual phases.

Qualitative Data Collection

Researchers will conduct 3 focus group discussions and interviews, with 1 focus group being devoted to each of the following roles: primary care professionals, recruited participants, and peer supporters. Each focus group (6-8 participants) will be led by 2 research team members with a third team member taking notes to be checked for accuracy against audiotapes of the group meetings. Content analyses will identify the common concepts across sites and across roles (patients, professionals, peer leaders). Similar methods will be used to evaluate implementation at the end of the study, also including interviews with patients, peer supporters, and primary care providers.

Quantitative Data Collection

The questionnaire will be developed by the research team. The questionnaire survey will be administered as face-to-face interviews for self-reported data by trained investigators.

Quantitative Data Analyses

Social demographic data and health status of the study subjects will be presented as frequencies (percentages) for categorical variables and means (SDs) for continuous variables. Comparison of patients' characteristics between the 3 settings will be checked by means of 2-tailed t tests, χ^2 tests, or nonparametric equivalents. In phase V, the evaluation will include an analysis of differences at 3 months compared to baseline in self-management practice, knowledge, self-efficacy, and perception of social support.

Ethics Approval and Informed Consent to Participate

The study was approved by the Biomedical Ethics Committee of Anhui Medical University (83220455) on October 13, 2022.

All participants are asked to provide informed consent by responding to the program survey. Participants are informed that consent includes their data being linked to primary care basic program electronic health records and agreeing to surveys and extraction of health record data at the end of the intervention during the evaluation in phase V without additional consent.

Each participant who attends the program will sign a consent form at the start of the intervention. Participants will be informed about the purpose of the study, about the course of the intervention, that it will be conducted in accordance with the study protocol, and that they are free to withdraw from the study at any time. All study data will be deidentified prior to analysis and presented only in anonymized forms.

Implementation Development

Phase I: Understanding the Current Situation of Diabetes Self-Management

Understanding the current situation regarding self-management practice and identifying factors that influence patients' self-management practice is crucial to developing the intervention program. A study questionnaire will be developed to collect patients' demographic data, current health status, and diabetes self-management practices. Psychosocial data will be collected by using validated measurement instruments (Table 1). Self-efficacy will be measured by the Chinese Diabetes Self-Efficacy Scale (C-DSES) [32]. Social support will be measured by the Medical Outcome Study Social Support Survey (MOS-SSS) [33], and self-management practices will be measured by the Summary of Diabetes Self-Care Activities (SDSCA) [34].

XSL•FO
RenderX

Table 1. Measurement domains and survey tools used at each data collection time point.

Variables	Quantitative measurement instruments	Baseline	3 months
Demographic and health status	Sex, age, ethnicity, education, marital status, occupation (ie, source of livelihood), co-habitants (ie, family members), length of diagnosis with diabetes, complications, and comorbidities	✓	
Psychosocial factors	CDSES[a], MOS-SSS[b]	✓	✓
Self-management practices	SDSCA[c]	✓	✓

[a]Chinese Diabetes Self-Efficacy Scale.

[b]Medical Outcome Study Social Support Survey.

[c]Summary of Diabetes Self-Care Activities.

Phase II: Identify Enablers and Barriers

Health programs and interventions most likely to be successful and achieve desired outcomes are based on a clear understanding of targeted health behaviors, the factors that influence them, and the environmental context in which they occur [13]. It is critical to thoroughly understand the local primary and chronic disease care delivered by family doctors or township public health professionals in rural communities and the factors that might influence the program implementation process. Meanwhile, it is also important to understand the current social network and support for the self-management of individuals with diabetes in the rural context. It is also necessary to know the characteristics of peer group meetings or activities (eg, frequency, duration, place, content, peer leader tasks) that individuals with diabetes, professionals, and peer leaders would find helpful and feasible. The research team will develop interview and focus group discussion guidelines to gather qualitative data regarding these issues. As described above, focus groups will include individuals with diabetes, professionals, and peer supporters. The results will guide development of real-world peer support intervention activities, contents, and delivery methods.

Phase III: Peer Supporter Recruitment and Peer Supporter Training

Peer supporters will be recruited by recommendations from both participating patients and village clinic doctors.

Inclusion Criteria

The inclusion criteria are as follows: (1) having been diagnosed with type 2 diabetes for ≥1 year; (2) commitment to attending a 12-hour training session at the beginning of the program; (3) commitment to organizing activities with other patients at least 2 times every month; (4) a basic education level, including reading and writing skills; (5) having supportive, nonjudgmental communication skills; (6) willingness to lead group meetings and activities; and (7) willingness to cooperate with primary care providers, including willingness to follow guidelines for when to let primary care providers know about problems participants may be having.

Peer Supporter Training

Recruited peer supporters will receive 12 hours of training. Training content will include the following: (1) an introduction to the peer support intervention program in terms of purpose, contents, group activities, and peer leader roles; (2) basic knowledge and skills in diabetes self-management practices; (3) basic health communication skills; (4) the key functions of peer support promoted by Peers for Progress [28], including assisting and encouraging daily diabetes management, providing social and emotional support, linking with community resources and primary care, and providing ongoing support; and (5) guidelines and rehearsal of when and how to seek support from primary care providers regarding participant concerns or problems that are outside their competence.

A peer supporter handbook that includes training materials will be developed for use with training participants.

Because the implementation of peer support needs to be supported within its organizational setting, primary care providers will also receive training related to program implementation, their role in encouraging participation in peer support, and how they can support the peer supporters.

Phase IV: Peer Supporter–Led Group Meetings and Activities

Participants will be divided into groups with 6 to 10 people and assigned to peer leaders for 3 months based on how close they live to the peer leaders. Groups will be encouraged to take part in biweekly (ie, every second week) group activities with peer supporters. Peer group members will also be encouraged to organize weekly casual activities such as phone calls, WeChat voice messages, physical exercise groups, and group member family visits.

The biweekly meeting content will be based on findings from phase II and adapted and developed together with primary care providers and peer supporters. The peer group sessions will aim to achieve the following key self-management practice objectives: increasing physical activity; promoting healthy eating habits; ceasing tobacco use; reducing alcohol consumption; adhering to medication; engaging in regular clinical care and diabetes management services provided in primary care settings, such as health education classes, blood sugar and blood pressure monitoring, and physical examinations; and coping with negative emotions.

Peer supporters will also be encouraged to contact participants in their groups between the formal group sessions in order to reinforce the program objectives, update on and discuss the content of missed sessions, and encourage goal attainment and attendance at the next peer group session. These contacts may be informal through meetings within their neighborhoods.

XSL•FO
RenderX

Phase V: Evaluation of Feasibility and Acceptability

The aim of this last phase is to evaluate the feasibility and acceptability of the peer support approach in rural primary care settings. Quantitative outcome variables will be measured at baseline and after 3 months to evaluate program feasibility. Qualitative assessments will evaluate the feasibility and acceptability of peer support implementation.

Quantitative Evaluation

Key evaluations will be the assessment of differences between baseline and after 3 months (after completion of the peer leader program) in terms of self-management practice, knowledge, self-efficacy, and perception of social support. Additionally, changes will be compared between villages through 2-tailed *t* tests or nonparametric equivalents.

Qualitative Evaluation

After 3 months, a descriptive parallel qualitative analysis will be carried out to evaluate the acceptability and feasibility of the program. Semistructured questionnaires and interview guides will be used to collect perceptions of the program from participants, peer supporters, and primary care providers. Questions will include barriers and benefits, individuals' experiences in the peer-led activities, and suggestions for future program revision and implementation. These will follow the methods for qualitative data collection from peer leaders, professionals, and participants and data analysis described above.

Focus group discussions of participants will be conducted to collect their perceptions, attitudes, experiences, and suggestions for improvement of the peer support program. The focus group discussion and interviews will be audio-recorded and transcribed.

The semistructured interviews with peer supporters will include their experience of the delivery of group interventions, as well as their experience of the process of receiving training and leading group activities. Peer supporters will be encouraged to discuss their feelings and sense of efficacy, the training experience, their motivations, and any positive or negative impacts on their own diabetes management.

Results

This study was funded in December 2021. Due to COVID-19 restrictions, the project implementation plan for activities in 2022 had to be delayed almost half a year. As of July 2022, we had developed and validated the survey questionnaires and completed interview guidelines. As of January 2023, focus group discussions with both primary care providers and individuals with diabetes had been completed.

Discussion

Anticipated Findings

The findings of this study will identify whether a peer support approach is an acceptable and feasible intervention in the rural primary care setting. It will provide evidence on whether the peer support program can enhance uptake, engagement, and maintenance of behaviors to reduce the risk of progression to diabetes. Findings from the study will provide invaluable information on required staff effort and key facilitators and barriers to implementing and sustaining this type of peer supporter–led group program. In addition, it will explore how the peer support self-management approach may be integrated into the NBPHSP in rural areas [4].

Generally, residents who live in the same village are familiar with each other and help each other. Group activities, such as playing mah-jongg and square dancing, are traditional in Chinese culture. This may enhance participation in the groups based on shared experiences and learning from each other. It may also contribute to participants' knowledge and self-efficacy for self-management through group sharing and activities [35].

There is an accumulating body of studies exploring feasible and acceptable diabetes self-management programs around the world, including those that use peer support. To our knowledge, however, no previous research has examined the feasibility, acceptability, and benefits of peer support for diabetes management in primary care settings in rural China. Thus, the results of this study will provide evidence and insights for developing a peer-led support program for diabetes self-management in this important setting.

We anticipate that the peer support approach for diabetes self-management will be adopted and accepted in rural China, and that participants in a peer supporter–led intervention will show improvement in psychosocial outcomes, adherence to health recommendations in the primary care setting, and better self-management practices. In addition, we hypothesize that the recruitment and training of volunteers with T2DM as peer supporters for participants with the same conditions will be integrated into current chronic disease management practices in primary care in rural areas. We expect that this qualitative research will reveal an in-depth perspective on the impact of this approach, both at the level of the patient as an individual and at the primary care setting level. Successful implementation of this study will provide evidence of the key functions of peer support. Moreover, the results of this study will influence future policies on diabetes management, as well as other chronic diseases in China.

Potential Limitations and Bias

This study has some limitations. First, outcome measures are primarily self-reported. Second, the study might be subject to selection bias since only voluntary and motivated patients will be included in our study. Third, the study design does not include a control group. The comparison of outcomes before and after the intervention may be biased by social desirability, as well as by other influences.

Impact and Future Directions

If the peer support approach is feasible and acceptable, we plan to develop the program further and test its effectiveness in a well-powered randomized controlled trial also focusing on the rural setting.

Acknowledgments

The project has been funded as part of the 2021 Anhui University's Humanities and Social Science Research Key Project (SK2021A0176) released on December 24, 2021. The project duration is 2 years, from 2022 to 2023. The funder had no influence on any part of the study, including, but not limited to, the writing of this protocol paper.

Data Availability

The data sets generated during and/or analyzed during this study will be made available from the corresponding author upon reasonable request.

Authors' Contributions

The principal investigator, XZ, conceived the proposal, obtained funding, contributed to the study design and manuscript writing, and approved the final draft. ML and XM participated in the literature review for proposal development and will be involved in data collection and analysis. SL participated in the study design and prepared the first manuscript draft. EBF provided advice for program design and implementation and assisted with manuscript revision. All authors reviewed this manuscript and approved the final version. All authors will participate in the implementation of the program.

Conflicts of Interest

None declared.

Protocol

Nudging Health Care Providers' Adoption of Clinical Decision Support: Protocol for the User-Centered Development of a Behavioral Economics–Inspired Electronic Health Record Tool

Abstract

Background: The improvements in care resulting from clinical decision support (CDS) have been significantly limited by consistently low health care provider adoption. Health care provider attitudes toward CDS, specifically psychological and behavioral barriers, are not typically addressed during any stage of CDS development, although they represent an important barrier to adoption. Emerging evidence has shown the surprising power of using insights from the field of behavioral economics to address psychological and behavioral barriers. *Nudges* are formal applications of behavioral economics, defined as positive reinforcement and indirect suggestions that have a nonforced effect on decision-making.

Objective: Our goal is to employ a user-centered design process to develop a CDS tool—the pulmonary embolism (PE) risk calculator—for PE risk stratification in the emergency department that incorporates a behavior theory–informed nudge to address identified behavioral barriers to use.

Methods: All study activities took place at a large academic health system in the New York City metropolitan area. Our study used a user-centered and behavior theory–based approach to achieve the following two aims: (1) use mixed methods to identify health care provider barriers to the use of an active CDS tool for PE risk stratification and (2) develop a new CDS tool—the PE risk calculator—that addresses behavioral barriers to health care providers' adoption of CDS by incorporating nudges into the user interface. These aims were guided by the revised Observational Research Behavioral Information Technology model. A total of 50 clinicians who used the original version of the tool were surveyed with a quantitative instrument that we developed based on a behavior theory framework—the Capability-Opportunity-Motivation-Behavior framework. A semistructured interview guide was developed based on the survey responses. Inductive methods were used to analyze interview session notes and audio recordings from 12 interviews. Revised versions of the tool were developed that incorporated nudges.

Results: Functional prototypes were developed by using Axure PRO (Axure Software Solutions) software and usability tested with end users in an iterative agile process (n=10). The tool was redesigned to address 4 identified major barriers to tool use; we included 2 nudges and a default. The 6-month pilot trial for the tool was launched on October 1, 2021.

Conclusions: Clinicians highlighted several important psychological and behavioral barriers to CDS use. Addressing these barriers, along with conducting traditional usability testing, facilitated the development of a tool with greater potential to transform clinical care. The tool will be tested in a prospective pilot trial.

Introduction

Background

US citizens receive only half of the recommended medical care [1], and one-third of the care received is unnecessary [2]. The disparity between usual and evidence-based clinical practice is the reason behind one-third of hospital deaths [3] and results in an estimated loss of US $380 billion each year [4]. Computerized clinical decision support (CDS) attempts to close this gap by bringing meaningful and relevant evidence to health care providers at the point of decision-making. Health care providers, policy makers, experts, and consumers have identified CDS tools as key tools for revolutionizing health care [5-7]. However, the moderate improvements in care resulting from CDS [8-14] have been significantly limited by consistently low health care provider adoption [15,16]. There is a critical need to identify strategies for increasing health care providers' adoption of CDS.

Health care provider attitudes toward CDS, specifically psychological and behavioral barriers, are not typically addressed during any stage of CDS development, although they represent an important barrier to adoption [17]. Psychological and behavioral barriers to use must be addressed along with traditional barriers to usability to improve adoption and, as a result, improve clinical impact. Our study's objective is to employ a user-centered design process to develop a CDS tool—the pulmonary embolism (PE) risk calculator (PERK)—for PE risk stratification in the emergency department that incorporates a behavior theory–informed nudge to address identified behavioral barriers to use.

PE Risk Stratification

The use of PE risk stratification tools in the emergency department setting can reduce unnecessary computed tomography (CT) scans [18,19]. The 2-tiered *Wells score for PE* clinical prediction rule classifies patients as those with a low or high probability of PE based on key elements of their histories and physical exams. This rule recommends the use of a laboratory value—the dimerized plasmin fragment D (D-dimer) assay—to rule out PE in low-risk patients. This eliminates the need for imaging in patients with a low probability of PE and a negative D-dimer assay result. The use of clinical prediction rules to assess pretest probability before performing a CT scan reduces testing by 25%, without any missed PEs [18,19]. This reduction in CT scan use is important, as each test carries a 14% risk of contrast-induced nephropathy [20] and a lifetime malignancy risk that can be as high as 2.76% [21]. Additionally, incidental findings requiring diagnostic follow-up are found in 24% of tests, increasing both the costs and the harms from repeat imaging [22].

Nudges and Behavioral Economics

The field of behavioral economics studies the effects of psychological, social, cognitive, and emotional factors on the economic decisions of individuals. This field is contributing to a growing body of research demonstrating the usefulness of addressing subtle attitudes, beliefs, and habits that result in individuals behaving irrationally [23,24]. In behavioral economics, nudges are used to influence behavior. *Nudges* are defined as positive reinforcement and indirect suggestions that have a nonforced effect on decision-making [25]. For example, the default options for organ donation consent result in striking differences in enrollment [26]. An example in health care is comparing health care providers to peers, which has been effective at reducing antibiotic prescribing for upper respiratory infections [27].

Nudges have been successful in influencing health care provider decision-making. There is a growing body of evidence demonstrating that health care provider decisions are also subject to variability resulting from psychological and emotional factors [28-30]. A recent meta-analysis found that direct education approaches did not result in sustained reductions in inappropriate antibiotic prescriptions [31]. However, a large randomized controlled trial found that a social comparison nudge decreased the rate of health care provider antibiotic prescribing for upper respiratory infections from 19.9% to 3.7% [27]. These results were durable at 3 months [32]. Integrating behavioral economics strategies into electronic health records (EHRs) by using CDS tools is a novel approach to improving guideline adherence that also seeks to minimize negative impacts on clinical workflows and cognitive loads.

The Observational Research Behavioral Information Technology Model for Behavioral Intervention Development

Our developmental work was guided by the revised Observational Research Behavioral Information Technology (ORBIT) model, which provides a tested framework for behavioral intervention development [33]. The model includes several phases with well-defined outcomes and milestones, culminating in the testing of the intervention in a large-scale effectiveness trial. The model features several bidirectional arrows, encouraging iterative development and refinement. The use of this model to support the development of behavioral interventions is key to ensuring that scientific developments contribute to the development of effective interventions. The work described herein details the development of our intervention (ie, Phase 1 Design).

Methods

Our study used a user-centered and behavior theory–based approach to achieve the following two aims: (1) use mixed methods to identify health care provider barriers to the use of an active CDS tool for PE risk stratification and (2) develop a new CDS tool—the PERK—that addresses behavioral barriers to health care providers' adoption of CDS by incorporating nudges into the user interface. These aims were guided by the revised ORBIT model.

Ethics Approval

All study activities took place at a large academic health system in the New York City metropolitan area and were approved by the Northwell Health Institutional Review Board (IRB# 18-0714).

Aim 1: Identification of Barriers to CDS Tool Adoption (Discovery)

Original CDS Tool for PE Risk Stratification

We previously developed a CDS tool for PE risk stratification in the emergency department, based on the Wells criteria for PE, that was found to be effective when used, with a 37% reduction in unnecessary CT scan use among adopters [34]. However, it was only used by 15% of health care providers. Low health care provider adoption significantly limited the impact of the tool on overall health care provider behavior. The original tool was active at 2 large academic emergency departments at the time of the development of the new tool, that is, emergency departments at the same institution where our study took place.

Additional details about the design, implementation, and evaluation of the original tool are available in a previous publication [34]. Briefly, emergency clinicians entering any electronic order for the diagnosis of PE (D-dimer testing, ventilation/perfusion scan, or CT scan) are routed to the tool if they answer "yes" to a dialog box asking "Are you considering PE?" The tool functions as an expanded order set that allows clinicians to formally calculate the pretest probability of PE, using the 3-tiered Wells criteria for PE. For low-risk patients, the tool only allows clinicians to order D-dimer laboratory testing, and for patients with an intermediate or high risk of PE, it allows for the ordering of D-dimer testing, ventilation/perfusion scans, or CT scans. At any time however, the tool can be dismissed by clinicians. The tool was developed by using adaptive principles of web and health information technology design, which are detailed in several previous publications [35-38].

Quantitative Assessment of Barriers to CDS Adoption

To determine the reasons for the low rate of health care provider adoption (15%), we surveyed 50 users (emergency department residents and attending physicians) of the original tool with a quantitative instrument that we developed based on the Capability-Opportunity-Motivation-Behavior (COM-B) behavior theory framework. The COM-B framework specifies that changing behavior requires changing capabilities, opportunities, and/or motivations (Figure 1) [39]. It divides *capability*, *opportunity*, and *motivation* into specific subcategories to allow for a detailed assessment of barriers in each category. These are further broken down into theoretical domain functions. The COM-B framework is intended to be comprehensive, parsimonious, and applicable to all behaviors, and it was developed based on existing theories of behavior at a US consensus meeting of behavioral theorists [39]. Our survey assessed the prevalence of 12 behavioral barriers. These 12 behavioral barriers were selected from the theoretical domain functions based on their relevancy to CDS use. Users identified 4 barriers as primary barriers to adoption; they were reported by greater than 70% (35/50) of participants. Almost all (91%, 45/50) of the users who reported low social opportunity also reported not having the intention to use the tool (Table 1).

Figure 1. The Capability-Opportunity-Motivation-Behavior model.

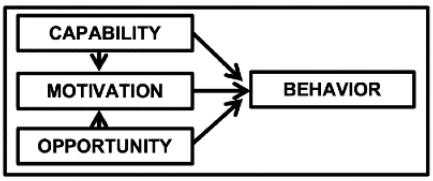

Table 1. Major barriers to clinical decision support tool use identified by the survey (N=50).

Example quotes	Capability-Opportunity-Motivation-Behavior domain	Respondents reporting the same barrier, n (%)
"my colleagues don't use the tool"	Low social opportunity (cultural norms)	35 (70)
"good doctors don't need the tool"	Low reflective motivation (professional identity)	39 (78)
"when I see the tool pop up I feel annoyed"	Low automatic motivation (emotion)	43 (86)
"the EMR has too many alerts to address"	Low psychological capability (attention)	45 (91)

Qualitative Assessment of Barriers to CDS Adoption

Based on the survey results and the COM-B framework, we developed a semistructured interview guide to further our understanding of behavioral barriers to tool use. Thematic saturation was reached after the 12th interview, with no new insights obtained by the 12th participant's interview. Inductive methods were used to analyze session notes and audio recordings, using the COM-B framework as a guiding theory. Interviews were conducted with 12 health care providers, (emergency department residents, attending physicians, and physician assistants). The interviews were 30 to 60 minutes long and were conducted by study personnel. Complete study methods and results are available in a previous publication [40].

The following six major barriers were identified: (1) *Bayesian reasoning*, (2) *fear of missing PEs*, (3) *time pressure/cognitive load*, (4) *gestalt includes the Wells criteria for PE*, (5) *missed risk factors*, and (6) *social pressure* (Table 2). Clinicians highlighted the belief that the tool was not useful to them because all elements of the Wells criteria for PE were

XSL•FO
RenderX

incorporated into their gestalt. The *fear of missing PEs* was another major theme. Clinicians felt worried about department quality improvement reviews or legal action. *Time pressure/cognitive load* was also highlighted as a major barrier to tool use. Although clinicians denied that cognitive loads kept them from using the tool, many clinicians spontaneously mentioned that they preferred the PE rule-out criteria due to their simplicity. The PE rule-out criteria are validated for use to rule out PE in low-risk patients if 8 criteria are not met [41].

Table 2. Major barriers to clinical decision support tool use refined by the semistructured interviews (n=12; adapted from *Barriers to the Use of Clinical Decision Support for the Evaluation of Pulmonary Embolism: Qualitative Interview Study* by Richardson et al [40]).

Theme	Quotes
Bayesian reasoning	"I don't think [pretest probability] matters for the CT scan.... I've been told if you order a CT, you'll either see it or you won't."
Fear of missing pulmonary embolisms	"…the environment with [quality improvement oversight] and the medical-legal situation, I might argue the threshold to test here is 0%."
Time pressure/cognitive load	"the biggest takeaway that you could take from interviewing ER providers is time, like that's the thing that matters most to us. Time and like ease of use."
Gestalt includes the Wells criteria for pulmonary embolism	"I never use [the clinical decision support tool], I have done the scoring in my head."
Missed risk factors	"my clinical gestalt has red flags for things that are not on Wells'....it doesn't have some of the younger woman risk factors like OCPs and smoking history"
Social pressure	"it does happen once in a while that I'll think this person, the patient, can get away with a D-dimer alone but the [physician assistant] or the learner wants to do a CT Scan, and I'm not averse to letting that go"

Additional themes included *Bayesian reasoning*, *missed risk factors*, and *social pressure*. The *Bayesian reasoning* theme reflected some clinicians not recalling that the posttest probability of PE would be impacted by the pretest probability of PE, which is predicted by the CDS tool, regardless of the results of the CT scan. The *missed risk factors* theme reflected clinicians' mistrust of the CDS tool, as the Wells criteria for PE do not explicitly include a few known risk factors for PE. The *social pressure* theme reflected many clinicians reporting that other members of the care team, including patients and their primary care physicians, could influence their decision to not use or not follow the recommendations of the tool.

Clinical Workflow Analysis

To discover clinical workflow barriers to CDS tool use that might not be provided by users during interview sessions, we shadowed 3 emergency department attending physicians for 1 to 2 hours each. The workflow analysis was adapted from the Agency for Healthcare Research and Quality recommendations on workflow assessments [42]. Direct observation sessions highlighted the significance of the barrier *time pressure/cognitive load* in the analysis of interview themes. All health care providers shadowed demonstrated high patient loads, task complexity, and task fragmentation. Health care providers juggled multiple complex patients simultaneously with constant interruptions. The clinical workflow steps were consistent with the reports that were detailed during the interviews for our study and the formative work for the development of the original tool. Health care providers typically reviewed the emergency department triage notes for patients' initial vitals and chief complaints. Afterward, they saw patients in their room to perform a history and physical examination. Finally, they placed orders in the EHR.

Aim 2: Develop a New CDS Tool—the PERK (Design—Phases 1A and 1B)

Development of Potential Nudges

Based on the survey results, semistructured interviews, and clinical workflow analysis, wireframes of 6 potential nudges were developed. Each potential nudge wireframe was designed to target an identified barrier to tool use and was informed by a COM-B category and subcategory (theoretical domain; Table 3). Wireframes are nonfunctional depictions of the user interface. Wireframes were reviewed and revised during a design thinking workshop and then developed into functional tool prototypes.

XSL•FO
RenderX

Table 3. Major barriers to clinical decision support use, Capability-Opportunity-Motivation-Behavior (COM-B) categories, theoretical domains, and potential nudges.

Barriers	COM-B categories	Theoretical domain	Potential nudge
Bayesian reasoning	Capabilities, psychological	Knowledge	Quiz addressing the false-positive rate of computed tomography scans for low-risk patients
Fear of missing pulmonary embolisms	Motivation, reflective	Beliefs about consequences	Text communicating the health system's support of tool use
Time pressure/cognitive load	Capabilities, psychological	Memory, attention, and decision processes	Estimated time to completion (12 seconds)
Gestalt includes the Wells criteria for pulmonary embolism	Motivation, reflective	Personal identity	Peer comparison (user compared to tool adopter)
Missed risk factors	Capabilities, psychological	Knowledge	List of conditions for showing when it is appropriate and inappropriate to use the tool
Social pressure	Opportunity, social	Social influences	Peer comparison (user compared to department mean)

Design Thinking Workshop

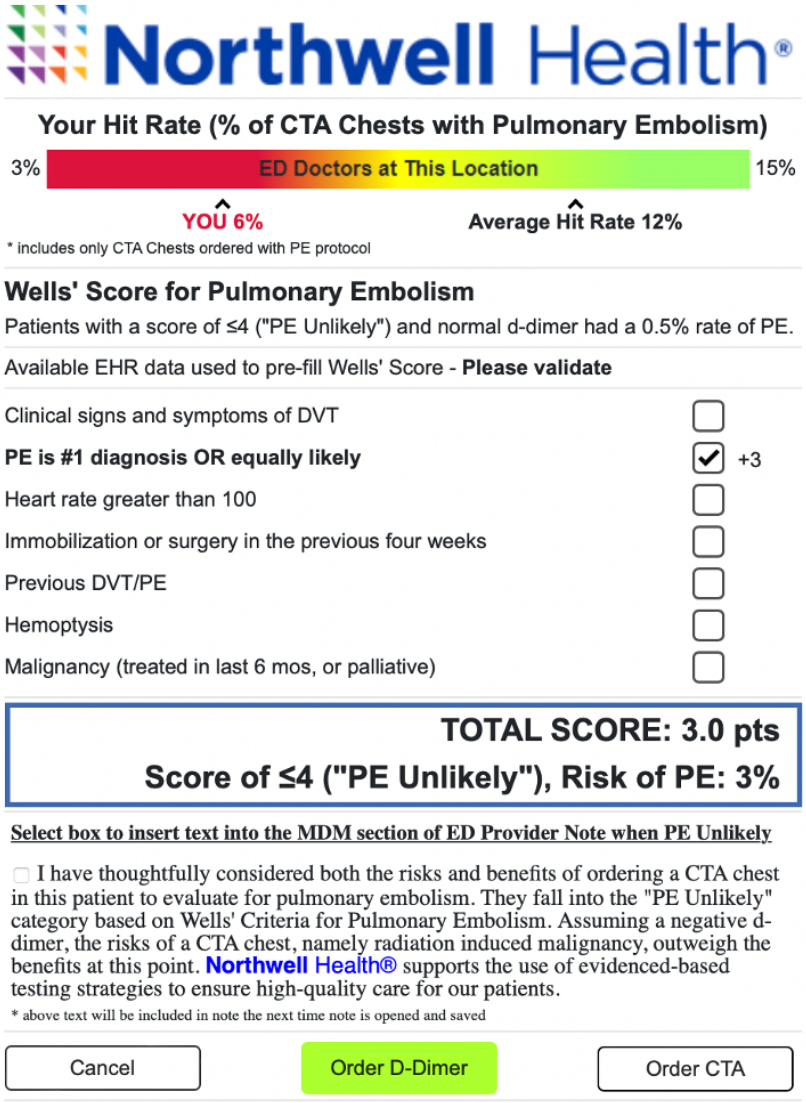
The results of the survey and semistructured interviews, the refined identified barriers to tool use, and the results of the workflow analysis were presented to several experts in health informatics, usability testing, behavioral science, and health services research and emergency department clinicians during a formal design thinking workshop. The session was guided by a user-centered design facilitation protocol that was used to lead the group through a presentation about behavioral economics concepts, CDS, and the emergency department clinical workflow before an idea generation exercise. Barriers were presented first, and participants were asked to create their own potential nudges for increasing health care provider adoption. Attendees worked in groups and submitted answers by using Post-it notes. Groups presented their ideas in a sharing and discussion session. Later wireframes of potential nudges were presented to the group for feedback. Insights from this workshop were used to further revise the potential nudges and build the tool prototypes.

Results

This section focuses on the initial testing of the decision support tool and how feedback from each phase of testing further influenced the content and design of the tool. The 6-month pilot trial for the tool was launched on October 1, 2021.

Usability Testing

CDS tool prototypes were built, using the prototype development software Axure RP 8 PRO (Axure Software Solutions). Think-aloud usability testing was conducted by using these prototypes with 6 health care providers (emergency department residents, attending physicians, and physician assistants). Prototypes are functional representations of the final user interface that mimic the full user experience. During think-aloud usability testing sessions, participants verbalized their thought processes while interacting with the tool prototype [43]. They were asked to complete the specific steps necessary for using the tool. They were given written clinical scenarios involving low-, intermediate-, or high-probability PE cases.



Following the usability testing sessions, the potential nudges were revised based on participant feedback. The layout, text, colors, and placement of each element of the CDS tool were all iteratively revised to facilitate ease of use and perceived usefulness. Several nudges were eliminated, and 2 were selected to be included in the final design. The nudge directed at the *Bayesian reasoning* barrier was eliminated based on feedback that health care providers would not take the time to respond to even a 1-question quiz during a patient care session. The nudge directed at the *fear of missing PEs* barrier was revised so that the language was clearer, more directed, and insertable into health care providers' notes. The nudge directed at the *time pressure/cognitive load* barrier was eliminated based on feedback that no estimated length of time for tool completion could be short enough to be perceived positively.

The nudge directed at the *gestalt includes the Wells criteria for PE* barrier was eliminated based on feedback from the health care providers that they did not see the relevance of comparing themselves to physicians outside of their department who might care for different patient populations. The nudge directed at *social pressure* was revised several times to address health care provider questions about how the data were calculated and to facilitate fast understanding. The final user interface was built to address the *fear of missing PEs*, *gestalt includes the Wells criteria for PE*, *time pressure/cognitive load*, and *social pressure* barriers. To address major concerns about *time pressure/cognitive load*, we developed an automated method for calculating the Wells criteria for PE, as well as a tool activation and suppression algorithm to reduce alert fatigue. A default was added to the user interface; recommended orders are highlighted in green, and 1 click is needed to proceed to ordering. Orders that are not recommended turn yellow if they are clicked once and are ordered if they are clicked a second time.

After iterative revision, the final PERK tool user interface was developed, as shown in Figure 2.

XSL•FO
RenderX

Figure 2. The pulmonary embolism risk calculator tool user interface.

Automatic Calculation of the Wells Criteria for PE

To address the major barrier *time pressure/cognitive load*, we designed an automated process by using data elements from the EHR and health information exchange to fill in information for each Wells criterion. A detailed description of the methodology for and results of the validation study are presented elsewhere [44]. Briefly, we used a combinatorial keyword search method to query free-text chief complaint and chief complaint quote fields for the criteria “clinical signs and symptoms of DVT” and “hemoptysis.” We used diagnoses listed in past medical histories for the “history of PE/DVT,” “malignancy,” and “immobilization or surgery in the previous 4 weeks” criteria. The presence of brief operative notes, including those regarding general anesthesia, was also used to identify patients who underwent recent surgery for the “immobilization or surgery in the previous 4 weeks” criterion. Vital signs taken during an encounter were used for the “heart rate greater than 100” criterion. All patients were given 3 points for the subjective criterion “an alternative diagnosis is less likely than PE” if a CT scan was ordered for the patients to evaluate for PE.

To validate the automated process, automatically calculated Wells scores were compared to those derived from a 2-clinician chart review. Patients classified as “PE likely” by the automated process (126/202, 62.4%) had a PE prevalence of 15.9% (20/126), whereas those classified as “PE unlikely” (76/202, 37.6%) had a PE prevalence of 7.9% (6/76). With respect to the classification of the patients as “PE likely,” the automated process achieved an accuracy of 92.1% when compared with the chart review. This methodology was used to automatically calculate patients’ Wells criteria for PE when the tool was triggered, as well as to prefill information for each criterion when the CDS was displayed to health care providers.

Tool Triggering and Suppression Algorithm

An algorithm was created to dictate the rules for triggering and suppressing the CDS tool. Our goals were to integrate the tool into the current clinical workflow for patients with suspected PE and to suppress the tool in cases where it was not likely to be helpful. The final rules for triggering and suppression were as follows. First, an assessment is triggered based on the placement of a “CTA Chest PE Protocol w/ IV Contrast” (CT scan) order. This assessment considers the automatically

XSL•FO
RenderX

calculated Wells criteria for PE and any orders that were placed for a D-dimer laboratory test during the patient encounter. Second, the tool is suppressed for patients with a Wells score >4 and/or if any order has been placed for a D-dimer laboratory test during the patient encounter. The tool is not suppressed for patients with a Wells score of 4 for whom a D-dimer test was not ordered.

Patients with a Wells score of >4 and/or a positive D-dimer test result are classified as "PE Likely" and should undergo a CT scan without interruption. Health care providers placing an order for a CT scan for patients with a Wells score 4 for whom a D-dimer test was not ordered are interrupted by the tool, as shown in Figure 1. The decision was made to suppress the tool for patients for whom a D-dimer test was not ordered, as opposed to suppressing the tool only for patients for whom the laboratory test was ordered and showed abnormal results, as the tool primarily attempts to prompt health care providers intending to order a CT scan for low-risk patients to instead place an order for a D-dimer test. If this has already been done and the health care provider has decided to not wait for the results or to place a CT scan for a low-risk patient with a normal D-dimer test result, then suggesting that they order a D-dimer test would not be likely to effectively influence their decision-making. Our goal was to minimize alert fatigue by increasing the efficiency of the tool.

Discussion

We describe the development of a CDS tool for PE risk stratification in the emergency department setting that incorporates behavior theory–informed nudges to address barriers to health care provider use. Behavioral barriers are not typically addressed during any stage of CDS development, although they represent an important barrier to adoption. We employed user-centered design principles and were guided by the ORBIT model, which advocates for an iterative development approach. Our developmental work included a mixed methods assessment of barriers to tool use and the frequent usability testing of functional prototypes. The COM-B behavioral framework guided the assessment of barriers to tool use. The final user interface included 2 nudges, in addition to a default, and addressed 4 of the 6 identified major barriers to tool use.

Our use of one of the tools of behavioral economics—nudges—is an innovative way to address common psychological, behavioral, and environmental barriers to CDS use. The development of the user interface of the PERK served as a key step and demonstrated that nudges can be incorporated into CDS. The next step is to establish the effectiveness of nudges in clinical practice. Such an evaluation is currently underway, with results expected in the coming months. If, as expected, we find that the adoption of the tool increases, we will conduct studies to evaluate which nudge works best, whom the nudges work best for, and when the nudges work best. These subsequent studies will be conducted by using the multiphase optimization strategy and will allow for the identification of the most effective intervention strategies [45]. This will pave the way for more tailored CDS tools.

There are several strengths and limitations to our approach. The strengths include the fact that the tool was designed for the emergency department clinical setting. The emergency department is one of the more difficult clinical settings to design CDS tools for, due to the high-pace, urgent, and fragmented nature of clinical care. The limitations include the single-center nature of our work. We included several types of emergency department health care providers from 2 hospitals in the same large academic medical center. Therefore, our results may not apply to other hospital systems.

Incorporating principles from behavioral economics into the development of CDS tools has shown increasing promise as a strategy for improving tool effectiveness while minimizing health care provider time and cognitive load burdens. Others have used principles of behavioral economics to influence health care provider behavior through asynchronous peer comparison emails, posters, and the grouping of treatment options [27,29,32,46]. Our work serves as a proof of principle for using this novel approach for CDS development.

Abstract

Background: Sexual and gender minority (SGM; ie, lesbian, gay, bisexual, transgender, and otherwise queer) young adults experience disparities in depression and other internalizing psychopathology. Although social media use is widespread and SGM people have more social media accounts and are more socially active on them than non-SGM individuals, few studies have examined the impact of social media on depression in this group.

Objective: The PRIDE iM study will be the first longitudinal, mixed methods research conducted to determine the impact of social media interactions and behaviors as pathways to depressive symptoms among SGM young adults living in the United States.

Methods: PRIDE iM uses a *bookends variation* of the longitudinal sequential mixed methods design. Participants will be recruited nationally from social media. First, between July 2019 and February 2020, we conducted a qualitative phase (T1) comprising web-based individual interviews (N=58) to inform the building and content of the quantitative survey. Second, from February 2022 to September 2022, we will conduct a series of web-based surveys (N=1000 at baseline) with 4 data points (T2-T5), each one collected every 6 to 8 weeks. Third, from October 2022 to December 2022, we will conduct a second qualitative phase (T6) of web-based interviews using outcome trajectories found in the longitudinal survey analyses to purposively sample survey participants and conduct web-based interviews to contextualize and explain survey findings. Qualitative data from T1 and T6 will be analyzed using a reflexive thematic analysis approach. As we sought to capture change over time in the association between the main predictors (ie, social media interactions and behaviors) and depressive symptoms, we propose analyzing T2 to T5 data using latent growth models with a structural equation modeling framework. Data integration at the method, interpretation, and reporting levels will be achieved through building and connecting and the use of a staged approach and joint displays, respectively. At all stages, we will assess the fit of data integration as recommended by the principles of best practice for mixed methods research in psychology.

XSL•FO
RenderX

Results: Data collection will be completed by December 2022. Qualitative data analyses will be completed by March 2023, and quantitative analyses of the primary outcome of interest will be completed by June 2023.

Conclusions: PRIDE iM will confirm, reject, or uncover the presence of potential relationships between social media interactions and behaviors and depressive symptoms among SGM people. This study represents fundamental groundwork to develop social media–based interventions that target modifiable interactions and behaviors that are most likely to influence mental health outcomes, thus seizing the opportunity to merge the popularity of this medium among SGM people with evidence-based approaches.

KEYWORDS

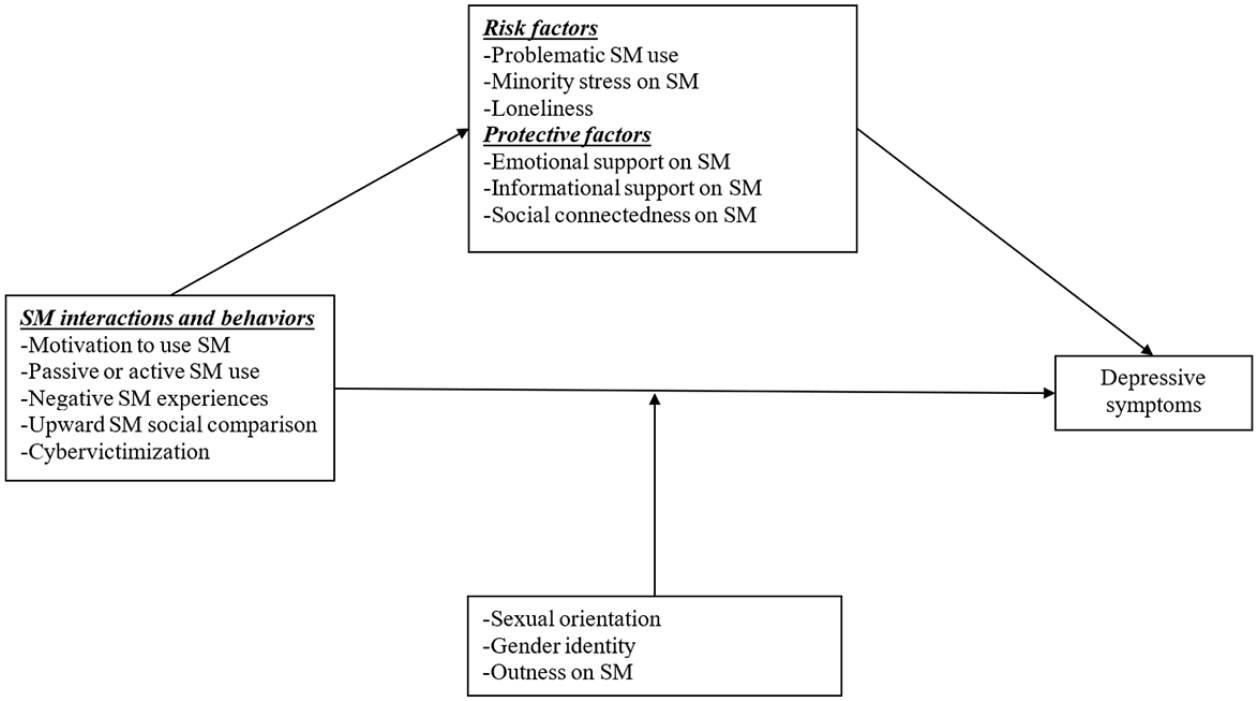
mixed methods; longitudinal; depression; sexual and gender minorities; social media

Introduction

Background

Sexual and gender minority (SGM; ie, lesbian, gay, bisexual, transgender, and otherwise queer [LGBTQ+]) young adults experience well-documented disparities in both internalizing [1,2] and externalizing psychopathology [3] compared with their cisgender heterosexual peers. These mental health disparities persist into adulthood and are present even among SGM people who identify as such late in their adolescence or young adulthood [4]. Minority stress theory [5] poses that, given the dominant culture, norms, and social structure, SGM people are likely subjects of an incongruence between information provided by society on how the world works and the minority person's experience of the world, determining stress processes that may worsen depression. Minority stress is the prevalent framework used to explain disparities seen in depression among SGM people; expansions of it have been developed for specific conditions such as substance use [6], cardiovascular disease [7], suicidal thoughts and behavior [1] and certain SGM groups such as adolescents [8,9] and transgender persons [10-13].

Social media encompasses a variety of websites and mobile apps (eg, TikTok, Snapchat, and WhatsApp) that enable users to create and share content and participate in web-based social networking [14]. Over 90% of adults in the United States have at least one social media account, which they use for an average of 2 to 4 hours daily, with YouTube, Facebook, and Instagram among the most popular platforms, and people aged 18 to 30 years being the group with the most sustained use growth among adults [15]. In addition, the affordances of social media (eg, asynchronicity, absence of physical cues, permanence of interactions, quantifiability via likes, and upvotes) have deeply changed the way in which people socialize, connect with others, build relationships, and seek and receive support and information [16,17].



On average, SGM people are more socially active on social media and more likely to have multiple social media accounts than non-SGM individuals [18-20]. Moreover, SGM persons seek and engage with more web-based support chats than their non-SGM peers [21]; seek web-based support resources to help them navigate challenging settings where both racial and sexual minority stigma might be salient [22,23]; and use social media to connect with others like them, increase their sense of belonging, and increase emotional well-being [24]. Despite these positive experiences, negative social media interactions also give way to social comparison, stigmatization, cybervictimization, and other forms of discrimination, which in turn might influence depressive symptoms [25,26] and other psychopathology [27,28].

Current Research Gaps

Although there is qualitative evidence available from SGM people indicating the salience of social media interactions to them [23,26], few studies have been conducted to determine the impact of social media interactions on mental health outcomes among SGM individuals, mostly among college students [29]. Moreover, the available studies follow the recent literature trend of focusing on determining the effect of the amount of time spent on social media (eg, time elapsed while using social media, number of checks per unit of time, and number of platforms used) on mental health. In the general population, the former approach showed mixed findings of positive [30,31], bidirectional [32], or no association [33] between quantity of social media use and mental health outcomes over time. These conflicting findings are indicators that we need a new approach that focuses on studying the factors that matter to SGM social media users, including the types of interactions and behaviors on social media platforms and their impacts on mental health. This is relevant as it is during these experiences on social media that SGM persons might encounter some of the minority stressors or protective factors [5,8]. On the basis of minority stress and our preliminary work [25], we propose a mediation model (Figure 1) in which the relationship between specific social media interactions and behaviors and depressive symptoms is mediated by both protective and risk factors (eg, emotional support experienced on social media). An additional issue that arises is that quantitative results alone are inadequate to describe and fully explain SGM young adults' social media behaviors and interactions or their effect on their mental health. Therefore, a mixed methods approach has the potential to unveil stressors and protective factors uniquely shaped by the affordances of social media, which may influence mental health outcomes in ways that could be different from similar offline interactions and behaviors.

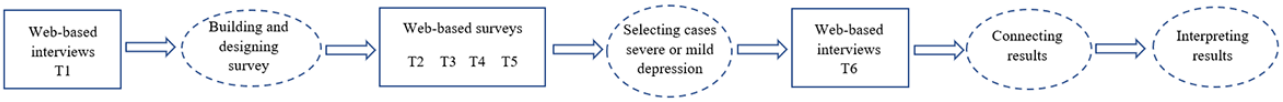
Figure 1. Model depicting risk and protective factors in the pathways of characteristics of social media interactions and behaviors and depressive symptoms among sexual and gender minority young adults. SM: social media.

Study Objectives



The PRIDE iM study will be the first longitudinal, mixed methods research conducted to determine the impact of several forms of social media interaction and behavior on the pathways of depression and other mental health outcomes among SGM young adults living in the United States (Multimedia Appendix 1). To address critical methodological factors needed to ensure a high-quality longitudinal study with SGM people, the main characteristics of PRIDE iM include (1) recruitment via social media to reach members of an often-marginalized group who are users of the technology under study, (2) recruitment of young adults aged 18 to 30 years as this age group recently experienced the most sustained growth in social media users, (3) presurvey qualitative assessments to identify relevant SGM-specific social media interactions and behaviors and add them to the survey, (4) repeated measures of potentially critical risk and protective interactions and behaviors on and off social media, (5) postsurvey qualitative assessments with survey participants to contextualize the trajectory of depressive symptoms, and (6) a mixing analysis phase to identify similarities and differences across groups. Upon completion, the PRIDE iM study will provide critical data in terms of intervention targets, such as reducing the occurrence or impact of risk factors (eg, upward social comparison) or boosting protective factors (eg, social connectedness) for depression and other negative mental health outcomes among SGM people—a high-need, underserved, and hardly reached population.

Methods

Study Design

Given the longitudinal nature of our study, we leveraged a multistage mixed methods framework in which we combined both exploratory and explanatory approaches [34]. PRIDE iM uses a *bookends variation* of the longitudinal sequential mixed methods design [35], which is a combination of prospective and retrospective studies. In this design, we gather qualitative data in the form of individual interviews at both the beginning (T1) and the end (T6) of the study and collect quantitative data in the form of 4 longitudinal web-based surveys (T2, T3, T4, and T5) at nonconcurring times with the collection of qualitative data. Figure 2 provides an overview of the study design, including timing of data points for both quantitative and qualitative data strains as well as for analyses, data mixing, and interpretation of results. Throughout this paper, we use T1 to T6 to designate each point of data collection.

Figure 2. PRIDE iM study design. T: time.

The design that we chose was appropriate for 3 reasons. First, we used a qualitative phase (T1) comprising web-based individual interviews to inform the building and content of the quantitative survey. Although the existing literature provided a list of potentially relevant risk and protective forms of social media interactions and behaviors for depression among the general population [36,37], we focused on social media experiences involving minority stress that are unique to SGM persons and that might help explain depressive symptoms among this group. We decided to conduct individual interviews, and

XSL•FO
RenderX

this was appropriate to balance a need for an in-depth understanding of the impact of social media experiences on mental health with the need to protect individuals' privacy and sensitive information. Second, we used a longitudinal web-based survey study with 4 data points (T2-T5), each one collected every 6 to 8 weeks. We sought to capture change in the association between the main predictors (ie, social media interactions and behaviors) and outcome variables (ie, depressive symptoms) over time. Using these 4 data points, our analyses will be able to identify trajectories of depressive symptoms over time. Third, given the limitation of quantitative data to fully explain the change in social phenomena over time, we will conduct a second qualitative phase of web-based interviews (T6). We will use the outcome trajectories identified in the T2 to T5 quantitative analyses and form groups based on these trajectories for conducting web-based interviews with SGM persons who participated in the survey in each of these groups. We will use the interviews to contextualize trajectories found in survey analyses and then conduct a comparative analysis of qualitative findings by groups identified in the survey (eg, respondents with severe vs mild depressive symptoms) to describe similarities and differences between said groups.

Ethics Approval

All recruitment and data collection procedures were approved by the University of Pittsburgh Institutional Review Board (study 19050007; approval June 20, 2019). We sought and obtained informed consent from potential participants before completing any of the research activities (web-based interviews or web-based surveys) of the study. Given that PRIDE iM study participants can be located anywhere in the United States and as the study posed minimal risk for participants, we obtained a waiver for documenting consent. We included all the standard components in the web-based informed consent forms, including study goals and description and estimated time required to complete the activity. Participants receive web-based gift cards in compensation for their time taking part in each of the research activities. We collected no identifiable information other than participant email addresses, phone numbers, and IP addresses (which were collected automatically by the web-based survey platform). This was necessary to schedule participation in the web-based interviews and to send gift cards to the participants after completing a research activity. Given the inclusion of sensitive topics and questions in both the interview and survey, we inform participants that they can choose to stop taking part at any time if they feel uncomfortable. In the web-based surveys, if the participant answers affirmatively to any of the suicide-related questions, a pop-up screen appears where we provide the contact information of nationally available resources for both SGM people and persons with suicidal ideation. These same resources appear listed at the end of the survey, and we provide the name and contact information of the principal investigator for more personalized resources.

Recruitment and Data Collection Procedures

Sample Selection

We used a purposive sampling approach throughout the 3 phases of the PRIDE iM study. This was appropriate as purposeful sampling permits identifying and selecting study participants who experience firsthand the phenomenon under study, making this approach ideal for mixed methods research studies [38]. To recruit participants, we used targeted advertisements on social media, which have been previously used with success for the recruitment of SGM people to both cross-sectional and cohort studies [39,40]. This was appropriate for multiple reasons. As noted previously, SGM people are heavy social media users, and social media recruitment facilitates the enrollment of a diverse sample of SGM individuals, including those who have not disclosed their sexual orientation or gender identity, those who live in rural areas, and those who do not participate in community-based organizations that serve SGM persons [41]. Throughout the 3 phases of the study, individuals were eligible if they were aged 18 to 30 years; resided in the United States (as determined by zip codes); identified as LGBTQ+; and had at least one social media account and used it on at least a weekly basis.

First Series of Web-Based Interviews (T1)

Recruitment

The recruitment approach described previously was appropriate for the purpose of these interviews, which was to inform constructs and items for survey development through learning from the lived experience of SGM young adults who use social media and whether and how this use affected their mental health and well-being. In this way, the qualitative data strain served the purpose of integration through *building*, in which the results of one data collection and analysis activity inform the data collection of the other research activity [34]. Recruitment took place between July 2019 and February 2020. To create our advertisements, we used the advertisement creation feature on Meta Ads Manager (Meta Platforms, Inc; which allows for cross-posting to Facebook and Instagram) and set advertisements to be shown solely to people living in the United States. At the time, the Facebook advertisement manager allowed for targeting specific audiences based on location, age, interests (including "Interest tags" specific to the LGBTQ+ community and LGBTQ+ topics), and activity. After seeing the advertisements, interested individuals clicked on "Learn more" and were redirected to a study website that provided more information about the study goals, expected involvement, information about compensation, and an anonymous link to an eligibility questionnaire housed on the Qualtrics survey platform (Qualtrics International, Inc). Eligible individuals were invited to provide their preferred method of contact (ie, phone number or email address) so that a research assistant could contact them to schedule a time and date for the interview.

A total of 72 hours before the web-based interview, potential participants were sent an email with a link to the web-based informed consent form for their preliminary review. We encouraged potential participants to read the informed consent form and reply to the email with any clarification questions they might have. The day before the interview, we sent a final email with the link to the web-based conference platform where the interview would take place. At the date and time agreed upon for the interview, potential participants clicked on the link provided; this link took them to the formal informed consent

XSL•FO
RenderX

form, and after providing consent, participants were admitted to the web-based conference room.

Data Collection

The web-based interviews were 60 minutes long. We used a Health Insurance Portability and Accountability Act–compliant platform [42]. To protect the individuals' privacy, only audio was recorded during each interview. The interviews explored motivations for using social media and perspectives on both positive and negative social media interactions as well as the perceived impact on mental health and well-being. After completing the interview, participants received US $50 gift cards in compensation for their time. The recordings were transcribed verbatim using a professional web-based service.

Web-Based Longitudinal Survey (T2-T5)

Recruitment and Initial Screening

Recruitment for the baseline assessment (T2) took place from February 2022 to March 2022 via targeted advertisements through Meta Ads Manager. However, as of January 2022, Meta updated its new audience targeting policy to protect the privacy of vulnerable populations [43]. The new policy eliminated the option of specifically targeting interests related to LGBTQ+ identities as well as religious or political interests. We chose an alternative option that consisted of creating a "custom audience" within the Meta Ads Manager tracking system to target future advertisements to a "lookalike audience." After publishing a set of advertisements, a custom audience is created using the first 1000 to 5000 users that click or tap on the ads. This custom audience is then used so that ads can be seen by people who previously interacted with content on Instagram and Facebook [44]. A "lookalike audience" comprises users who are similar to the custom audience that first interacted with the advertisement published on Instagram and Facebook [45]. Once this custom audience is created, future iterations of the advertisements are shown to new people who share similar characteristics (ie, "lookalike") with the custom audience.

In total, 7 copyright-free images that would appeal to a broad base of SGM persons were purchased from iStock by Getty Images for web-based advertisements. Images depicted same-sex or queer-gendered couples, a group of smiling young adults of various backgrounds and hairstyles, and a rainbow-colored heart light-emitting diode light without any humans. Figure 3 shows an example of one of the advertisements published on social media. After clicking on the advertisement, persons were directed to an institutional study website where they could find more detailed information that was beyond the character limit allowed on social media advertisements, including the goals of the study, eligibility criteria, expected commitment (ie, completing four 30-minute surveys over 7-8 months), and participant compensation. Those who remained interested were able to click on a link to an eligibility screening questionnaire housed on the Qualtrics survey platform. If eligible, potential participants were invited to provide informed consent so that they could gain immediate access to the full web-based baseline questionnaire.

After completing the baseline survey, participants were asked to provide their email address for payment, their phone number, and their preference for a contact methodology (eg, email, phone call, or SMS text message). Email addresses were used to send web-based gift cards to all participants who completed at least half of the baseline questionnaire as well as reminders for follow-up surveys.

Figure 3. Example of one of the PRIDE iM social media recruitment advertisements. LGBTQ+: lesbian, gay, bisexual, transgender, and queer.

Participant Retention Strategies for Follow-up Surveys (T3-T5)

Given both the web-based nature and the longitudinal design of this study phase, reducing participant attrition was a major concern. A recent meta-analysis found that using a mix of retention strategies delivered via the internet improved participant retention rates in longitudinal cohort studies [46]. First, we sought to reduce barriers to participation by prioritizing survey measures hypothesized to have an association with the primary outcome of interest (ie, depression) according to the existing literature and our conceptual model (Figure 1) and

XSL•FO
RenderX

allowing for extended data collection windows (up to 1 week) for each wave. Second, to build a community around the study and our research program, we created a study brand (PRIDE iM study) and a logo, website, and social media presence on 3 social media platforms (Twitter, Instagram, and Facebook). Social media accounts and websites were created 6 to 12 months before the formal study started and were used to update our followers about ongoing research conducted by our team and others on the topic of use of communication technologies and LGBTQ+ mental health. Third, we used a variety of reminders and follow-up strategies, including bimonthly e-newsletters (sent using Mailchimp [Rocket Science Group], a web-based platform and email service that allows for managing mailing lists) in between periods of data collection, email reminders sent 72 hours before the next follow-up survey, SMS text message reminders (only in cases of participants who authorized being sent SMS text messages), and incentives of increasing value over time (gift cards of US $10 for T2, US $15 for T3, US $20 for T4, and US $25 for T5). Finally, toward the end of each data collection period, we sent targeted emails or SMS text message reminders (according to each person's preference) to participants whose responses we still had not received.

Eligibility Determination for Follow-up Surveys (T3-T5)

Preventing and detecting fraud in web-based survey studies with participants recruited from social media is an ongoing challenge among researchers [47]. Fraudulent surveys include duplicate responses from the same participant using different email addresses, providing response patterns, or reaccessing the survey with false responses after being deemed ineligible in the first attempt. To minimize these risks, we implemented a series of combined red flags based on previous literature [39,40,48,49] and our own team's experience. Once data collection for the baseline (T2) survey was completed, we downloaded all the data from Qualtrics. A team of research assistants not involved in data analysis or interpretation created variables representing aspects related to survey participation that could be useful to identify fraudulent responses, such as geographic location (including approximate latitude and longitude), IP address, start and end date and time, survey completion and time duration for completion, attention-control questions [50], phone number, and email address. We used 3 criteria to determine fraudulent responses (Textbox 1).

Textbox 1. Criteria to determine fraudulent survey responses.

1. Location outside the United States according to *one* of the following:
   - Location data from Mailchimp (Rocket Science Group)
   - Latitude and longitude data from Qualtrics (Qualtrics International, Inc)
2. More than 1 response per IP address:
   - If only 2 responses, keep both if they did not meet criterion 1
   - If >2 responses, keep the first 2 if none of the responses met the previous criterion 1; if any of the responses meet criterion 1, remove all of them
   - Responses that started or ended <3 minutes apart (in these cases, only the first response was retained as part of the data)
3. More than 1 response per either email address or phone number (in these cases, only the first response was retained as part of the data)

Responses that met any of the criteria listed in Textbox 1 were removed from the baseline data; those participants did not receive compensation and were no longer contacted for the follow-up surveys. In addition, some baseline participants completed the survey but provided low-quality data, either because their completion time was <6 minutes or because they completed less than two-thirds of the survey. In these cases, participants were compensated for the baseline survey but were no longer contacted for follow-up surveys, and their responses were removed from the data.

Data Collection for Follow-up Surveys (T3-T5)

Eligible participants were sent email invitations and reminders for T3 to T5 surveys starting in early April 2022 (1 week after we completed baseline data collection). Follow-up surveys were hosted on Qualtrics, and responses were collected for 30 days during May 2022 (T3), July 2022 (T4), and September 2022 (T5). On the first day of each month, we sent an email to each participant with a unique link to the survey. To protect individuals' right to timely information about the study, we sought reconsent from all participants before allowing access to every follow-up survey. To maintain rapport and participants' interest in the study, we sent 1 e-newsletter during the month in between data collection (mid-April, mid-June, and mid-August) and 1 reminder 3 days before sending the survey links. Finally, we sent target emails or SMS text message reminders (depending on their preference for receiving direct communication) to the participants who had not yet completed the follow-up survey 1 week before the end of each data collection period.

Survey Measures

The baseline (T2) and follow-up (T3-T5) surveys incorporated different sections in which we administered the measures outlined in Textbox 2 based on our conceptual model (Figure 1).

XSL•FO
RenderX

Textbox 2. Measures administered during the baseline (T2) and follow-up (T3-T5) surveys.

Primary outcome of the study

- We seek to determine changes in depressive symptoms, which have been consistently described in the literature as disproportionately more prevalent among sexual and gender minority (SGM) individuals. *Depressive symptoms were assessed* using the 9-item Patient Health Questionnaire [51]. In addition, we assessed other mental health problems that have been consistently found to be more prevalent among SGM people, including *generalized anxiety disorder symptoms*, measured using the Generalized Anxiety Disorder-7 [52]; *sleep disturbance symptoms*, measured using the 4-item Patient-Reported Outcomes Measurement Information System (PROMIS) [53]; *suicide ideation in the past month*, measured using a subscale of the Columbia Suicide Severity Rating Scale [54]; *eating disorder symptoms*, measured using the Sick, Control, One, Fat, Food screening questionnaire [55,56]; *cigarette smoking*, measured using 2 modified items from the Behavioral Risk Factor Surveillance System questionnaire [57]; *alcohol use in past month*, measured using a modified version of a 1-item screener by Smith et al [58]; and *marijuana use in the past month*, measured using an item modified from the Youth Risk Behavior Survey [59].

Primary predictor

- Given that the focal interest of this study is determining the influence of social media behaviors and interactions on mental health symptoms, our main predictors comprise a variety of individual characteristics, behaviors, and interactions that users may have while using social media, including *passive and active social media use* [60], *motivations for using social media* [29], *negative social media experiences* (measured using a 4-item scale [25]), *upward social comparison on social media* (measured using a 2-item scale [61]), *cybervictimization on social media* (measured using an 8-item scale [62]), and *time elapsed during and frequency of social media usage* (measured using items previously developed by our team [63-65]).

Demographic variables

- We used the following items to determine study eligibility: *current location* (in or outside the United States); *age in years*(<18, 18-24, 24-29, and >30); *current sexual orientation*, measured using the item "Which of the following best describes your current sexual orientation?" (lesbian; gay; bisexual; pansexual; asexual; queer; same gender–loving; straight or heterosexual; and other, with a text box to type in) as recommended by the Sexual Minority Assessment Research Team group [57,66]; *sex assigned at birth*, measured using the question "What gender were you assigned at birth, on your original birth certificate?" (male or female); and *current gender identity*, measured using the item "Which best describes your current gender identity?" (woman, man, transgender woman, transgender man, and nonbinary or genderqueer) [57,67]. Both the current gender identity and current sexual orientation questions were also part of the attention-control questions and were asked twice (first in the eligibility screener and then in the demographics section). Other sexual identity questions included *sexual behavior*, measured using the item "In the last 5 years, who did you have sex with? By sex we mean any activity you personally define as sexual activity. Please mark all that apply" (*women, nontransgender*; *men, nontransgender*; *transgender women*; *transgender men*; *nonbinary/genderqueer*; and I have not had sex with anyone in the last 5 years) [57,66]; *sexual attraction*, measured using the question "Please indicate how sexually attracted you are to the following types of people" (*women, nontransgender*; *men, nontransgender*; *transgender women*; *transgender men*; and *nonbinary/genderqueer*) [68]; and *gender nonconformity*, measured using a 2-item scale that asked "A person's appearance, style, or dress may affect the way people think of them. On average, how do you think people would describe your appearance, style, or dress?" and "A person's mannerisms (such as the way they walk or talk) may affect the way people think of them. On average, how do you think people would describe your mannerisms?" Both items had responses on a 7-point Likert-type scale from "very feminine" to "very masculine" [69]. Other demographic variables included *current relationship status* (member of an unmarried couple, in a polyamorous relationship with more than 1 person, legally married or recognized civil union, and not currently in a relationship or a special commitment to someone) [57]; *current living situation*, which allowed for multiple choices (by myself; with a parent or guardian, significant other, spouse, child or children, friends, or roommate or acquaintance; or other, with a text box to type); *month and year of birth* (our team decided not to collect day of birth to preserve the privacy of study participants, crucial given the longitudinal nature of the study and the repeated contact with participants via email or SMS text messages); *race/ethnicity*, which allowed for multiple answers (American Indian or Alaskan Native; Asian or Asian American; Black or African American; Hispanic or Latina, Latino, or Latinx; Native Hawaiian or other Pacific Islander; White; or other, with a text box to type); *educational attainment* (never attended school or only attended kindergarten, grades 1 to 8, grades 9 to 11, grade 12 or general educational development, 1 to 3 years of college, college graduate, and graduate school [some or completed]); *household income* (US <$15,000, US $15,000 to <$25,000, US $25,000 to <$50,000, US $50,000 to <$75,000, US $75,000 to <$100,000, and US ≥$100,000); *current employment situation* (employed for wages; self-employed; out of work for ≥1 year; out of work for <1 year; homemaker; student; unable to work; and other, with a text box to type); *current zip code*; and *current state of residence*. Finally, the T5 survey included 1 item asking participants whether they would be willing to be recontacted within the subsequent three months for additional research opportunities *(yes or no)*.

Covariates

-

XSL•FO
RenderX

Covariates (protective and risk factors) were selected as they related to constructs included in minority stress [5], and whenever possible, we included modified items or measures to explore the same factors on social media. These included *outness in offline life*, measured using the question "In your everyday life (NOT on social media), are you out as an LGBTQ+ person to all, most, some, or to none of you're a) family, b) straight friends c) co-workers" and the options "all, most, some, none, do not know" [57,70]; *outness on social media*, measured using a modified item that asked "On the social media site/app you use the most to keep in touch with the people you care about, are you out as an LGBTQ+ person to all, most, some, or to none of your..." with the same categories of people and options as in the previous question; *emotional and informational support offline*, measured using the PROMIS 8-item scale for these constructs [71]; *emotional and informational support on social media*, measured using a modified version of the PROMIS 8-item scale [72]; *social connectedness offline*, measured using a 20-item scale [73]; *social connectedness on social media*, measured using a 20-item scale [74]; *adverse childhood experiences*, measured using the Adverse Childhood Experiences 10-item questionnaire [75]; *loneliness*, measured using the 3-item University of California, Los Angeles Loneliness Scale [76]; *social isolation*, measured using a PROMIS 4-item scale [77]; *problematic social media use*, measured using a 6-item scale [78]; and *minority stress experiences offline and on social media*, measured using 24 items modified from the Sexual Minority Adolescent Stress Inventory (SMASI) [8]. Although the original instrument includes 11 subscales to cover a wide array of discriminatory experiences, we selected items to cover experiences that would most likely match those of young adults both offline and on social media. These included the following SMASI subscales (and their respective items): negative expectancies (3 items), negative disclosure experiences (5 items), homonegative communications (5 items), intersectionality experiences (3 items), and social marginalization (8 items).

Additional measures

- Although not the principal focus of our study, later waves of data collection included additional scales to explore emerging topics in the literature related to objective measures of social media use and use of geospatial dating apps. These included instructions for participants to take screenshots of their screen time app, average use time, most used apps, number of check-ins, use of mobile dating apps in the past year and past 2 weeks, number of check-ins on these apps, time elapsed during use, motivation for using dating apps, success in using dating apps, belongingness scale, perceived thriving, and reasons for stopping the use of mobile dating apps.

Second Series of Web-Based Interviews (T6)

The primary goal of the second qualitative phase in the PRIDE iM study is to help describe, compare, and explain the quantitative results from the longitudinal survey conducted in T2 to T5. We will group survey participants according to their outcome trajectories (eg, severe or mild depressive symptoms). Next, we will use a purposive sampling approach [38] among outcome trajectory groups identified in T2 to T5 for interviewing select "case" participants and contextualizing trajectories found in survey analyses. For example, if we identify 2 trajectory groups—"severe" and "mild" depressive symptoms—we will recruit 20 participants from each group (n=40). This approach is appropriate when the study goals include explaining significant results, positive performing cases, outliers, or confusing results [79].

The "cases" will be identified once we complete the statistical analysis of the longitudinal relationship between social media experience and behaviors and depressive symptoms. Within 30 days of completing the T5 survey, a research assistant with access to the contact information of survey participants will link the participant ID number with the respective contact information. This team member will contact "case" survey participants via email or SMS text message and invite them to participate in a web-based interview with the purpose of reviewing and contextualizing their survey results to shed light on what (if anything) other than their experiences and behaviors on social media might have influenced the results. Interested individuals will be offered to schedule a date and time for the web-based interview. Preinterview reminder activities on the day of the interview, data collection procedures and software, and postinterview transcribing will mimic those already described for T1. We plan to start recruitment for T6 in November 2022.

Data Analysis Plan

Qualitative Analyses

Transcriptions will be entered into NVivo (version 12; QSR International) [80] for analysis. For both T1 and T6, we will analyze the data using reflexive thematic analysis with an experiential and realist framework [81-83]. This approach will allow us to describe and connect themes driven by the data collected from SGM participants, highlighting the specific meanings and perspectives from their lived experiences. Coding will be conducted using a hybrid inductive and deductive approach, which is appropriate given that our coding framework will partly derive from research on social media use and mental health among some groups of SGM young adults [25]. However, the paucity of research related to the impact of specific social media interactions and behaviors on depression among SGM persons requires describing concepts that are not clearly articulated in the empirical evidence available [84]. We will train independent coders and triangulate among the members of the study team to enhance trustworthiness [84].

Quantitative Analyses

We propose analyzing T2 to T5 data using latent growth models (LGMs) with a structural equation modeling (SEM) framework. LGMs in SEM are appropriate for our data as our assessments will measure the same construct at each data point, will have the same metric across time, and are tested at the same time intervals [85]. Crucial to our study, SEM allows for the use of latent variables or constructs in the models (eg, attitudes toward and beliefs about social media) as well as modeling mediating and moderating effects [86]. We will conduct descriptive analyses, including means, SDs, and bivariable associations between all variables included in the study. We will build SEM models at baseline and cross-sectionally and then, with each wave of longitudinal data, test whether baseline predictor characteristics are associated with depressive symptoms over the study period, as well as between- and within-person effects

XSL•FO
RenderX

[87]. We will examine model fit, including fit statistics such as standardized root mean square residual and comparative fit index, according to standard guidelines [88,89]. We will use Stata software (StataCorp) [90] for conducting these analyses and follow best-practice guidelines for reporting latent trajectory studies [91].

To estimate the sample size, guidelines for estimating power to detect mediated effects using the product of coefficients test suggest that, for power >0.8 with an α level of .05, a sample size of 100 is needed to detect medium effects, and a sample size of 500 is needed to detect small effects [92]. Thus, we proposed starting at T2 with 1000 participants and, with an overall attrition rate of 50% throughout T3, T4, and T5, we will have 500 participants who completed T2 to T5, which gives us power to detect small, mediated effects. For the longitudinal mediation using LGM, a sample size of approximately 200 is needed for power >0.8 to detect a medium effect size with 5 measurement occasions. As statistical power increases as the number of measurement occasions increases and we will have 4 measurement occasions, we expect adequate power for longitudinal mediation models [92,93]. Although an attrition of 50% is expected, previous studies on risk or protective factors and health outcomes have shown that this phenomenon did not significantly affect estimates of associations between variables or demographic differences between groups [94-96].

Integrative Analyses

Our mixed methods study integrates quantitative and qualitative strains of data at the design, method, and interpretation and reporting levels [34,97]. We addressed the integration at the design level in the previous sections. In this section, we will describe other levels of mixed methods data integration and analyses that we will conduct in PRIDE iM. We will achieve method integration through *building* and *connecting* [97].

First, qualitative data from T1 helped us *build* the T2 to T5 quantitative surveys in that we were able to identify important constructs and potential items that were included in the questionnaires. Next, we will *connect* the quantitative data collected during T2 to T5 with the qualitative data that will be collected in T6 through purposive sampling. To do this, we will use outcome trajectories (eg, depressive symptoms) found in structural equation models and form groups based on these trajectories for inviting potential participants to the web-based interviews in T6, with the goal of describing similarities and differences across groups and explaining these differences [79].

Finally, we will integrate our quantitative and qualitative data at the interpretation and reporting level using narrative manuscripts with a *staged approach* comprising separate manuscripts to report the results of each phase of the study. This is often the case with mixed methods studies such as PRIDE iM that have a multistage approach [34]. We will use *joint displays* to bring the data together and present new insights beyond those gained from the separate quantitative and qualitative results. At all stages, we will assess the fit of data integration as recommended by the principles of best practice for mixed methods research in psychology [98,99].

Results

Data collection will be completed by December 2022. Qualitative data analyses will be completed by March 2023, and quantitative analyses of the primary outcome of interest will be completed by June 2023.

Discussion

Principal Considerations

To our knowledge, PRIDE iM is the first national mixed methods study with a longitudinal quantitative phase (T2-T5) conducted in the United States to determine the relationship between a variety of social media interactions and behaviors and depression and other mental health problems that overburden SGM young adults. Moreover, our study is the first to adapt the minority stress model to explain the path by which social media interactions and behaviors may affect depressive symptoms among SGM young adults. Since the time when minority stress theory was initially developed [5], social media has disrupted most societal processes, from the way young adults make friends to the way they keep themselves informed and become involved with their communities, and this seems to be even more true for minoritized groups. The proposed study is appropriate, timely, and innovative in several aspects, from the social media–based recruitment (which allows for the participation of SGM persons who may not interface with offline recruitment venues and, thus, may be less likely to participate in research) to the study and survey design. Our study will dramatically expand on previous research [26] that focused on identifying that social media and other communication technologies influence resilience and coping among SGM youth. PRIDE iM results will provide important information about the impact of social media on mental health for researchers that seek to better understand health inequities among persons who are minoritized because of their sexual orientation, gender identity, and race or ethnicity and reduce those inequities via interventions.

Limitations

This study has limitations to consider. First, our recruitment through social media (ie, Instagram and Facebook) might represent a barrier to participation for SGM young adults who do not use these specific platforms. However, this is unlikely given that a large majority of young adults who use social media have an Instagram or Facebook account [15]. Second, our surveys assessed social media interactions and behaviors via self-report, which subjects these reports to recall bias related to experiences on social media. To reduce this, surveys were collected every 6 to 8 weeks, and all measures asked participants only about their social media experiences “over the last 30 days.” Nevertheless, future studies would benefit from more objective methods for collecting social media data related to individuals’ interactions and behaviors. Third, we used survey assessments that are quite comprehensive, which might discourage some participants from responding to all survey items or cause them to do so hastily. To remedy this, we implemented several forms of participant engagement (eg, progressively increasing incentives, building a community

XSL•FO
RenderX

around the study, and survey reminders) and data quality checks (eg, survey completion time, attention-control questions, and survey completion progress).

Conclusions

PRIDE iM builds upon minority stress theory, a foundational model used to understand mental health disparities among minoritized groups, and will contribute to our current understanding of how sociocultural factors influence SGM individuals' depression outcomes in a new media environment such as social media. Our study will confirm, reject, or uncover the presence of potential relationships between social media interactions and behaviors and depressive symptoms as well as temporality and direction. We will disseminate our findings via relevant academic journals and infographics on the PRIDE iM social media presence on Instagram, Twitter, and Facebook. This study will provide fundamental groundwork to develop social media–based interventions that target modifiable interactions and behaviors that are most likely to influence mental health outcomes, thus seizing the opportunity to merge the popularity of this medium among SGM people with an evidence-based approach.

Acknowledgments

The research conducted in this study is supported by the National Institutes of Health (grant R00 - MD012813). RWSC's participation was supported by the National Institutes of Health (grant K01 - AA027564). The funding source played no role in the study design; collection, analysis, and interpretation of the data; writing of the report; or decision to submit the paper for publication.

Data Availability

The data sets generated and analyzed during this study are not publicly available yet because of (1) the ongoing nature of the study and (2) preliminary and main outcome analyses being conducted at the time of publication of this protocol, but specific data sets might be available from the corresponding author upon reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: Echocardiography (ECHO) is a type of ultrasonographic procedure for examining the cardiac function and morphology, with functional parameters of the left ventricle (LV), such as the ejection fraction (EF) and global longitudinal strain (GLS), being important indicators. Estimation of LV-EF and LV-GLS is performed either manually or semiautomatically by cardiologists and requires a nonnegligible amount of time, while estimation accuracy depends on scan quality and the clinician's experience in ECHO, leading to considerable measurement variability.

Objective: The aim of this study is to externally validate the clinical performance of a trained artificial intelligence (AI)–based tool that automatically estimates LV-EF and LV-GLS from transthoracic ECHO scans and to produce preliminary evidence regarding its utility.

Methods: This is a prospective cohort study conducted in 2 phases. ECHO scans will be collected from 120 participants referred for ECHO examination based on routine clinical practice in the Hippokration General Hospital, Thessaloniki, Greece. During the first phase, 60 scans will be processed by 15 cardiologists of different experience levels and the AI-based tool to determine whether the latter is noninferior in LV-EF and LV-GLS estimation accuracy (primary outcomes) compared to cardiologists. Secondary outcomes include the time required for estimation and Bland-Altman plots and intraclass correlation coefficients to assess measurement reliability for both the AI and cardiologists. In the second phase, the rest of the scans will be examined by the same cardiologists with and without the AI-based tool to primarily evaluate whether the combination of the cardiologist and the tool is superior in terms of correctness of LV function diagnosis (normal or abnormal) to the cardiologist's routine examination practice, accounting for the cardiologist's level of ECHO experience. Secondary outcomes include time to diagnosis and the system usability scale score. Reference LV-EF and LV-GLS measurements and LV function diagnoses will be provided by a panel of 3 expert cardiologists.

Results: Recruitment started in September 2022, and data collection is ongoing. The results of the first phase are expected to be available by summer 2023, while the study will conclude in May 2024, with the end of the second phase.

Conclusions: This study will provide external evidence regarding the clinical performance and utility of the AI-based tool based on prospectively collected ECHO scans in the routine clinical setting, thus reflecting real-world clinical scenarios. The study protocol may be useful to investigators conducting similar research.

Introduction

Background

Echocardiography (ECHO) is a type of ultrasonographic scan used for examining the cardiac function and morphology [1]. Due to the practicality of image acquisition, relatively low cost, and little-to-no-risks for the patient, ECHO remains the most widely used cardiac imaging examination [2]. Of pivotal importance for patient evaluation is the assessment of the left ventricular (LV) systolic function [3], with recommended evaluation parameters being the ejection fraction (EF) and global longitudinal strain (GLS) [4]. EF is the percentage of blood ejected from the ventricle in each contraction, measured as the ratio of stroke volume (difference between end-diastolic and end-systolic volume) over the end-diastolic volume. GLS describes the myocardial deformation across the ventricular longitudinal axis, measured as the relative length change of the ventricular myocardium between end-diastole and end-systole.

Estimation of LV-EF and LV-GLS from ECHO scans is performed by cardiologists either manually or semiautomatically using a dedicated software [5]. One or more cardiac cycles and apical views of the LV can be used in the estimation of both parameters. Different apical views (typically 4-chamber, 2-chamber, and apical long axis views) are obtained by different placements of the ultrasound probe relative to the heart apex [1]. The estimation process is usually laborious and time-consuming, especially when considering medical emergencies, while accuracy depends on the cardiologist's experience in ECHO and the quality of scans [6], leading to considerable measurement variability [4,7]. Improving measurement precision and reliability is necessary, as it has been shown that EF and GLS values and their impairments are closely connected to patients' prognosis and course [8,9].

Deep learning [10], the most recent advancement in artificial intelligence (AI), has revolutionized computer vision over the past decade. Deep neural networks can be trained on annotated images without the need for feature engineering and perform fully automated image analysis. Inevitably, deep learning–based systems have been used in medical imaging, with a recent surge in applications for cardiovascular imaging [11]. Such advanced AI and associated software could support cardiologists of various levels of expertise in LV function assessment with the automatic and more accurate estimation of LV-EF and LV-GLS, and at the same time reduce the time of ECHO examination and the variability of measurements. In conjunction with point-of-care ultrasonography, such AI-based assistance may significantly improve relevant case management in demanding health care settings, such as emergency departments.

Objectives

This study aims at evaluating the clinical performance and producing preliminary evidence regarding the utility of a trained AI-based tool that automatically estimates LV-EF and LV-GLS from transthoracic ECHO scans. Two study phases are planned. The specific primary and secondary objectives of each study phase are listed in Textbox 1.

XSL•FO
RenderX

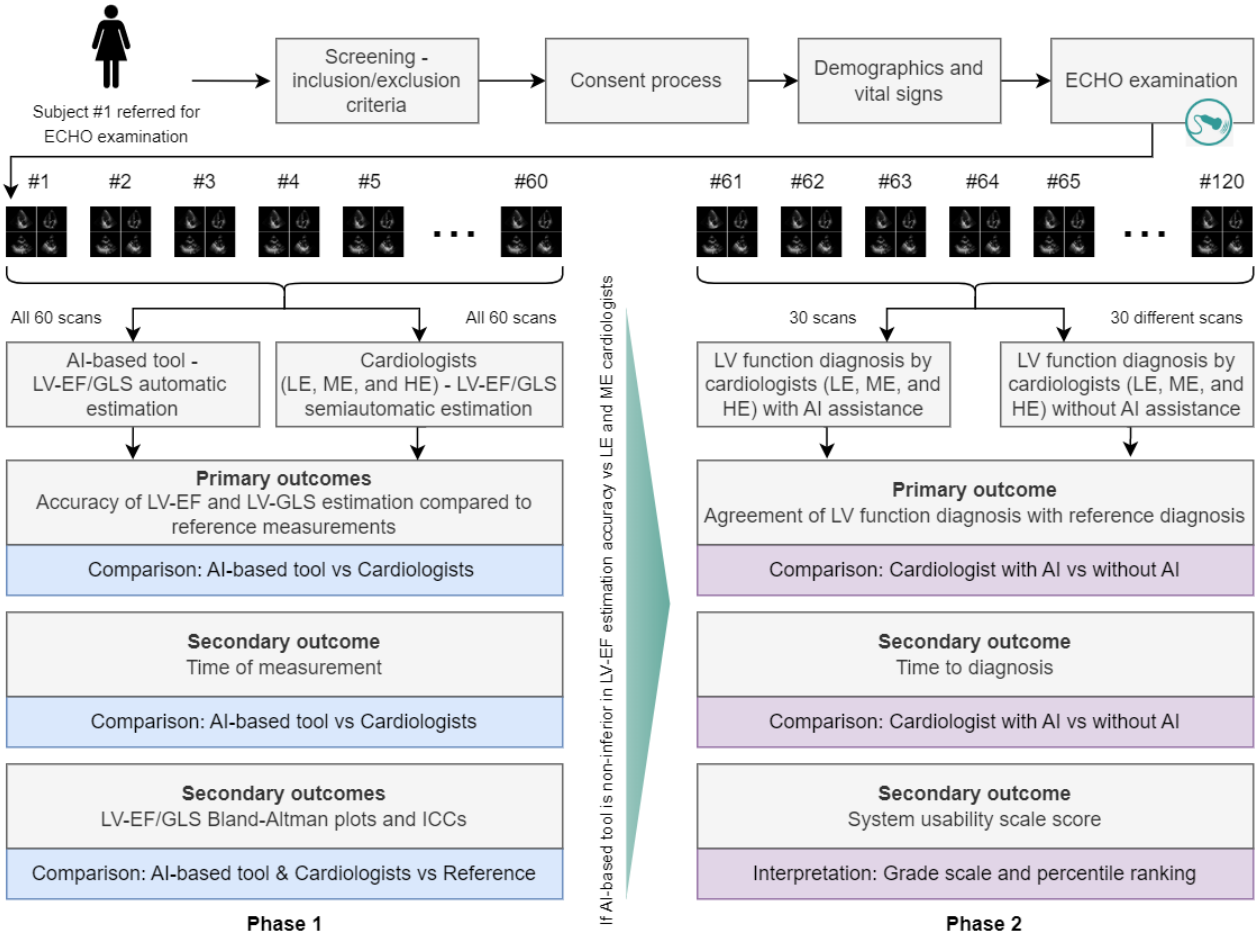
Textbox 1. Primary and secondary objectives of the 2 phases of the study.

Phase 1

- Primary objective
  - Determine if the automatic estimation of left ventricular ejection fraction and left ventricular global longitudinal strain from echocardiography scans by the artificial intelligence–based tool is noninferior in terms of accuracy to semimanual estimations by cardiologists of different experience levels.
- Secondary objective
  - Evaluate the time required for left ventricular ejection fraction and left ventricular global longitudinal strain measurement from echocardiography scans by the artificial intelligence–based tool and by semimanual estimations of cardiologists of different experience levels.

Phase 2

- Primary objective
  - Determine if the combination of the cardiologist and the artificial intelligence–based tool is superior to the routine examination practice of the cardiologist in terms of correct diagnosis of left ventricular function (normal or abnormal) based on examination of echocardiography scans, accounting for the cardiologist's level of experience.
- Secondary objective
  - Evaluate the time required for diagnosis with and without the assistance of the artificial intelligence–based tool.
  - Evaluate the usability of the artificial intelligence–based tool based on cardiologists' feedback after use.



Methods

Study Design

This is a prospective cohort study conducted in 2 phases, involving multireader, multicase diagnostic measurement, and diagnostic performance evaluation. Data (ECHO scans) collection is common between the 2 phases. The specific objectives of each study phase were detailed in Textbox 1. In both phases, reference measurements and reference diagnoses will be provided by a panel of 3 highly experienced cardiologists, via a collective intelligence process. We will proceed with the second phase if and when the AI-based tool is proven to be noninferior in terms of (at least) LV-EF estimation compared to (at least) low- and medium-experienced cardiologists in the first phase. Figure 1 provides an overview of the study.

XSL•FO
RenderX

Figure 1. Study overview. After enrollment in the study, an ECHO scan will be acquired from each participant. In total, 120 scans are planned to be collected, with 60 scans used in the first phase of the study evaluating the performance of the AI-based tool in LV-EF and LV-GLS estimation compared to the semimanual estimation by cardiologists of different experience levels and the rest in the second phase evaluating the utility of the AI-based tool in LV function diagnosis by cardiologists of different experience levels. AI: artificial intelligence; ECHO: echocardiography; EF: ejection fraction; GLS: global longitudinal strain; HE: high experience; ICC: intraclass correlation coefficient; LE: low experience; LV: left ventricle; ME: medium experience.

Clinical Site

The study will be conducted in the Third Cardiology Department of the Aristotle University of Thessaloniki (AUTH) in the Hippokration General Hospital, Thessaloniki, Greece. The hospital is equipped with a dedicated laboratory for ECHO acquisition (ECHO laboratory).

Participants

ECHO scans will be acquired from 120 participants (data collection participants) referred for transthoracic echocardiography as part of routine clinical practice in Hippokration Hospital. In total, 15 cardiologists will be involved in the study (serving as comparators in phase 1), divided into three groups according to the relevant level of experience: (1) the low experience (LE) group will include residents of cardiology with ECHO experience of fewer than 5 years, (2) the medium experience (ME) group will include cardiologists with ECHO experience of more than 5 and less than 10 years, and (3) the highly experienced (HE) group will include cardiologists with more than 10 years of experience or certification in echocardiography from the European Association of Cardiovascular Imaging (EACVI) or the National Cardiac Society.

A panel of 3 expert cardiologists (reference panel) with more than 10 years of experience and certification in echocardiography from the EACVI or the national cardiac society, not participating in the HE group, will provide the reference measurements and diagnoses.

Recruitment

Data collection participants will be recruited in the Third Cardiology Department of the Hippokration General Hospital. In particular, participants referred for transthoracic ECHO as part of routine clinical practice, including all possible diagnoses except those constituting exclusion criteria, will be invited to participate in data collection. Cardiologists serving at the Third Cardiology Department of the Hippokration General Hospital will be invited to participate in the examination of acquired echocardiograms.

Inclusion and Exclusion Criteria for ECHO Acquisition

Participants eligible for data collection must meet the following criteria: (1) female or male, (2) older than 18 years, and (3) participants must be in sinus rhythm during the examination.

XSL•FO
RenderX

Participants will be excluded from data collection and processing based on the following criteria: (1) presence of atrial fibrillation, (2) presence of sinus or other tachycardia (heart rate>100 bpm), (3) presence of pacing rhythm, (4) complex congenital heart disease, (5) myocardial hypertrophy, (6) need for a contrast agent to improve echocardiographic resolution, (7) bad imaging quality with 2 or more myocardial segments not viewed in each apical view, and (8) incapability of providing full consent.

Duration

The study is expected to last for approximately 2 years. The study is estimated to complete the enrollment of participants for data collection and of cardiologists within 6 months from initiation. However, enrollment in both cases will remain open until the study goal is met. Each cardiologist is expected to complete the tasks of both study phases in a maximum of 18 months. The second phase will only begin if and when the tool is proven to be noninferior in (at least) LV-EF measurement accuracy compared to (at least) the LE and ME groups of cardiologists in the first phase.

Data Collection

Enrollment of Data Collection Participants and ECHO Scan Acquisition

Participants referred to the Third Cardiology Department of the Hippokration General Hospital for cardiovascular examination including ECHO (see “Recruitment” section) and deemed eligible for data collection will be invited to participate in the study. Enrollment in the study and ECHO scan acquisition will be performed on the same day. Participants will first review the study information sheet and undergo informed consent. Once consented, participants will be assigned a coded identification number. Afterward, basic demographics, anthropometrics, and vital signs (age, gender, height, weight, and blood pressure), as well as relevant medical history (known cardiovascular conditions), will be recorded. ECHO acquisition will follow the standard clinical practice. All ECHO scans will be performed at the Hippokration Hospital ECHO laboratory, by 1 experienced cardiologist with EACVI certification in ECHO. Scans will be acquired using the GE Vivid S5 ultrasound system (GE Healthcare) or the Clarius PA HD ultrasound scanner (Clarius Mobile Health Corp). Three views (a 2-chamber, a 3-chamber, and a 4-chamber apical view) will be acquired per scanning procedure, with 3 cardiac cycles per view. Views will be reviewed for diagnostic quality, and if a view does not meet the criteria set, the acquisition will be repeated.

Enrollment of Cardiologists

Cardiologists serving at the Hippokration Hospital will be invited to participate in the study. Cardiologists will first review the study information sheet and undergo informed consent. Once consented, they will be assigned a coded identification number. Demographics (age and gender) and experience, including career stage and experience in ECHO, will be recorded. Each cardiologist will be assigned to 1 of the 3 experience groups (LE, ME, and HE) according to the self-reported experience in ECHO.

Reference Measurements and Diagnoses

Acquired scans will be independently examined by the highly experienced cardiologists of the reference panel, who will estimate LV-EF and LV-GLS and provide a binary diagnosis of LV function (normal or abnormal) for each case. Examination of scans by the reference panel will take place on a single, dedicated computer (also referred to as a workstation) in the ECHO laboratory of the Hippokration Hospital. Cardiologists will examine scans in batches on different days, depending on their availability.

LV-EF and LV-GLS will be estimated using the same methods and standards applied in routine clinical practice. A commercially available speckle-tracking software (EchoPAC version 202.0, GE Healthcare) will be used. LV-EF will be estimated using the biplane Simpson method [4] from 2 and 4-chamber apical views after cardiologist-adjusted tracing of the LV cavity. For LV-GLS, the 2-dimensional speckle-tracking method [7] will be used. For each captured view, the cardiac cycle with the best image quality will be first selected out of the 3 captured cycles. If the image quality is similar among all 3 cycles, the intermediate one will be selected. To reduce bias due to user interaction, the beginning and end of the cardiac cycle will be the time points that will be automatically defined by the software, usually based on automatic QRS detection on the echocardiogram. In the second step, the endocardial border will be traced, and a region of interest will be constructed. Manual adjustments will be made after visual inspection of the segmental tracking results throughout the cardiac cycle, to obtain the best possible tracing of all myocardial segments. The peak systolic strain value per view, as automatically provided by the software, will be noted. Finally, LV-GLS will be calculated as the average peak strain of the 3 apical views.

Regarding LV-EF and LV-GLS, the reference measurement for each scan will be the average of measurements estimated by the 3 cardiologists, provided that there is a <20% discrepancy between the measurements. Regarding LV function, the reference diagnosis will be the majority diagnosis among the 3 equally weighted diagnoses, that is, at least 2 out of the 3 cardiologists of the reference panel arrived at this diagnosis. For cases where there is a discrepancy of ≥20% between at least 2 of the 3 LV-EF and LV-GLS measurements provided by the reference panel, the 3 cardiologists will examine them and estimate the reference measurements together.

Phase 1: Processing of ECHO Scans for LV-EF and LV-GLS Measurement

Out of the 120 ECHO scans to be acquired, the first 60 scans will be used for assessing the noninferiority of the AI-based tool in measuring LV-EF and LV-GLS.

Processing of scans by the AI-based tool will take place on the dedicated computer of the ECHO laboratory. For each scan, the AI-based tool will output an LV-EF and an LV-GLS measurement, along with the time required for producing both measurements. All 3 values will be recorded.

Comparator cardiologists of the 3 experience groups will independently examine each scan and estimate the LV-EF and LV-GLS. LV-EF and LV-GLS will be estimated using the same

XSL•FO
RenderX

software and semimanual methods as in the case of the reference panel. For each scan, the LV-EF and LV-GLS values will be recorded along with the time required for estimation. The time required for estimation is defined as the time (in minutes) that elapsed from the moment a scan is loaded by the software until both measurements are estimated.

Cardiologists will examine scans in batches on different days, during working hours, and depending on their availability. A schedule with time slots will be communicated to them based on which they will be able to indicate their availability for the examination of each batch. Examination of scans will take place at the dedicated workstation of the ECHO Lab. At the end of phase 1, all 60 scans are expected to be processed by each cardiologist.

Phase 2: Examination of Scans for LV Function Diagnosis

In phase 2, the second batch of 60 scans will be used for assessing the superiority of the combination of the cardiologist and the AI-based tool in terms of LV function diagnosis from ECHO scans. Cardiologists of the 3 experience groups will independently examine batches of ECHO scans with and without the AI-based tool, and for each case, they will be asked to provide a binary diagnosis of LV function (normal or abnormal) based on visual inspection of the echocardiogram and measurements of LV-EF and LV-GLS. The decision will be recorded along with the time required to arrive at the diagnosis. For scans examined with AI assistance, cardiologists will use the AI-based tool that will allow them to view scans and automatically produce LV-EF and LV-GLS measurements. For scans examined without AI assistance, cardiologists will use the same software for viewing and estimating LV-EF and LV-GLS as in phase 1. For each cardiologist, ECHO scans reviewed with AI assistance will be different from those reviewed without AI assistance.

Before examining phase 2 cases, each cardiologist will be presented with materials describing how to use the AI-based tool and they will be given the opportunity to practice using the tool with 2 sample cases (independent of the study cases).

Examination of scans will take place on the same workstation of the ECHO laboratory as in phase 1, via scheduled time slots. At the end of phase 2, each cardiologist is expected to review and provide a diagnosis for 30 scans with AI assistance and 30 without AI assistance. Cardiologists that will examine at least 10 scans with AI assistance will be asked to complete the Greek version of the system usability scale (SUS).

Outcomes

Phase 1

Primary Outcomes

The primary outcomes of phase 1 are the accuracy of LV-EF and LV-GLS measurements with respect to the reference measurements defined as the absolute error of estimated average LV-EF and the absolute error of estimated average LV-GLS over 3 apical views (2-chamber, 3-chamber, and 4-chamber), respectively.

Secondary Outcomes

The following secondary outcomes will be produced in phase 1: (1) a Bland-Altman plot of LV-EF measurements produced by the AI-based tool with respect to reference measurements; (2) Bland-Altman plots of LV-EF measurements produced by LE, ME, and HE cardiologists with respect to reference measurements; (3) a Bland-Altman plot of LV-GLS measurements produced by the AI-based tool with respect to reference measurements; (4) Bland-Altman plots of LV-GLS measurements produced by LE, ME, and HE cardiologists with respect to reference measurements; (5) intraclass correlation coefficient (ICC) of LV-EF measurements produced by the AI-based tool with reference measurements; (6) ICCs of LV-EF measurements produced by LE, ME, and HE cardiologists with reference measurements; (7) ICC of LV-GLS measurements produced by the AI-based tool with reference measurements; (8) ICCs of LV-GLS measurements produced by LE, ME, and HE cardiologists with reference measurements; (9) time required by the AI-based tool for producing LV-EF and LV-GLS measurements from an ECHO scan; and (10) time required by LE, ME, and HE cardiologists for producing LV-EF and LV-GLS measurements from an ECHO scan.

Phase 2

Primary Outcomes

The primary outcome of phase 2 is the agreement rate of the LV function diagnosis of LE, ME, and HE cardiologists with the reference diagnosis.

Secondary Outcomes

The secondary outcomes of phase 2 are the time required by LE, ME, and HE cardiologists for examining an ECHO scan and arriving at the diagnosis of LV function and the SUS score.

Statistical Analysis Plan

Sample Size

The sample size of this study was determined based on realistic recruitment goals and comparability to the sample sizes of similar landmark studies [12,13]. In total, the study will recruit 120 individuals and each one will undergo a single ECHO examination. Half the scans will be used for phase 1 and the rest for phase 2. In total, 15 cardiologists, approximately 5 per experience group (LE, ME, and HE), will be recruited and participate in both study phases.

Statistical Analyses

In phase 1, errors of LV-EF and LV-GLS measurements produced by the AI-based tool will be compared to errors in the same measurements estimated semimanually by cardiologists, accounting for their experience level. We will use noninferiority tests for these comparisons. We will also compare the time required by the AI-based tool and by the comparator cardiologists to produce the measurements, using a superiority test. Bland-Altman analysis will also be performed to evaluate the agreement between the AI-based measurements, measurements by cardiologists of the 3 experience groups, and reference measurements and to detect bias and outliers. Moreover, ICC to assess interobserver variability regarding

XSL•FO
RenderX

both LV-EF and LV-GLS measurements will be used. In phase 2, agreement rates of cardiologists' diagnosis with the reference diagnosis with and those without the help of the AI-based tool will be compared. The same applies to the time to diagnosis. We will use superiority tests for these comparisons. Regarding usability, the SUS score will be interpreted according to a grade scale [14] and percentile ranking [15].

Ethical Considerations

Approval

The study has been approved by the research ethics committee of AUTH, Thessaloniki, Greece (protocol 102808/2022). Any modifications to the protocol, which may impact the conduct of the study or may affect participant safety, will require a formal amendment to the protocol and subsequent review and approval by the research ethics committee of AUTH before the changes are implemented to the study.

Consent

Prospective participants will be provided with a participant information sheet and a consent form. They will be given sufficient time to read the material and ask any questions. Participants will be informed of the study aim, requirements for participation, risks and benefits, their rights, the usage and storage of personal data, and the contact for any issues related to the study. They will be explicitly informed that study participation is voluntary and that choosing against participation will not affect the care received for treatment, in the case of data collection participants, and their residency or work, in the case of cardiologists. Written and informed consent will be obtained from all participants before any study-related procedures.

Data Confidentiality and Management

All data collected will be handled in compliance with the General Data Protection Regulation (GDPR) of the European Union. The collection of personal participant information is limited to the amount necessary to achieve the aims of the research. Participants will be assigned a coded identification number that will be used for reference in all records to protect participant confidentiality through pseudonymization. All records, electronic or hard copy, will be securely stored in password-protected computers or locked cabinets, respectively, while those containing direct identifiers, such as signed consent forms, will be stored separately from other records, with limited access.

Only pseudonymized data will be used for data analysis. Investigators who are authorized by the principal investigator will be given access to the acquired, pseudonymized data sets. In case of data transfer over a computer network, this will take place via the secure shell (SSH) file transfer protocol (SFTP). Study participants will be able to request access, correction, limited processing, or deletion of the data they contributed to the study, in compliance with the respective mandates of the GDPR. Participants will also have the right to data portability.

Withdrawal

All participants, including data collection participants and cardiologists, are free to withdraw from participation at any time, for any reason, specified or unspecified, and without prejudice. Participants can also request for the data they contributed to be deleted. Reasonable attempts will be made by the investigator to provide a reason for participant withdrawals.

Safety

Data will be collected from participants referred for echocardiography based on routine clinical practice. Thus, there are no additional safety concerns arising from their participation in the study. Standard clinical procedures will be followed for acquiring ECHO scans. Any distress or other adverse effects that may occur during ECHO will be handled according to standard clinical practice. Measurements and diagnoses produced during both phases of the study will only be used for evaluating the performance and utility of the AI-based tool, and they will not affect the formal diagnosis, treatment, or care that the participant will receive, which will be based on standard clinical practice.

Results

Enrollment began in September 2022. Participant recruitment and ECHO scan collection are ongoing. The results of the first phase are expected by summer 2023. The study is expected to conclude in May 2024, with the completion of the second phase.

Discussion

Principal Anticipated Findings

This is a 2-phase, prospective cohort study aiming at externally validating the clinical performance of and producing preliminary utility evidence regarding an AI-based tool that automatically estimates LV-EF and LV-GLS from transthoracic ECHO scans. ECHO scans will be collected from 120 participants referred for ECHO examination in the Hippokration General Hospital, Thessaloniki, Greece. The first phase will evaluate the accuracy of the AI-based tool, its reliability, and measurement time compared to semimanual estimations of cardiologists of different experience levels. We expect to find that the AI-based tool is noninferior in terms of LV-EF and LV-GLS estimation accuracy compared to at least LE and ME cardiologists, yields more consistent measurements, and is superior in terms of time required for LV-EF and LV-GLS estimation compared to cardiologists of all experience levels.

Provided that the AI-based tool proves noninferior in terms of at least LV-EF estimation accuracy compared to at least LE and ME cardiologists, the second phase will determine whether the tool can assist cardiologists of different experience levels in classifying LV function as normal or abnormal correctly and in less time. We expect to find that the combination of the cardiologist and the AI-based tool is superior in terms of agreement with the reference LV function diagnosis (normal or abnormal) and time to diagnosis compared to the cardiologist's routine examination practice, at least in the cases of LE and ME cardiologists. The second phase will also yield usability evidence regarding the tool.

XSL•FO
RenderX

Comparison to Prior Work

To our knowledge, at the time of approval, this was the first prospective cohort study aiming to evaluate the clinical performance and utility of an AI-based tool for automatic estimation of both LV-EF and LV-GLS from ECHO scans. Prior studies focused on evaluating the performance of AI-based tools for either EF or GLS automatic estimation. In the study of Salte et al [13], the performance of an AI-based system for automatic LV-GLS estimation was assessed by comparing AI-based GLS measurements to reference, semiautomatic GLS measurements by a single experienced observer in 200 ECHO scans. Pearson correlation coefficient, the mean absolute difference, and Bland-Altman analysis metrics were used to compare the 2 types of measurements, with LV function (measured using LV-EF) and the quality of scans considered as covariates. The study also investigated intraobserver variability by comparing initial GLS measurements with measurements performed after 4 weeks by the same observer in 25 ECHO scans, as well as interobserver variability by comparing the GLS measurements of the experienced observer to measurements by a second experienced observer performed on the same 25 scans. In a recent work [16], a retrospective study was carried out to compare LV-EF measurements of an AI-based tool to physician-measured LV-EFs with cardiac magnetic resonance imaging–derived EFs as the reference. ECHO scans from 242 patients were used, while physician-measured LV-EFs were obtained from formal clinical reports. Pearson correlation coefficient and Bland-Altman analysis metrics were used for comparisons, with the use or not of ultrasound-enhancing agent during ECHO acquisition considered as a covariate.

Strengths and Limitations

This study has several strengths. First, it will generate external evidence regarding the clinical performance of a trained AI-based tool for automatic estimation of LV-EF and LV-GLS based on prospective data collected in the routine clinical setting, thus reflecting real-world clinical scenarios. Second, it will provide preliminary evidence of the utility of such a tool in the diagnosis of LV function. Last, it will take into account the experience of the cardiologist in ECHO as a covariate both in EF and GLS measurement, as well as the diagnosis of LV function. A key limitation of this study is that the sample size was not determined through exhaustive power analysis but based on a realistic recruitment rate and sample sizes of previous studies with similar objectives and outcomes.

Dissemination Plan

After the completion of the study, we plan to publish the findings in peer-reviewed, open-access biomedical journals with a multidisciplinary readership spanning medicine, data science, and engineering. We will also report on the findings in deliverables and on the website of the associated project, at medical and biomedical engineering conferences, as well as in events with relevant stakeholders. The publication or presentation of any study findings will be done with respect to participants' privacy. Publications or presentations will not include any identifying participant information.

Future Directions

Depending on the findings of the study, future work may include the design and conduct of a randomized control trial to comprehensively evaluate the clinical utility of the AI-based tool, that is, its potential to lead to improved patient outcomes when used in a specific clinical setting.

Conclusions

Through the present study, we anticipate generating evidence on the clinical performance and utility of an AI-based tool for the automatic estimation of LV-EF and LV-GLS from echocardiograms. Such a tool has the potential to advance the process of ECHO examination through accurate, consistent, and fast estimation of key LV functional parameters that may lead to improved patient outcomes, especially in demanding care settings such as emergency rooms. Validation of clinical performance and preliminary proof of utility are the first steps in the assessment process of the tool toward its regulatory approval and use in clinical practice. The detailed description of the protocol presented here may be useful for clinicians and researchers planning similar studies.

Abstract

Background: Glucose variability increases cardiometabolic disease risk. While many factors can influence glucose levels, postprandial glucose response is the primary driver of glucose variability. Furthermore, affect may directly and indirectly impact glucose variability through its effect on eating behavior. Continuous glucose monitors (CGMs) facilitate the real-time evaluation of blood glucose, and ecological momentary assessment (EMA) can be used to assess affect in real time. Together, data collected from these sources provide the opportunity to further understand the role of affect in glucose levels.

Objective: This paper presents the protocol for a study that aims to (1) evaluate the feasibility and acceptability of using CGMs along with EMA in nondiabetic populations and (2) examine the bidirectional relationship between affect and glucose in nondiabetic adults with overweight or obesity using a CGM and EMA.

Methods: Eligibility criteria for the study include participants (1) aged 18 to 65 years old, (2) with a BMI of ≥25 kg/m^2, (3) who are able to read and write in English, and (4) who own a smartphone. Individuals will be excluded if they (1) have type 1 or 2 diabetes or have any other condition that requires glucose monitoring, (2) are pregnant, (3) use any medications that have the potential to alter blood glucose levels or interfere with the glucose sensing process, or (4) have a diagnosed gastrointestinal condition or eating disorder. In a 14-day observational study, participants will wear a FreeStyle Libre Pro CGM sensor (Abbott) and will receive mobile phone–based EMA prompts 6 times per day (randomly within six 2-hour windows between 8 AM and 8 PM) to assess positive and negative affect. Participants will also wear a Fitbit Inspire 2 (Fitbit) to continuously monitor physical activity and sleep, which will be included as covariates in the analysis. Multilevel linear regression models will be used to evaluate the acute relationship between glucose level and affect.

Results: Recruitment started in October 2022 and is expected to be completed in March 2023. We will aim to recruit 100 participants. As of December 12, 2022, a total of 39 participants have been enrolled.

Conclusions: The results of this study will further elucidate the role of affect in glucose variability. By identifying affective states that may lead to glucose excursions, our findings could inform just-in-time behavioral interventions by indicating opportunities for intervention delivery.

KEYWORDS

affect; glucose; eating behavior; glucose variability; glucose excursion; ecological momentary assessment; continuous glucose monitoring; continuous glucose monitor

Introduction

Effective intervention strategies are required to reduce the immense burden of cardiometabolic disease. Standard behavioral interventions to reduce cardiometabolic disease risk are typically based on population averages [1,2]; however, variability in response to dietary interventions suggests the need for personalized approaches [3]. Precision approaches aim to tailor interventions to an individual's unique characteristics and contexts [4,5]. For example, just-in-time adaptive interventions aim to facilitate behavior change by delivering an intervention at times and in contexts when individuals are more receptive to behavior change [6]. Identifying opportunities for change requires an understanding of the time-varying factors that influence behaviors.

The potential to measure time-varying factors has increased with the availability of wearable sensors. The use of continuous glucose monitors (CGMs) has resulted in the identification of glucose variability, that is, intraday fluctuations in blood glucose, as a risk factor for the development of cardiometabolic disease [7]. Greater glucose variability predicts increases in glycated hemoglobin (HbA_{1c}) in both diabetic and nondiabetic populations [8,9]. Among persons with type 2 diabetes who maintain good glycemic control ($HbA_{1c} \leq 7.0\%$), greater glucose variability was an independent risk factor for coronary artery disease during a 10-year follow-up period [10]. Though evidence in nondiabetic populations is sparse, mechanistically, it has been proposed that glucose variability increases cardiovascular disease risk through increased oxidative stress and inflammation [11], an effect that has been observed among individuals with normal insulin function [12].

While several factors influence glucose levels (eg, stress, physical activity, etc), glucose variability is primarily driven by increases in postprandial glucose [13]. Controlled laboratory studies have demonstrated that several dietary factors impact postprandial glucose, such as meal composition [14,15], meal timing [16], and meal frequency [17]. In real-world settings, eating behavior, and thus glucose variability, is influenced by several individual-level factors. One example of an individual factor that influences eating behavior is affect [18-21]. The relationship between eating behavior and affect appears to be bidirectional as fatigue, stress, and negative mood are associated with increased cravings and food consumption [19-22], while variations in glucose in response to eating may relate to affective and physical feeling states [23-26]. However, research in this area has primarily relied on dietary assessment recall methodologies, which may be prone to bias and recall error [27]. Pairing data from CGMs with data on affect using ecological momentary assessment (EMA), which involves repeated sampling of affect in real time and in an individual's natural environment, improves the validity of responses [28] and dramatically decreases the time between measurement of mood and glucose.

Combining CGM and EMA data to investigate the relationship between affective states and glucose variability presents an opportunity to support the development of precision interventions to prevent chronic disease by identifying situations that are likely to lead to large glucose increases (ie, an opportunity for change). A recent review [29] of mood and glucose variability in type 1 and 2 diabetes identified only 1 study that used CGMs and EMA to evaluate mood and glucose [25] and called for more research evaluating the relationships between mood or affect and glucose variability. To date, only a small (n=15) pilot study has combined EMA responses with CGM data to evaluate its association with affective and physical feeling states in nondiabetic samples [18]. Thus, the aims of this study are to (1) evaluate the feasibility of conducting a study using CGMs and EMA and (2) examine the bidirectional relationship between affect and glucose in adults using CGM and EMA data.

Methods

This is a 14-day observational study. Enrolled participants (N=100) will wear a CGM and receive EMA prompts to assess affect 6 times per day over the 14-day period (detailed below).

Ethics Approval

The study protocol was approved by the Texas A&M University Institutional Review Board (IRB2021-1412F).

Participants

Participants will be recruited through online social media advertisements, flyers in community settings, and emails to community members who have indicated previous interest in research participation. Interested individuals will complete a brief web-based screening questionnaire to determine study eligibility. Inclusion and exclusion criteria for the study are outlined in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria for study participation.

Inclusion criteria:

- Aged 18 to 65 years old
- Have a BMI of ≥25 kg/m^2
- Able to read and write in English
- Own a smartphone

Exclusion criteria:

- Diagnosed with type 1 or type 2 diabetes or any other condition that requires glucose monitoring
- Pregnant women
- Use of any medications that have the potential to alter blood glucose levels or interfere with the glucose sensing process (eg, corticosteroids, metformin, ascorbic acid, aspirin, acetaminophen, etc)
- Diagnosed with a gastrointestinal condition
- Diagnosed with an eating disorder

Baseline Visit

Upon confirmation of eligibility, participants will attend a baseline visit. Prior to completing any study-related activities, participants will sign an institutional review board–approved consent form. Participants will complete questionnaires to collect demographic data (age, sex, gender, race, ethnicity, and zip code), and study staff will measure participants' height and weight. Height will be measured with a Seca 213 stadiometer (Seca GmbH). Two measurements will be taken and recorded in centimeters. If a discrepancy of greater than 0.5 cm is noted, additional measurements will be taken until 2 consecutive measurements within 0.5 cm occur. An average of those 2 measures will be recorded for height. Similarly, weight will be measured using a Seca Clara 803 scale, recorded in kilograms, and taken until 2 consecutive measures within 0.5 kg occurs.

Glucose Monitoring

Participants will wear a FreeStyle Libre Pro CGM sensor (Abbott) on the upper arm of the participant's choosing for 14 days. The FreeStyle Libre Pro collects blinded interstitial glucose levels at 15-minute increments.

Affect

During the 14-day data collection period, participants will receive EMA prompts delivered to their smartphone via the Ethica mobile app (Ethica Data). Prompts will be delivered 6 times per day. One prompt will be delivered at a random time within each 2-hour window between 8 AM and 8 PM (8 AM-10 AM, 10 AM-12 PM, 12 PM-2 PM, 2 PM-4 PM, 4 PM-6 PM, and 6 PM-8 PM). Each prompt will consist of 10 Likert-scale items that will assess both positive and negative affect, with responses ranging from 1 (not at all) to 4 (extremely): "How (happy, cheerful, relaxed, stressed, anxious, angry, sad, energetic, tired, lonely) do you feel?" The survey will also include 2 "yes" or "no" questions: "Are you (bored, hungry) right now?"

The order of the 10 items will be randomized at each time point. Assessment questions have been validated for their use in daily or momentary assessment [30-32].

Covariates

Physical Activity and Sleep

Each participant will be provided a Fitbit Inspire 2 (Fitbit) to track physical activity and sleep over the 14-day data collection period. In the primary analyses, these variables will be included as covariates, but collection of this data will also facilitate secondary analyses of the complex interaction effects of physical activity, sleep, and affect on glucose level. Data from the Fitbit devices will be processed using Fitabase (Small Steps LLC).

Survey

A baseline survey will collect participants' demographic information and the following covariates:

- Depression symptoms; Patient Health Questionnaire-9 (PHQ-9): the 9-item PHQ-9 is designed to measure depressive symptoms [33].
- Anxiety symptoms; Generalized Anxiety Disorder-7 (GAD-7): the 7-item GAD-7 is a brief scale to identify probable cases of generalized anxiety disorder and to assess symptom severity [34].
- UCLA (University of California, Los Angeles) Loneliness Scale: this is a 20-item scale designed to measure one's subjective feelings of loneliness as well as feelings of social isolation with established validity and reliability [35].
- Self-Compassion Scale–Short Form (SCS-SF): the 12-item SCS-SF is a short version of the original Self-Compassion Scale [36].
- Coping Strategy Indicators (CSI): the 33-item CSI is a self-report measure of situational coping encompassing the strategies of avoidance, problem-solving, and seeking social support [37].
- Salzburg Stress Eating Scale (SSES): the 10-item SSES questionnaire measures eating in response to stress [38].
- Weight Efficacy Lifestyle Questionnaire–Short Form (WEL-SF): the 8-item WEL-SF measures patients' confidence in their ability to control eating behavior in challenging situations and was developed as a brief measure for use in research and clinical practice [39].

XSL•FO
RenderX

- Food Cravings Questionnaire-Trait-reduced (FCQ-T-r): the 15-item FCQ-T-r questionnaire measures the frequency and intensity of food craving experiences [40].
- Experience in Close Relationship Scale (ECR-S): the 12-item ECR-S questionnaire concerns romantic relationships [41].

Follow-up Visit

Upon completion of the 14-day study, each participant will be asked to complete a follow-up visit. Poststudy weight will be measured at the visit (to potentially control for weight change in statistical analysis), and participants will complete a questionnaire to assess their experience during the study. The questionnaire will include both Likert-scale and open-ended questions aimed at identifying any barriers to device compliance. Participants will return the Fitbit and CGM sensor at this follow-up visit.

Analysis

We will determine compliance to CGM and Fitbit wear (% of wear time) and response rates to EMA prompts (% of prompts responded to). Predetermined compliance values (CGM and Fitbit wear ≥80%) and EMA response rates (75%) will be used to assess the feasibility of the study procedures.

Multilevel linear regression models, which adjust the standard errors for the clustering of EMA and glucose data within individuals and partition the variance of between- and within-person effects, will be used to evaluate the acute relationship between glucose level and affect. The following two outcome variables will be evaluated: (1) average glucose level in the time period between 2 EMA prompts and (2) occurrence of a glucose excursion (defined as a glucose level greater than 1 SD above the mean 24-hour glucose level). Predictor variables will be 2 separate composite scores for positive affect (average of "happy," "cheerful," "relaxed," and "energetic") and negative affect (average of "stressed," "anxious," "angry," "sad," and "tired"). Secondary analyses will be used to predict the interaction effects of physical activity, sleep, and affect on glucose level. Similar models will evaluate positive and negative affect as the outcome variable and average glucose level in the hour prior as the predictor. Covariates in the model will include age, sex, BMI, time of day, day of week, physical activity since the previous EMA prompt, and previous night's sleep. Additional baseline measures will be evaluated as potential covariates and included in the final model if found to significantly improve model fit. Instances of missing EMA or CGM data will be excluded from the analysis.

Results

Recruitment started in October 2022. As of December 12, 2022, a total of 39 participants have been enrolled. We expect to enroll 100 participants by a target completion date of March 2023.

Discussion

This project will generate data to elucidate the relationship between affective states and glucose variability, with an aim of ultimately informing intervention development to reduce glucose variability. We hypothesize that a bidirectional relationship exists by which greater negative affect will predict greater glucose variability, while greater glucose variability will predict greater negative affect.

Technological innovations hold promise for improving approaches to understand the relationship between affective states and glucose variability in real-world settings. CGMs allow for real-time collection of data related to postprandial response, while EMA allows for real-time collection of mood states. Pairing these approaches will facilitate a more valid evaluation of the relationships between affective states and eating behavior, as well as provide opportunities for real-time precision nutrition interventions that consider individuals' physiological and cognitive states. Precision intervention approaches, such as just-in-time interventions, aim to intervene during moments of opportunity [6]. Compliance data, along with the postparticipation questionnaire, will inform changes to study procedures to address the barriers experienced by participants. Evaluation of the relationship between glucose level and affect will aim to identify situations in which glucose excursions occur (opportunity) and can inform interventions to be delivered during those opportunities (ie, meditation or physical activity to improve affect and dietary suggestions that minimize glucose excursions).

Acknowledgments

This work is funded through the Texas A&M University Nutrition & Obesity Research Center Pilot and Feasibility Projects program (principal investigator: CDR)

Abstract

Background: Nonsuicidal self-injury (NSSI) is a major mental health concern. Despite increased research efforts on establishing the prevalence and correlates of the presence and severity of NSSI, we still lack basic knowledge of the course, predictors, and relationship of NSSI with other self-damaging behaviors in daily life. Such information will be helpful for better informing mental health professionals and allocating treatment resources. The DAILY (Detection of Acute rIsk of seLf-injurY) project will address these gaps among individuals seeking treatment.

Objective: This protocol paper presents the DAILY project's aims, design, and materials used. The primary objectives are to advance understanding of (1) the short-term course and contexts of elevated risk for NSSI thoughts, urges, and behavior; (2) the transition from NSSI thoughts and urges to NSSI behavior; and (3) the association of NSSI with disordered eating, substance use, and suicidal thoughts and behaviors. A secondary aim is to evaluate the perspectives of individuals seeking treatment and mental health professionals regarding the feasibility, scope, and utility of digital self-monitoring and interventions that target NSSI in daily life.

Methods: The DAILY project is funded by the Research Foundation Flanders (Belgium). Data collection involves 3 phases: a baseline assessment (phase 1), 28 days of ecological momentary assessment (EMA) followed by a clinical session and feedback survey (phase 2), and 2 follow-up surveys and an optional interview (phase 3). The EMA protocol consists of regular EMA surveys (6 times per day), additional burst EMA surveys spaced at a higher frequency when experiencing intense NSSI urges (3 surveys within 30 minutes), and event registrations of NSSI behavior. The primary outcomes are NSSI thoughts, NSSI urges, self-efficacy to resist NSSI, and NSSI behavior, with disordered eating (restrictive eating, binge eating, and purging), substance use (binge drinking and smoking cannabis), and suicidal thoughts and behaviors surveyed as secondary outcomes. The assessed predictors include emotions, cognitions, contextual information, and social appraisals.

Results: We will recruit approximately 120 individuals seeking treatment aged 15 to 39 years from mental health services across the Flanders region of Belgium. Recruitment began in June 2021 and data collection is anticipated to conclude in August 2023.

Conclusions: The findings of the DAILY project will provide a detailed characterization of the short-term course and patterns of risk for NSSI and advance understanding of how, why, and when NSSI and other self-damaging behaviors unfold among individuals seeking treatment. This will inform clinical practice and provide the scientific building blocks for novel intervention approaches outside of the therapy room that support people who self-injure in real time.

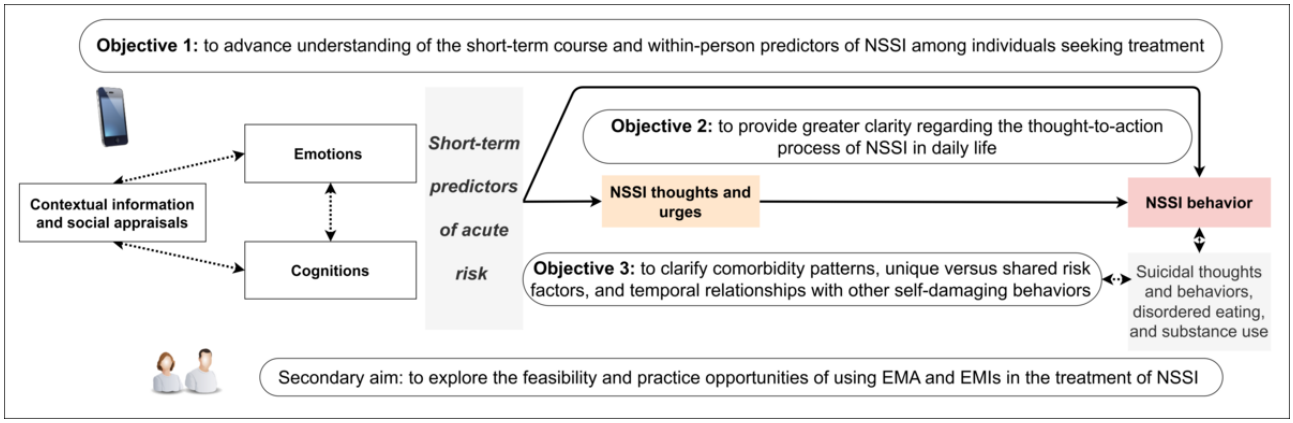
Introduction

Background

Nonsuicidal self-injury (NSSI), the direct and deliberate damage of one's body tissue without suicidal intent (eg, cutting and hitting oneself), is a major mental health concern worldwide. Epidemiological surveys indicate that 1 in 5 individuals engage in NSSI before the age of 25 years [1-3], with 12-month rates in the 8% to 19% range [1,2] and many individuals reporting persistent NSSI for several years [4]. These rates are considerably higher among individuals seeking treatment [5-7], with more than half of adolescent inpatients and 1 in 10 emerging adult and adult outpatients reporting monthly NSSI [8,9]. Furthermore, the presence of NSSI predicts rehospitalization [10], is highly stigmatized [11], and is uniquely associated with an increased risk for psychiatric disorders [2,9,12-15] and suicidal thoughts and behaviors (STB). For instance, research shows that people who engage in NSSI are more likely to make a suicide attempt independent of mental disorders [16,17], with those engaging in repetitive persistent NSSI being most likely to attempt suicide and experience adverse psychosocial outcomes [18]. As such, there is an urgent need to better understand, predict, and prevent self-injury among people who frequently engage in these behaviors.



Unfortunately, we still lack basic knowledge of the descriptive nature of NSSI and how, why, and when self-injury unfolds in everyday life [19], a prerequisite for risk screening and intervention to prevent NSSI and clinically associated outcomes (eg, suicide attempts). This lack of progress is largely because most empirical studies have focused on establishing the prevalence and correlates of the presence and severity of NSSI using cross-sectional designs. Although longitudinal studies have been conducted, they typically used observation windows from months to years [19-21], providing a long-distance view of who is at greater risk of engaging in NSSI compared with others. However, such a nomothetic approach does not clarify *when* someone is at risk in the short term and in what daily life contexts they are more at risk and will thus not help clinicians to decide whether an individual is likely to self-injure within the next days and weeks. Making these decisions requires an idiographic approach and knowledge of the course, contexts of risk, and the relationship of NSSI with other self-damaging behaviors in daily life. Such information would be helpful for better informing mental health professionals and allocating treatment resources.

Similar to other frequently co-occurring self-damaging behaviors (eg, attempting suicide, binge eating, purging, and binge drinking) [2,13,22], NSSI cannot be ethically induced in the laboratory but occurs in people's everyday lives. Although studying NSSI as it unfolds in real time has historically been challenging, recent technological advancements have made it possible to do exactly this, which has the potential to substantially improve our understanding and inform prevention efforts [19,23]. Ecological momentary assessment (EMA; also called experience sampling, ambulatory assessment, or real-time monitoring) involves prompting individuals multiple times per day via their mobile phone to provide in-the-moment information on social appraisals, emotions, cognitions, and behavioral patterns as they are lived in the flow of daily life [24-26]. Prior research suggests that NSSI thoughts can change substantially across hours [27], essentially necessitating EMA to (1) capture these real-time changes and (2) enable the identification of factors that predict these changes in daily life.

Advancing insight into the course and contexts of elevated risk for NSSI thoughts (ie, *thinking about deliberately hurting oneself*), NSSI urges (ie, *a difficult-to-control desire to self-injure*), self-efficacy to resist NSSI (ie, *confidence in one's ability not to engage in self-injury*), and NSSI behavior (ie, *engagement in self-injury*) would uniquely inform researchers and clinicians about how self-injury unfolds and is experienced by those at highest risk. This *in-the-moment* information can transform our ability to prevent and manage NSSI among individuals seeking treatment by providing the scientific building blocks for novel digital interventions that support people who self-injure in real time [19,28,29]. The DAILY (Detection of Acute rIsk of seLf-injurY) project aims to address these gaps using a 28-day EMA protocol among individuals seeking treatment. This protocol paper presents the project's aims, design, and materials used. Figure 1 provides a graphical presentation of the primary objectives of the DAILY project.

XSL•FO
RenderX

Figure 1. Graphical overview of the study objectives. EMA: ecological momentary assessment; EMI: ecological momentary intervention; NSSI: nonsuicidal self-injury.

Objectives

The first primary objective is to clarify the short-term course and within-person predictors of NSSI. Initial work among community samples suggests that NSSI thoughts are usually short-lived and moderate in intensity [30-32], with a higher risk of more intense and persistent NSSI thoughts toward the evening [32] and an average of 1.6 (SD 1.1) NSSI behaviors per week [30]. Surprisingly, however, the short-term clinical course of NSSI remains to be comprehensively investigated among individuals seeking treatment. The intensive nature of the longitudinal data we collect will allow for a detailed picture of the thought and behavioral patterns and help us to address several critical unanswered questions about the course of NSSI among individuals seeking treatment: how much do NSSI thoughts, NSSI urges, self-efficacy to resist NSSI, and NSSI behavior (1) vary between people seeking treatment, (2) vary within people seeking treatment, (3) vary throughout the day and the week, and (4) covary and predict each other prospectively in daily life?

Guided by contemporaneous models of NSSI [33-35] and emerging work [36-38], we will evaluate contextual information, social appraisals, emotions, and cognitions as within-person risk and protective factors for cognitive and behavioral NSSI outcomes. We hypothesize that the risk of NSSI behavior will be higher when people are alone [30], after situations characterized by negative social appraisals and perceived conflict [39,40], and after increased negative and decreased positive affect [41]. Given that specific emotions may incrementally predict higher risk (eg, feeling stressed) [30,42] or protect more strongly against NSSI (eg, feeling relaxed) [27], the findings will also be analyzed using specific emotions as units of analysis. On the basis of the benefits and barriers model of NSSI [34,43], which argues for a unique role of self-critical thoughts in explaining NSSI behavior, we will evaluate the association between momentary fluctuations in self-critical thinking and NSSI urges and NSSI behavior. Building upon the emotional cascade model [35,44], which posits that reinforcing cyclic cascades between rumination and negative affect form a dynamic process in which self-injury is suggested to break this cycle by distracting from rumination, the utility of momentary ruminative thinking and the interplay with negative emotions in predicting NSSI behavior will be investigated. However, because the relevance of these theoretically inspired within-person risk factors for NSSI might differ between individuals [45,46], we will also determine variability in individual risk associations.

A second primary objective is to advance understanding of the transition from NSSI thoughts and urges to NSSI behavior. Although existing theoretical models of NSSI do not distinguish between NSSI thoughts or urges and NSSI behavior, contemporary “ideation-to-action” theories of suicide explicitly make this distinction [47] and suggest that the factors that lead to suicidal thoughts or urges are not necessarily the same factors that lead to behavior (ie, suicide attempts). Emerging evidence indicates that incorporating ideation-to-action thinking might be equally relevant for NSSI. For instance, preliminary work suggests that previously identified risk factors for NSSI behavior (eg, emotional factors) might uniquely predict NSSI thoughts but not the occurrence of NSSI behavior [27]. Inspired by the cognitive-emotional model of NSSI [33], we anticipate that momentary self-efficacy to resist NSSI will be a potent protective factor against NSSI behavior. People retrospectively report that the transition between NSSI thoughts or urges and NSSI behavior is typically <30 minutes [30,31], meaning that there might be a brief window of opportunity to intervene during these moments of acute risk for NSSI behavior. Therefore, in an attempt to inform and facilitate such intervention efforts, we will make a thought-to-action distinction and clarify the specificity of risk and protective factors to identify factors that increase or decrease the likelihood of transitioning from NSSI thoughts or urges to NSSI behavior in real time among individuals seeking treatment.

A third primary objective is to provide novel data on the co-occurrence of NSSI with other self-damaging behaviors in daily life that may represent different forms of behavior that serve the same function (ie, disordered eating, substance use, and STB) [13,30,48-51]. For example, previous daily diary studies found that 42% to 53% of the adolescents and emerging adults who engage in NSSI reported at least 1 episode of disordered eating and suicidal ideation [40,52], with suicidal thoughts being present on most days when adolescents engaged in NSSI [53]. Similarly, Nock et al [30] observed that NSSI thoughts co-occurred 13% to 18% of the time with thoughts of substance use and disordered eating. Therefore, disordered eating (ie, restrictive eating, binge eating, and purging),

XSL•FO
RenderX

substance use (ie, binge drinking and smoking cannabis), and STB will be assessed as secondary outcomes. From a transdiagnostic approach, this will help to clarify comorbidity patterns, unique versus shared risk factors, and temporal relationships with other self-damaging behaviors in daily life [13,19,54]. In addition, it will allow us to address whether the dynamic characteristics of NSSI thoughts or urges (ie, an individual's within-person average and variability) and frequency of NSSI behavior—as observed in the EMA—predict changes in NSSI trajectories and the presence of comorbid self-damaging behaviors among individuals seeking treatment [55]. For instance, it may be that persistently high NSSI urges and frequent NSSI behavior increase the risk of STB [53]. Alternatively, there could also be a behavior shift such that a reduced frequency of NSSI leads some individuals to take up another behavior that serves a similar function.

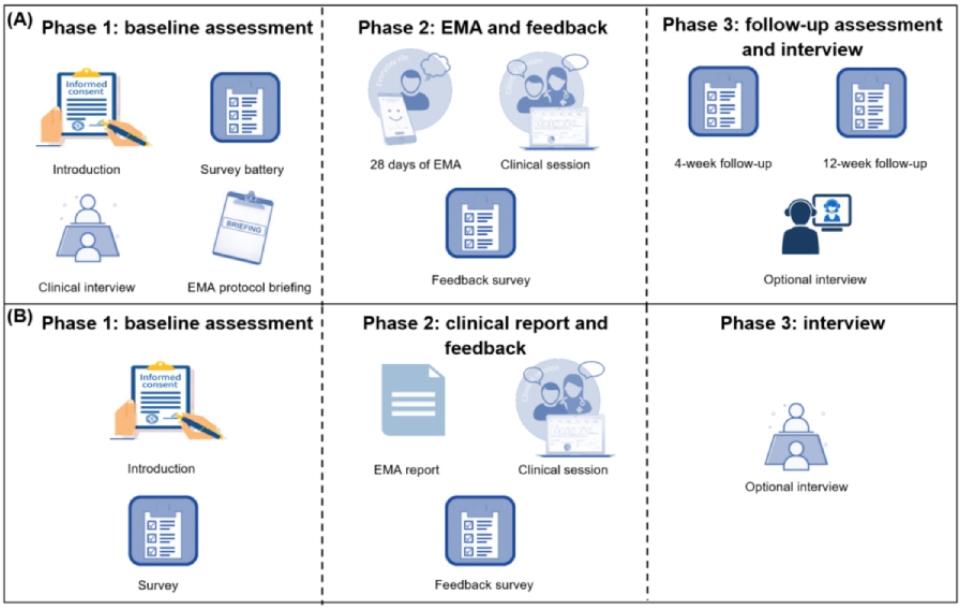
Finally, a secondary aim is to evaluate the perspectives of individuals seeking treatment and mental health professionals regarding the feasibility, scope, and utility of digital self-monitoring and novel interventions. There is a growing awareness that the clinical implementation of EMA and ecological momentary interventions (EMIs), which use EMA to deliver support in real-time, provides new opportunities to make individuals more actively involved in their treatment and to better match treatments to their needs [19,24,56,57]. For instance, EMA could facilitate self-insight about relevant processes [19,58,59], whereas EMIs would allow for providing support outside of the therapy room in daily life. Initial findings indicate the acceptability and potential of EMIs for NSSI and suicide prevention [29,60,61], but, despite the clear clinical potential, this remains a largely underexplored area. Importantly, however, the development of EMIs will advance more rapidly and be more easily clinically implemented when a user-centered design is employed. Such a design actively involves and acknowledges end users from the initial stage of development to understand the goals, challenges, and motivations for future EMIs that seek to facilitate young people's recovery from self-injury and other self-damaging behaviors [62].

Methods

Target Population and Recruitment

To investigate the objectives of the DAILY project, the target population is adolescents (aged 15-18 years), emerging adults (aged 19-29 years), and adults (aged 30-39 years) seeking treatment and their mental health professionals. They are recruited from mental health services across the Flanders region of Belgium, including 9 inpatient services, 8 outpatient services, and 4 services with a hybrid care model. Of these services, 11 focus on emotion dysregulation and mood disorders, 5 focus on social-emotional difficulties in transitioning from adolescence to emerging adulthood, 3 focus on eating disorders, and 2 are private practices. Potential eligible participants are informed about the study via mental health professionals, study flyers, and information moments at these mental health services. The inclusion criteria for patients are as follows: (1) being aged between 15 and 39 years, (2) having sufficient Dutch-language proficiency, (3) past-month NSSI thoughts/behaviors, and (4) receiving inpatient or outpatient treatment. Individuals with cognitive deficits that preclude comprehension of materials are excluded from participation. Although adult participants (aged ≥18 years) could opt to continue participation when they decided to stop treatment, a treating mental health professional had to be involved for minors (<18 years) during the entire monitoring period, meaning that participation automatically ended when they interrupted their treatment before the end of the 28-day EMA protocol. The inclusion criterion for mental health professionals is being a licensed psychiatrist, clinical psychologist, or mental health nurse.

Ethics Approval



All phases of the DAILY project were approved by the Ethics Committee Research UZ/KU Leuven on February 10, 2021 (s64989 and B3222020000343), and all procedures align with the 1964 Helsinki declaration and its later amendments.

Procedure and Protocol

The DAILY project consists of 3 phases, including a baseline assessment (phase 1), 28 days of EMA followed by a clinical session and feedback survey (phase 2), and 2 follow-up surveys and an optional interview (phase 3). Figure 2 provides a graphical overview of the project.

XSL•FO
RenderX

Figure 2. Graphical overview of the study procedures for (A) individuals seeking treatment and (B) mental health professionals. EMA: ecological momentary assessment.

Phase 1: In-Person Baseline Assessment of Individuals Seeking Treatment

In the first phase, a psychologist meets with the patient (hereinafter referred to as the participant) to give them detailed information, conduct the baseline assessment, and provide training on completing the EMA protocol. The informed consent process informs participants about the study demands and goals, the safety protocol, reimbursement scheme, the researchers' responsibility concerning risk monitoring, and the implications of this responsibility (ie, when the duty of care overrides the confidentiality principle). All participants provide written informed consent or assent. In addition, parents or legal caregivers provide written informed consent for minors aged 15 to 17 years. The baseline assessment consists of a survey battery and a clinical interview. Table 1 presents the constructs covered in the survey battery assessed via REDCap (Research Electronic Data Capture; Vanderbilt University) [63]. The clinical interview assesses the participants' history of NSSI and STB using the well-validated Self-Injurious Thoughts and Behaviors Interview [64,65]. In addition, the Structured Clinical Interview for DSM-5 [66], is used to assess common comorbid mental disorders, including major depressive disorder, alcohol use disorder, substance use disorder, panic disorder, generalized anxiety disorder, posttraumatic stress disorder, and eating disorders [2,15,22]. Interrater reliability will be examined within a subset of 20% of the diagnostic interviews (approximately 24 participants) by calculating the percentage of agreement and Cohen κ coefficients for overall diagnosis [67]. During the clinical interview, participants are asked about personal strategies that they consider helpful to resist engaging in NSSI and other self-damaging behaviors (see *Phase 2: Safety Measures and Risk Monitoring* section).

Phase 1 concludes with an orientation and training on completing the EMA protocol via m-Path, a user-friendly and secure smartphone app and platform created by researchers at KU Leuven that is General Data Protection Regulation (GDPR)–compliant for real-time and real-world data collection [68]. We assign all participants a study alias to ensure that no identifying information is shared with the software platform. All communication between participants' smartphones and the server is end-to-end encrypted and securely uploaded after each interaction [68]. Participants without a smartphone are loaned a device with a prepaid data plan for data collection. Study staff help participants to download the app on their phone (Android or IOS) or the loaned device (Android), discuss the EMA protocol's content and procedures, answer participants' questions, and initiate a practice EMA survey for the participant. Phase 1 takes approximately 3 to 4 hours to complete.

[a]UPPS-P: urgency, premeditation, perseverance, sensation seeking, and positive urgency.

[b]Reassessed in the web-based follow-up surveys 4 and 12 weeks after the 28-day real-time monitoring period.

[c]NSSI: nonsuicidal self-injury.

[d]FBT: forward-backward translation.

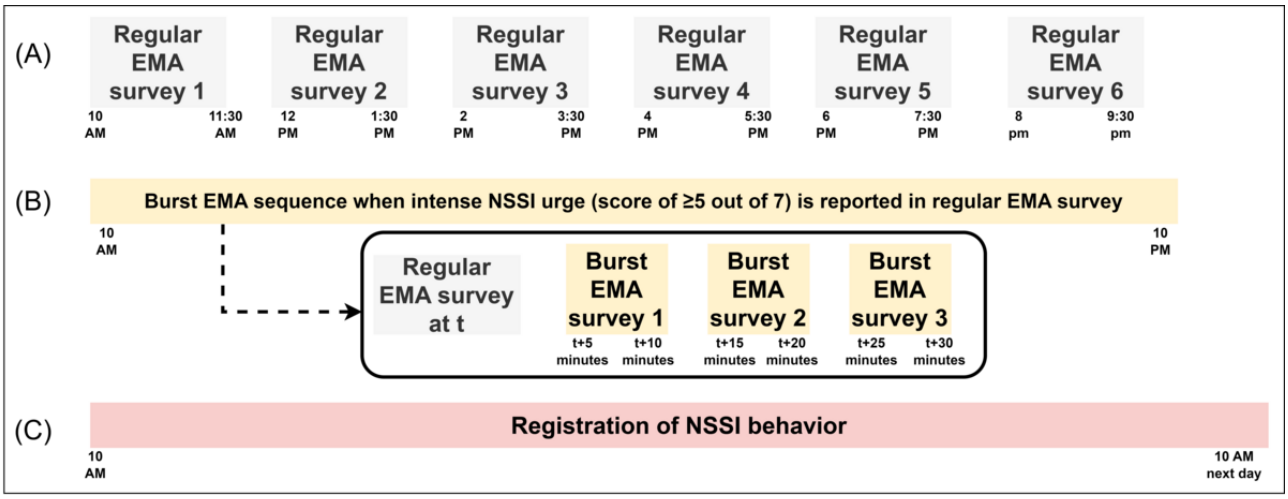
[e]N/A: not applicable.

[f]DSM-5: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition.

Phase 1: Web-Based Baseline Assessment of Mental Health Professionals

Each mental health professional also provides informed consent the first time and completes a brief survey assessing sociodemographic (age and gender) and professional information (profession, level of education, and years of experience). In addition, they can provide the research team with 1 to 3 additional EMA questions when considered relevant for a specific individual.

Phase 2: EMA Sampling Design and Content



The second phase starts on the morning after the baseline assessment. It involves a 28-day EMA protocol that consists of (1) six semirandom regular EMA surveys administered on average every 2 hours during waking hours between 10 AM and 9:30 PM, (2) three burst EMA surveys spaced at a higher frequency of 5 to 10 minutes apart in the 30 minutes after intense NSSI urges are reported in the regular EMA surveys (score of ≥5 on a 7-point item), and (3) event registrations via a push button to record the timing of NSSI behavior. Figure 3 shows the sampling schedule of the DAILY project, which includes a minimum of 168 regular EMA surveys and a theoretical maximum of 672 EMA surveys (when a burst sequence is triggered during each regular survey). To ensure that we capture people in their ongoing activities and to avoid retrospective reporting, participants must register responses to the regular EMA within 15 minutes of receipt and to the burst EMA surveys within 5 minutes of receipt. In case of nonresponse to the regular EMA surveys, 1 reminder is sent after 10 minutes. After the first day and each week subsequently, a team member telephoned the participants to check whether everything is going well, provide feedback about study compliance, and respond to concerns or difficulties concerning the app and the self-monitoring.

Table 2 presents the EMA constructs and items in the DAILY project, including emotions and cognitions (block A); contextual information and social appraisals (block B); NSSI thoughts, NSSI urges, self-efficacy to resist NSSI, and NSSI behavior (block C); and the screening of other self-damaging behaviors and experienced momentary burden (block D, part 1). EMA items were as much as possible selected or modified from prior EMA studies and conventional survey questionnaires [27,86,90,106-108]. Questions are branched so that participants only have to complete relevant EMA items (eg, social appraisals are context specific). The order in which emotions and cognitions are presented is randomized within individuals across the EMA surveys (because these items are not conditional on each other). Specific emotions for negative and positive affect are selected because they represent all 4 quadrants of the affective circumplex defined by valence and arousal dimensions [109]. All continuous EMA items are assessed on 7-point rating scales ranging from not at all or absent to very much or very strong (Table 2). Although NSSI behavior is assessed retrospectively during each EMA survey (ie, “Since the last beep, have you deliberately hurt yourself without wanting to die?”), participants are instructed to register the timing of NSSI behavior through an event marker. This occurred on a wearable wireless device (Chill Band +; IMEC International) for the first 12 participants. However, owing to practical and technical issues with these devices, the remaining participants used an event registration push button in the m-Path app [68].

During each regular EMA survey, we also screened whether participants experienced thoughts, had an urge, or engaged in 6 other self-damaging behaviors, including restrictive eating, purging, binge eating, STB, binge drinking, and smoking cannabis (block D, part 1). If they answer ≥1 of these self-damaging behaviors affirmatively, additional items assess thoughts, urges, behavior engagement, and self-efficacy to resist the endorsed behavior(s) (block D, part 2, Table 3). Finally, participants rate the extent to which they consider an EMA survey burdensome. The regular EMA surveys include 28 to 31 items (excluding optional individual-specific questions), with 4 additional items for each of the other self-damaging behaviors endorsed on the screening item (Table 3). The burst EMA surveys include 21 to 22 items, assessing only emotions and cognitions (block A) and NSSI outcomes (block C).

Table 2. Ecological momentary assessment (EMA) constructs and items.

EMA constructs[a]	Items	Response category
Block A: emotions and cognitions (17 items)		
Momentary negative affect	• [Right now]: "I feel anxious," "I feel stressed," "I feel irritated," "I feel sad," and "I feel insecure"	• 7-point scale (ranging from not at all to very much)
Momentary positive affect	• [Right now]: "I feel cheerful" and "I feel relaxed"	• 7-point scale (ranging from not at all to very much)
Momentary emptiness	• [Right now]: "I feel empty"	• 7-point scale (ranging from not at all to very much)
Momentary loneliness	• [Right now]: "I feel lonely"	• 7-point scale (ranging from not at all to very much)
Momentary emotion dysregulation	• [Right now]: "My emotions are overwhelming me"	• 7-point scale (ranging from not at all to very much)
Momentary rumination	• [Right now]: "I am repeatedly thinking about the same problem"	• 7-point scale (ranging from not at all to very much)
Momentary self-criticism	• [Right now]: "I am disappointed in myself"	• 7-point scale (ranging from not at all to very much)
Momentary other-criticism	• [Right now]: "I am disappointed in others"	• 7-point scale (ranging from not at all to very much)
Momentary body image	• [Right now]: "I am satisfied with the way I look" and "I feel at ease in my body"	• 7-point scale (ranging from not at all to very much)
Momentary identity	• [Right now]: "I doubt who I am" and "I know what I stand for"	• 7-point scale (ranging from not at all to very much)
Block B: contextual information and social appraisals (5-7 items)		
Momentary situational context	• "Where are you?"	• (a) At home; (b) at a friend's or family's place; (c) school or work; (d) car, train, bus; (e) other indoors; (f) other outdoors
Momentary activity	• "What were you doing just before the beep?" • (If g) "Please describe briefly what you are doing"	• (a) Nothing, (b) work or studying, (c) household chores, (d) conversation, (e) leisure active (eg, sports), (f) leisure passive (eg, watching television), (g) something else
Momentary appraisal of activity	• "I enjoy this activity"	• 7-point scale (ranging from not at all to very much)
Momentary social context	• "Are you alone or with others?" • (If b) "Who are you with physically?" • (If c) "Who are you with online?"	• (a) Alone, (b) others physically, (c) others on the web • (a) Partner, (b) family, (c) friends, (d) colleagues, (e) acquaintances, (f) other patients, (g) unfamiliar people
Momentary appraisal of social context	• (If a): "I like being alone" • (If b): "I enjoy the company of these people" • (If c): "I feel connected to those I am online in contact with"	• 7-point scale (ranging from not at all to very much) • 7-point scale (ranging from not at all to very much) • 7-point scale (ranging from not at all to very much)
Block C: NSSI[b] (4-5 items)		
Retrospective thoughts	• "Since the last beep, have you considered deliberately hurting yourself without wanting to die?"	• 7-point scale (ranging from not at all to very much)
Momentary urge	• "Right now, how strong is the urge present to hurt yourself without wanting to die?"	• 7-point scale (ranging from absent to very strong)
Retrospective behavior	• "Since the last beep, have you deliberately hurt yourself without wanting to die (for example, cut, scratched, or hit yourself)?"	• (a) No, (b) yes

XSL•FO
RenderX

EMA constructs[a]	Items	Response category
Retrospective behavior (method)	• (If b): "How have you self-injured?"	• (a) Cutting or carving, (b) scratching, (c) hitting, (d) burning, (e) biting, (f) head banging, (g) wound interfering, (h) other method (describe briefly)
Momentary self-efficacy to resist	• "Right now, how confident are you that you can resist engaging in NSSI?"	• 7-point scale (ranging from not at all to very)
Block D (part 1): screen other self-damaging thoughts or behaviors and interference (2 items)		
Screen comorbid thoughts or behaviors	• "Indicate all other behaviors you thought about or engaged in since the last beep, or for which you have an urge right now"	• (a) Restrictive eating, (b) binge eating, (c) vomiting deliberately, (d) killing myself, (e) binge drinking, (f) using cannabis, (g) none of these
Interference	• "This beep disturbed me."	• 7-point scale (ranging from not at all to very much)

[a]Blocks A to D are assessed in the regular EMA surveys. Blocks A and C are only assessed in the burst EMA surveys.

[b]NSSI: nonsuicidal self-injury.

Table 3. Ecological momentary assessment of other self-damaging behaviors[a].

Block D (part 2): Other self-damaging behaviors and items	Response category
Restrictive eating (4 items)	
Retrospective thoughts	
Since the last beep, have you thought about eating less to control your weight?	7-point scale (ranging from not at all to very much)
Momentary urge	
Right now, how strong is the urge to eat less to control your weight?	7-point scale (ranging from absent to very strong)
Retrospective behavior	
Since the last beep, have you eaten less to control your weight?	(a) No, (b) yes
Momentary self-efficacy to resist	
Right now, how confident are you that you can resist eating less to control your weight?	7-point scale (ranging from not at all to very)
Binge eating (4 items)	
Retrospective thoughts	
Since the last beep, have you thought about eating an unusually large amount of food?	7-point scale (ranging from not at all to very much)
Momentary urge	
Right now, how strong is the urge to eat an unusually large amount of food?	7-point scale (ranging from absent to very strong)
Retrospective behavior	
Since the last beep, have you experienced a binge-eating episode?	(a) No, (b) yes
Momentary self-efficacy to resist	
Right now, how confident are you that you can resist eating an unusually large amount of food?	7-point scale (ranging from not at all to very)
Purging (4 items)	
Retrospective thoughts	
Since the last beep, have you thought about vomiting deliberately?	7-point scale (ranging from not at all to very much)
Momentary urge	
Right now, how strong is the urge to vomit deliberately?	7-point scale (ranging from absent to very strong)
Retrospective behavior	
Since the last beep, have you vomited deliberately?	(a) No, (b) yes
Momentary self-efficacy to resist	
Right now, how confident are you that you can resist vomiting deliberately?	7-point scale (ranging from not at all to very)
Suicidality (4 items)	
Retrospective thoughts	
Since the last beep, have you thought about killing yourself?	7-point scale (ranging from not at all to very much)
Momentary urge	
Right now, how strong is the urge to kill yourself?	7-point scale (ranging from absent to very strong)
Retrospective behavior	
Since the last beep, have you made a suicide attempt?	(a) No, (b) yes
Momentary self-efficacy to resist	
Right now, how confident are you that you can resist attempting suicide?	7-point scale (ranging from not at all to very)
Binge drinking (4 items)	
Retrospective thoughts	
Since the last beep, have you thought about consuming an unusually large amount of alcohol?	7-point scale (ranging from not at all to very much)
Momentary urge	

XSL•FO
RenderX

Block D (part 2): Other self-damaging behaviors and items	Response category
Right now, how strong is the urge to consume an unusually large amount of alcohol?	7-point scale (ranging from absent to very strong)
Retrospective behavior	
Since the last beep, have you consumed an unusually large amount of alcohol?	(a) No, (b) yes
Momentary self-efficacy to resist	
Right now, how confident are you that you can resist consuming an unusually large amount of alcohol?	7-point scale (ranging from not at all to very)
Cannabis use (4 items)	
Retrospective thoughts	
Since the last beep, have you thought about smoking cannabis?	7-point scale (ranging from not at all to very much)
Momentary urge	
Right now, how strong is the urge to smoke cannabis?	7-point scale (ranging from absent to very strong)
Retrospective behavior	
Since the last beep, have you smoked cannabis?	(a) No, (b) yes
Momentary self-efficacy to resist	
Right now, how confident are you that you can resist smoking cannabis?	7-point scale (ranging from not at all to very)

[a]These other self-damaging behaviors are only assessed when screened positively in block D (part 1; Table 2) in the regular ecological momentary assessment surveys.

Phase 2: Safety Measures and Risk Monitoring

Participants are provided a 1-page information sheet with the contact information of the research team (study-specific telephone number and email address) as well as suicide and crisis hotlines during the baseline enrollment (phase 1). Although research suggests no reactivity or iatrogenic effects of repeated questioning about self-injurious thoughts and behaviors [110-112], there should be a proper safety protocol that not only matches participants' needs [113] but also does not inadvertently defeat the study's observational purpose [19,114]. Therefore, several measures are in place to support and safeguard participants' safety during the EMA period. First, an automatic pop-up screen with resources is shown at the end of a regular EMA survey whenever a participant indicates an intense urge for NSSI or any other self-damaging behavior (response 6 or 7 on a 7-point scale). This pop-up item contains either standard resources that signpost participants to relevant support organizations, family and friends, and their mental health professional or the personal resources provided by the participant during phase 1 (randomized within individuals across surveys with an equal probability of 0.5).

Second, a safety protocol is activated whenever a participant reports having attempted suicide or is at imminent risk for attempting suicide, operationalized as having an intense urge to attempt suicide (response 6 or 7 on a 7-point scale) combined with momentary low self-efficacy to resist this suicidal urge (responses 1-3 on a 7-point scale). A second automatic pop-up screen is triggered whenever this response pattern occurs, encouraging participants to provide more in-the-moment information within an open text field. After submitting this item (even when left blank), this response pattern issues an alert to the research team (ie, flagged email to the study account that is consistently monitored during recruitment hours). This information is then shared via telephone with clinical staff members on duty at the care facility for inpatients, after which they take appropriate action. The participating mental health professional also receives an email with this information. When the safety alert concerns an outpatient, a licensed clinical psychologist from the research team conducts the risk assessment by telephone. For minors, the parents or legal guardians are also contacted by telephone when a minor participant cannot be reached or when the clinical psychologist of the research team considers this necessary after a risk assessment.

Phase 2: Feedback Report, Clinical Session, and Feedback Surveys

After the EMA period, a feedback report is shared with the mental health professional to be discussed during a regular therapy session. The report contains person-specific data on (1) general psychological functioning (ie, emotions and cognitions) and contextual information (eg, distribution of time alone vs with others face-to-face or on the web and activities in daily life); (2) the course of NSSI thoughts, NSSI urges, self-efficacy to resist NSSI, and NSSI behavior; and (3) the occurrence and intensity of other self-damaging thoughts and behaviors during the 28-day monitoring period. The section on general functioning includes pie charts displaying the proportion of time that someone spends across different contexts and box plots showing the median and variability of emotional and cognitive states. The section on NSSI provides information on the distribution and single-day average of NSSI thoughts, urges, and self-efficacy to resist NSSI (box plot and time series graphs). For example, high-risk days are operationalized as days on which the single-day average urge of NSSI is high (ie, mean response between 5-7 on a 7-point scale), coupled with low single-day average self-efficacy to resist NSSI (ie, mean response between 1-3 on a 7-point scale). In addition, the frequency of NSSI behaviors and types of methods are

XSL•FO
RenderX

described, and NSSI urges are visualized across different situational, activity, and social contexts (bar charts). We also provide information about the occurrence of other self-damaging behaviors during the 28-day monitoring period. If the enrolled mental health professional cannot discuss the EMA feedback report (eg, because of treatment dropout or organizational issues), the patient can decide to have this session with another mental health professional or a clinical psychologist from the research team.

After the clinical session, an email is sent containing a link to a survey that assesses patients' and mental health professionals' experience of EMA and their perspectives on the EMA feedback report (Table 4). In case of nonresponse, 2 weekly reminders are sent. At this initial stage, we explore intrapersonal (ie, self-reflection and insight, self-efficacy, and subjective experiences) and interpersonal changes (ie, working alliance and helpful aspects during the clinical session) associated with the experience of EMA and the use of the EMA feedback report in treatment. The feedback survey also includes open questions assessing attitudes about self-monitoring, the content of the items, the feasibility of EMA, and the potential of EMIs for NSSI and other self-damaging behaviors (Table 4).

XSL•FO
RenderX

Table 4. Overview of constructs assessed in the feedback survey.

Survey battery	Measure and example item	Source	Items, n; response scale
Self-insight and reflection in general[a]	Adapted Self-Reflection and Insight Scale: "The self-monitoring made me more aware of my feelings and thoughts"	Original [116] and Dutch translation: FBT[b]	8; 6-point Likert scale
Self-efficacy in general	Adapted Self-Efficacy Scale: "By what I learned about myself through the self-monitoring, I feel that I am better able to solve difficult problems if I try hard enough"	Original [99] and Dutch translation [100]	10; 4-point Likert scale
Self-insight and reflection with respect to NSSI[c] and other self-damaging behaviors[a]	Adapted Self-Reflection and Insight Scale: (1) experience of EMA[d]: "The self-monitoring made me more aware of my triggers for self-injury" and (2) use of EMA in therapy: "Discussing the monitoring results together with my clinician made me more aware of my triggers for self-injury"	Original [116] and Dutch translation: FBT	10; 6-point Likert scale
Self-efficacy resisting NSSI and other self-damaging behaviors	Adapted Self-Efficacy Scale: (1) experience of EMA: "By what I learned about myself through the self-monitoring, I now know better what to do when I am experiencing an urge to self-injure" and (2) use of EMA in therapy: "By discussing the monitoring results together with my clinician, I now know better what to do when I am experiencing an urge to self-injure"	Original [99] and Dutch translation [100]	10; 4-point Likert scale
Effect of discussing EMA results in therapy on the working alliance[a]	Adapted Working Alliance Inventory (short version): (1) task: "Discussing the results together helped us to understand which changes I need to make," (2) bond: "I feel my clinician understands me better because of the monitoring results," and (3) goal: "Discussing the results together makes me feel we are both working toward the same goals in therapy"	Original [117] and Dutch translation: FBT	12; 6-point Likert scale
Helpful aspects during clinical session[a]	Questions assessing any helpful or hindering aspects of the session and experience of clinician and therapeutic session as engaging and supportive, open and authentic, empathic, explorative, confrontational, and making positive progress: "I believe that my problems can be addressed through therapy"	Original [118] and Dutch translation [119]	40; mixed
Subjective experiences of EMA	Questions assessing (1) negative experience: "The self-monitoring questions caused me stress," (2) positive experience: "I enjoyed the self-monitoring," (3) learning experience: "I would describe the self-monitoring as a learning experience," and (4) facilitates self-regulation: "The self-monitoring questions helped me to structure my thoughts"	Self-developed	12; 5-point Likert scale
Expectations of feedback and compensation	Questions assessing the overall and relative importance of receiving study findings, personal feedback, and financial compensation	Items from Kiekens et al [19] and self-developed	11; mixed
Qualitative feedback	Questions assessing attitudes about self-monitoring, content of the items, length of questionnaires, experience and feasibility of self-monitoring, utility and potential effect on the therapy process, and utility and scope of future interventions	Self-developed	10; open questions

[a]Clinician version also included these questions.

[b]FBT: forward-backward translation.

[c]NSSI: nonsuicidal self-injury.

[d]EMA: ecological momentary assessment.

Phase 3: Follow-up Surveys After 1 and 3 Months and (Optional) Interviews About Experiences and Attitudes Toward EMA and EMIs

Phase 3 includes 2 brief web-based follow-up surveys after 4 and 12 weeks and an optional interview. The surveys assess past-week psychological distress and the presence of NSSI and other self-damaging behaviors since completing the self-monitoring (first survey) or between the follow-up surveys (second survey; see questionnaires indicated with subscript in Table 1). In case of nonresponse, 2 weekly reminders are sent. The qualitative interviews assess more in depth the experiences of using EMA and the utility, content, and design of future EMIs for NSSI among a voluntary subsample of individuals seeking treatment (online after the feedback session) and mental health professionals (on site after they have participated with at least

XSL•FO
RenderX

2 patients in the study). The interview guides can be consulted on the project's Open Science Framework (OSF) page [115].

Participant Incentives and Engagement

Participants are recognized as valued contributors to the research and receive financial incentives, information about the overall findings, and feedback on their data. Patients are financially compensated via a structured financial scheme when (1) the feedback survey (if the EMA report was discussed) and (2) at least 1 of the follow-up surveys are completed: €35 (approximately US $38) if compliance with the monitoring protocol is >33% (or >55 EMA surveys), €70 (approximately US $76) if compliance is >65% or (>109 EMA surveys), and €100 (approximately US $109) if compliance is >83% (or >139 EMA surveys). Otherwise, patients receive €20 (approximately US $22) in financial compensation. In addition, personalized feedback reports are provided so that relevant information can be fed back into the therapy room. Patients can also opt in to receive updates on the general findings of the project. Finally, mental health professionals receive €10 (approximately US $11) as compensation for completing the feedback survey after the clinical session in which they discuss the EMA feedback report. We do not provide a financial incentive for participation in the interviews (phase 3).

Research Training and Well-being

All research activities are performed by clinically trained research staff. Risk monitoring of people who frequently self-injure requires good-quality training in working with individuals who engage in NSSI and are at increased risk for suicide [19]. Therefore, research staff who interact with participants and are part of the risk-monitoring team are licensed clinical psychologists who have received additional training that covered how to support participants during an acute suicidal crisis. In addition, although there is a psychologist *on call* outside of office hours, responsibility is always shared with the first and second authors (GK: PhD level and good clinical practice certified and LC: PhD level and cognitive behavioral therapist), who are available for supervision by telephone during recruitment hours. Finally, there are regular debriefings to ensure the well-being of all team members throughout the study's data collection period.

Statistical Analyses

Overview

The psychometric properties of baseline measures (eg, Cronbach α), EMA multi-item scales (eg, multilevel reliability [120]), and interrater reliability of diagnostic interviews (a subset of 20% of the sample, approximately 24 participants) will be reported. To accommodate the hierarchical structure of the EMA data (eg, observations nested within individuals), our 3 primary aims will be analyzed by using a combination of statistical techniques. First, descriptive statistics (eg, means, modes, SDs, intraclass coefficients, and correlations) will be used to describe the sample in terms of baseline characteristics; compliance rates; presence; comorbidity patterns; and moment-to-moment variability of NSSI outcomes across minutes, hours, days, and weeks. Second, we will use dynamic structural equation modeling (DSEM), which integrates three modeling approaches [121,122]: (1) time series analysis, which allows for modeling the lagged relation between repeated measures in a single participant; (2) multilevel modeling, which takes the higher-order data structure into account and models these relationships for multiple participants while capturing variability within and between persons over time; and (3) structural equation modeling, which takes measurement error into account and allows for multiple outcome variables, latent variables, and mediation effects [123].

Using DSEM will clarify the extent to which momentary factors at time point t_{-1} (eg, negative affect) predict NSSI thoughts, NSSI urges, self-efficacy to resist NSSI, and NSSI behavior (or other self-damaging behaviors) at time point *t*, above and beyond the lagged version of the outcome variable (ie, the autoregressive parameter) and confounding variables at time point t_{-1} (eg, NSSI urges in the prediction of NSSI behavior). We will attempt to include random intercepts (predictors and outcomes) and random slopes (predictors) for momentary variables, with an unrestricted correlation structure if models converge (the maximum number of iterations is 50,000 by default). The time interval (Tinterval) statement will account for unequally spaced intervals owing to missing data and random sampling within blocks, with missing data handled using a Kalman filter approach [122]. Given that all participants have a recent history of NSSI but do not necessarily engage in other self-damaging behaviors, models that investigate within-person associations with disordered eating, substance use, and STB will be based on a subsample of participants that show variation in these secondary outcomes.

Third, we will use group iterative multiple model estimation (R package *gimme* [124]) to assess between-person variability in risk associations. Group iterative multiple model estimation estimates a unified structural equation model that includes lagged and contemporaneous relations in a network model [124,125] and accurately recovers group-, subgroup-, and individual-level associations in time series data. Fourth, fully idiographic modeling will be applied based on each participant's time series data to identify the most relevant factors for each individual without overfitting models [126,127]. Elastic net regularization will be used as a statistical classification approach, which produces sparse models through coefficient penalization with k-fold cross-validation (R package *glmnet* [128]). Fifth, survival analysis will be used to investigate the factors that predict the transition from intense NSSI urges to behavior [129]. Importantly, however, as the analysis of intensive longitudinal data is a burgeoning field, newly available methods will also be considered (eg, continuous-time and Markov switching models [130-133]).

Finally, the secondary objective will be analyzed using a mixed methods approach. We will use thematic analysis to evaluate open-ended questions and interview data regarding end users' experiences and perspectives [134]. Quantitative questionnaire data will be analyzed using descriptive statistics and regression analyses to explore associations with demographic and clinical characteristics.

XSL•FO
RenderX

Expected Sample Size

We intend to recruit 120 individuals seeking treatment. Analyses that include 100 to 120 participants will yield sufficient statistical power (≥0.80) to detect within-person effects as small as 0.07 to 0.09 in multilevel autoregressive models. These power calculations were conducted using Monte Carlo simulations with the following conservative estimates [135]: a 1:0.67 ratio of random intercept to within-person residual deviation, a 1:0.25 ratio of random intercept to random slope SD, first-order and slope-intercept correlations of 0.5, and compliance of 60% to the regular EMA surveys. Recent studies have used pooled machine learning models with fewer observations and participants [127]. In addition, it has been shown recently that as few as 60 assessments from 25 individuals allow robust estimation of general, shared, and person-specific temporal associations in intensive longitudinal data [136].

Open Science Statement

All materials of the DAILY project can be consulted on the project's OSF page [115]. We will make the analysis plan, materials, and code of results in scientific publications available on the OSF page [137]. In addition, preprints will be uploaded on the PsyArXiv platform to ensure that findings are available to the wider research community. We do not have institutional review board approval to make the master data set publicly available, but we will make deidentified data available upon request for reproducibility purposes.

Results

The study is funded by a postdoctoral fellowship from the Research Foundation Flanders (Belgium) awarded to the first author (June 2020: 12ZZM21N; Multimedia Appendix 1). The recruitment of participants began in June 2021 and data collection is anticipated to conclude in August 2023.

Discussion

Principal Findings

The DAILY project is expected to advance scientific knowledge of (1) the short-term course and within-person risk and protective factors of NSSI thoughts, NSSI urges, self-efficacy to resist NSSI, and NSSI behavior among individuals seeking treatment; (2) the transition from NSSI thoughts and urges to NSSI behavior; and (3) the comorbidity patterns, unique versus shared risk factors, and temporal relationships of NSSI with other self-damaging behaviors. Such information will inform clinical practice about how, why, and when self-injury and other self-damaging behaviors unfold in the everyday lives of individuals seeking treatment. Building upon these findings, we will explore the experiences and perspectives of end users (ie, people with lived experience and their mental health professionals) about the feasibility, scope, and utility of EMA and EMIs as digital clinical tools in treatment. This will provide the scientific building blocks for novel intervention approaches outside of the therapy room to support individuals who self-injure in real time. For instance, a sophisticated EMI that shows promise for dynamic behaviors such as NSSI and STB is just-in-time adaptive interventions [29,138,139]. This highly innovative intervention design adapts the provision of support in terms of type, intensity, and timing to an individual's changing status and context to facilitate real-time interventions when and where they are needed most in everyday life and in ways that are appropriate and evidence based [140].

Limitations

Although EMA is a powerful methodology that can now more readily be used to provide previously unavailable information about the course, within-person predictors, comorbidity patterns, and clinical outcomes of NSSI in daily life [19], it is crucial to consider the implications and limitations of the protocol used and the design when interpreting the project's findings. First, although measures are in place to ensure that recruitment is inclusive and geographically representative, with recruitment sites spread across the entire Flanders region of Belgium, it should be acknowledged that we use convenience sampling, with the targeted sample comprising individuals currently receiving mental health treatment. This implies that the findings should not be generalized to nonclinical populations because the short-term course of NSSI will likely differ in severity for community samples. Relatedly, adolescents can only participate from the age of 15 years, meaning that the findings are not generalizable to early adolescents (aged 10-14 years) and should be studied in this population. Second, the intensive sampling scheme matches the project's research objectives but involves a higher burden than traditional longitudinal studies (typically 1-5 surveys months to years apart) and most EMA studies (typically lasting 1 week) [26]. Although scholars have observed increased burden with longer questionnaires but not with increased sampling frequency among community samples [141], it should be investigated to what extent the current EMA sampling scheme and duration were considered feasible by all individuals seeking treatment. Third, we implemented safety measures for NSSI and other self-damaging behaviors (including the monitoring of suicide risk) based on prespecified cutoffs of momentary urges and low self-efficacy to resist a behavior. Future research would benefit from evaluating risk thresholds and the utility of different safety measures (eg, personal vs standard message and human-led vs automatic action) at varying risk levels for self-damaging behaviors.

Fourth, we operationalize NSSI and other self-damaging behaviors comprehensively (ie, thoughts, urges, and behavior) and assess a broad range of theoretically relevant factors (emotions, cognitions, contextual information, and social appraisals); however, as a consequence, most constructs rely on single EMA items that were selected from prior EMA studies or modified from conventional survey questionnaires to keep the workload for participants under control [141]. However, against the backdrop of a lack of psychometrically validated items for assessing psychological constructs with EMA [142] and a need to develop standardized measures [143], we will calculate the multilevel reliability of composite constructs (eg, negative affect) and made all EMA items (for the original Dutch items see the OSF page) publicly available [107]. Fifth, we provided additional (shorter) EMA surveys when participants report intense NSSI urges and contact participants and clinical staff when there is an increased suicide risk, which might result in underreporting of NSSI urges and STB. Sixth, because all

XSL•FO
RenderX

participants receive mental health treatment, there might be structural changes in the descriptive patterns of self-damaging thoughts and behaviors across the monitoring period. We will evaluate this, and if the assumption of stationarity is violated, we will include days since study enrollment as a covariate for the outcome under investigation. Finally, we may miss moments leading up to self-damaging behaviors in the late evening and overnight as no EMA surveys are scheduled after 10 PM. Although we can assess to what extent this is the case for NSSI behavior (as people could register self-injury via the push button in the m-Path app), future research might benefit from sampling schemes adapted to people's sleep and wake-up times.

Conclusions

Notwithstanding the limitations, the findings of the DAILY project will provide a detailed characterization of the course and patterns of risk for NSSI during treatment by considering NSSI thoughts, NSSI urges, self-efficacy to resist NSSI, and NSSI behavior in the daily lives of individuals seeking treatment. This will help to increase our understanding of how NSSI unfolds across minutes, hours, days, and weeks. Filling these critical knowledge gaps using EMA will lay the foundation for, and guide, the development of novel interventions that support people when and where it matters most in daily life [29,138]. This scientific endeavor may facilitate young people's recovery from self-injury and ultimately could help us prevent loss of life.

Acknowledgments

The authors wish to thank all patients and mental health professionals for their participation and the following individuals for their assistance in the setup and execution of the DAILY (Detection of Acute rIsk of seLf-injurY) project: Silke Apers, Kristina Eggermont, Elise van Laere, Louise Staring, Daphne Tuyaerts, and Martien Wampers. The involvement of Kristina Eggermont was funded by the Internal Funds of the KU Leuven Research Council (C14/21/052; principal investigator: KL) and Research Foundation Flanders (Belgium; G070620N; principal investigator: KL). The involvement of NDFK, SS, Louise Staring, and Daphne Tuyaerts was funded by the FWO Odysseus program (G0F8416N; principal investigator: IM-G). The authors also gratefully acknowledge all mental health services for their collaboration and contributions: Alexianen Zorggroep Tienen, Bethanië Zoersel, Karus (JOVO) Gent, Openbaar Psychiatrisch Zorgcentrum Rekem, Psychiatrisch Centrum Sint-Hiëronymus Sint-Niklaas, People Development Leuven, Psychotherapiepraktijk Katrien Oosterlynck Aalst, Psychiatrisch Ziekenhuis Asster Sint-Truiden, Psychiatrisch Ziekenhuis Onze-Lieve-Vrouw Brugge, Universitair Psychiatrisch Centrum KU Leuven, Stuvo KU Leuven, Universitair Psychiatrisch Centrum Duffel, and Universitair Ziekenhuis Gent.

Abstract

Background: Suicide is the second leading cause of death in adolescents, and self-harm is one of the strongest predictors of death by suicide. The rates of adolescents presenting to emergency departments (EDs) for suicidal thoughts and behaviors (STBs) have increased. Still, existing follow-up after ED discharge is inadequate, leaving a high-risk period for reattempts and suicide. There is a need for innovative evaluation of imminent suicide risk factors in these patients, focusing on continuous real-time evaluations with low assessment burden and minimal reliance on patient disclosure of suicidal intent.

Objective: This study examines prospective longitudinal associations between observed real-time mobile passive sensing, including communication and activity patterns, and clinical and self-reported assessments of STB over 6 months.

Methods: This study will include 90 adolescents recruited on their first outpatient clinic visit following their discharge from the ED due to a recent STB. Participants will complete brief weekly assessments and be monitored continuously for their mobile app usage, including mobility, activity, and communication patterns, over 6 months using the iFeel research app. Participants will complete 4 in-person visits for clinical assessment at baseline and at the 1-, 3-, and 6-month follow-ups. The digital data will be processed, involving feature extraction, scaling, selection, and dimensionality reduction. Passive monitoring data will be analyzed using both classical machine learning models and deep learning models to identify proximal associations between real-time observed communication, activity patterns, and STB. The data will be split into a training and validation data set, and predictions will be matched against the clinical evaluations and self-reported STB events (ie, labels). To use both labeled and unlabeled digital data (ie, passively collected), we will use semisupervised methods in conjunction with a novel method that is based on anomaly detection notions.

Results: Participant recruitment and follow-up started in February 2021 and are expected to be completed by 2024. We expect to find prospective proximal associations between mobile sensor communication, activity data, and STB outcomes. We will test predictive models for suicidal behaviors among high-risk adolescents.

Conclusions: Developing digital markers of STB in a real-world sample of high-risk adolescents presenting to ED can inform different interventions and provide an objective means to assess the risk of suicidal behaviors. The results of this study will be the first step toward large-scale validation that may lead to suicide risk measures that aid psychiatric follow-up, decision-making, and targeted treatments. This novel assessment could facilitate timely identification and intervention to save young people's lives.

Introduction

Background

Suicide is the second-leading cause of death globally among adolescents. Adolescence is a critically vulnerable developmental period for suicidal thoughts and behaviors (STBs). Youth emergency department (ED) visits for STB increased in many countries, particularly during the COVID-19 pandemic [1,2]. These incidents extend into long-term risk, as a history of suicide behaviors among youth is associated with an increased risk of repeat attempts and subsequent death [3]. The weeks and months following ED admission are at the highest risk for reattempts and suicide [4]. Suicidal crises in adolescents are often brief and episodic, with considerable potential for recurrence [5]. Adolescents are susceptible to interpersonal belonging, rejection, and conflict that may predispose them to imminent STB [6]. They have limited ability to regulate emotions and use cognitive control to inhibit problem behaviors, including suicidal acts when facing acute stress [5]. Therefore, the rapid-fluctuating acute suicidal states in adolescents warrant an improved proximal prediction of imminent STB.

Identifying proximal predictors for STB is critical to a better understanding of when individuals are most at risk [7]. It is distinguished from the unsuccessful scientific and clinical attempts to predict who is at risk [8] at the population level. In other words, the critical problem is to predict whether an individual with well-known preexisting risk factors is at imminent suicide risk (ie, within the next hours, days, or weeks) [9]. Two presuicidal mental state-specific diagnoses have been recently proposed in this context. Acute affective disturbance and suicide crisis syndrome are 2 conditions suggested to lead to imminent suicidal thoughts or behaviors [10,11]. Acute suicidal affective disturbance [12] is characterized by a sudden increase in suicidal intent and marked social alienation. Suicide crisis syndrome [13] is characterized by an intense sense of being trapped or unable to see any other way out. This condition is accompanied by experiencing affective disturbance, loss of cognitive control, and difficulty functioning in their social lives. The transdiagnostic approach suggested by these 2 diagnoses not only enables a more accurate and objective assessment of imminent suicide risk but could also facilitate research in developing digital markers of suicide risk.

Intensive longitudinal methods (ie, repeatedly assessing individuals over time) provide the unique opportunity to study proximal predictors of STB within individuals. Recent studies have begun using real-time mobile and wearable devices to predict STB, and the feasibility and acceptability of intensive monitoring in adolescents have been established [14,15]. Existing efforts are mainly focused on using intensive self-report assessments such as ecological momentary and daily diaries. These studies provided valuable information about the temporal dynamics of suicidal ideation [16,17] and significant proximal predictors, such as sleep problems and interpersonal stress [18-20]. However, the substantial reliance on self-reports requires insight and compliance, and the associated assessment burden limits study durations and applicability to real-world settings. Passive sensing of mobile data has been proposed as a promising direction for future research [14,21]. It allows naturalistic and continuous data collection with minimal burden, including social, communication, activity, and sleep patterns [22], in which change may indicate imminent STB. Recognizing objective web-based and offline social behavior patterns preceding STB may be particularly beneficial for adolescents. Pioneering studies have demonstrated that passive mobile sensing by actigraphy [23-26] may predict STB. An existing study demonstrated the usefulness of predicting symptoms in patients with major depressive disorder through passive data collection (electrodermal activity, sleep patterns, motion, communication, location changes, and phone usage patterns) from built-in sensors in phones and a wearable device [23-26]. Another study demonstrated the feasibility of predicting patients' moods using machine learning algorithms with privacy-preserving techniques through multimodal data collection (text, audio, and sensor data) from patients' mobile devices [23-26]. However, to our knowledge, there are no studies investigating proximal predictors of youth STB via real-time mobile passive sensing, including communication and activity patterns, and clinical and self-reported assessments over 6 months.

Unlike previous research that considered individual risk factors, a machine learning approach to passive mobile sensing can examine multiple risk factors and their combinations to build superior prediction models. This approach may identify complex real-life patterns and relationships and improve the near-term identification of risk and timely interventions [27,28]. However, the performance of passive sensing and machine learning over traditional methods for suicide risk classification and the interpretability of their findings demand further research [29-31]. Additional work in naturalistic settings is needed to unlock the potential of active and passive sensing and machine learning prediction models for suicide prevention. In addition, further research is required to develop prediction models optimized for implementation in clinical settings [28-30,32,33]. A longer follow-up period is needed to examine proximal predictors of suicidal behaviors (ie, recurrent attempts, ED admissions, and hospitalization) that may be clinically informative for suicide risk management in clinical settings. Furthermore, previous studies typically involved substantial payments for study participation, intensive compliance strategies, and safety procedures that may not be generalizable to real-world settings. This study addresses these challenges and will use intensive digital monitoring of self-reported and behavioral data in a real-time and real-world outpatient clinical setting.

Study Aims and Objectives

Overview

This study will address the knowledge gap in real-time proximal predictors of youth STB. It will be the first to use active and passive digital monitoring in a longitudinal prospective study among high-risk adolescents in a real-world clinical setting. The current research, therefore, attempts to provide a proof of concept for digital markers of imminent STB to classify adolescents with high-risk STB versus those with lower risk, enabling a more accurate and objective assessment of imminent suicide risk. The project's objectives integrate multiple digitally derived data sources, including behavioral, interpersonal, and frequent subjective self-reports, using comprehensive and nonintrusive techniques. This project has 2 main aims.

Aim 1

The first aim is to demonstrate the clinical utility of digital weekly self-reports in the identification of adolescents at risk for STB in a real-world high-risk clinical setting.

- Hypothesis 1: There will be satisfactory compliance (>60%) for weekly digital assessments of STB and main risk factors, and it will be accepted among adolescents, parents, and mental health professionals for routine clinical suicide risk management and care.
- Hypothesis 2: The weekly digital assessments of STB and main risk factors will demonstrate concurrent and prospective associations with clinical assessments of STB at the 1-, 3-, and 6-month follow-up, measured by the Columbia Suicide Severity Scale (C-SSRS) [34], and ED admissions.

Aim 2

The second aim is to develop an integrated prediction model using passive mobile sensing data for STB prediction.

- Hypothesis 3: The passively derived mobile usage data will accurately classify adolescents with high-risk STB versus those with lower risk over 6 months of follow-up as determined by clinical evaluations.
- Hypothesis 4: The passively derived mobile usage data will predict same- and next-week adolescents' self-reported STB.
- Hypothesis 5: Integrating passive sensing and active self-reports will predict high-risk STB more accurately than each data source alone.

Overall, this project aims to use state-of-the-art digital technologies to identify proximal predictors of youth STB. These methods may provide the invaluable capacity to develop real-time prediction models, crucial steps toward clinical applications, and life-saving interventions.

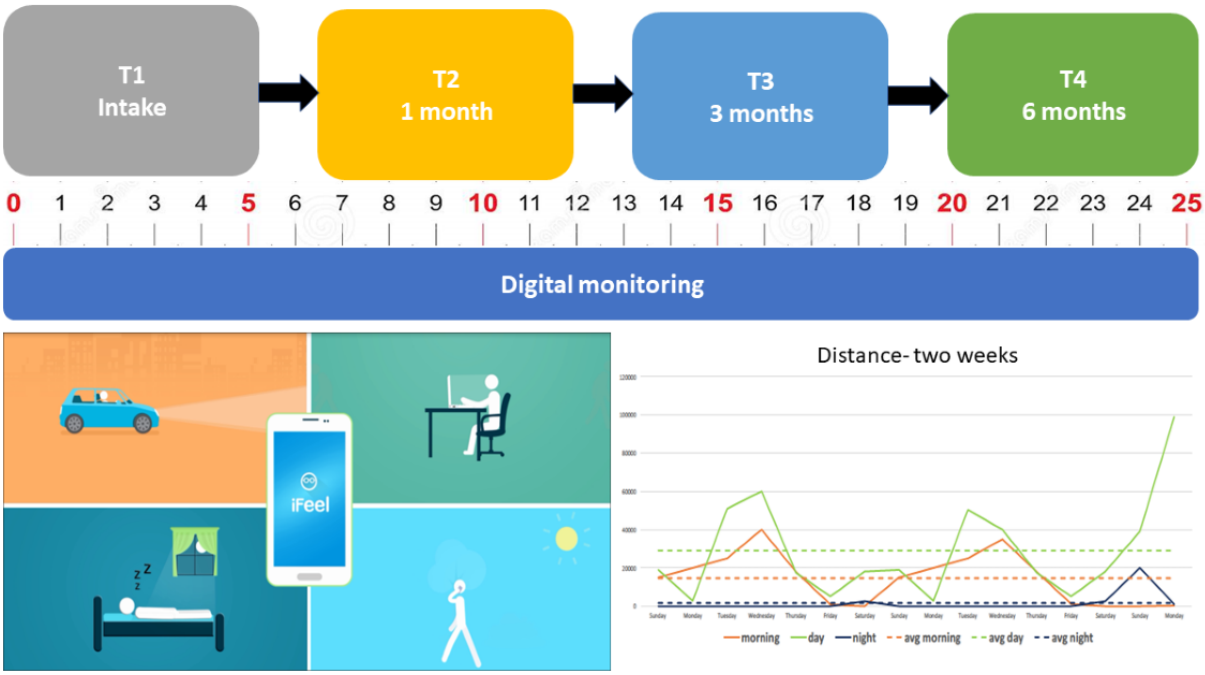
Methods

Study Design

The study target sample includes 90 high-risk adolescents aged 11-18 years presenting to the ED with recent STB and recruited at the Depression and Self-Harm Clinic at Schneider Children's Medical Center of Israel. All eligible patients identified in the ED will be referred to the Depression and Self-Harm Clinic. Participants will complete brief weekly assessments and be monitored continuously for their mobile app usage, including mobility, activity, and communication patterns, over 6 months using the iFeel (inManage Ltd) research app. Participants will complete 4 in-person visits for clinical assessment at baseline and at the 1-, 3-, and 6-month follow-ups.

Procedures

Consecutive admissions to the clinic will be recruited for the study. Clinical staff will notify the research staff of potential eligible recruitment. Senior research staff will explain the study in detail according to local ethical requirements, followed by signed parental consent and the child's signed assent (if over 16 years). Study participation, or lack thereof, will not affect the standard psychosocial and pharmacological services provided to participants. The response rate and time between ED admission and clinic admission will be recorded and examined in this study.



The inclusion criteria includes (1) adolescents between the ages of 11 and 18 years presenting with recent (past month) suicidal ideation or suicidal behavior (3 months), as defined by the C-SSRS [34] (preparatory acts, aborted, interrupted, and actual suicide attempts, or nonsuicidal self-injury), and (2) Android phone users (required for the iFeel app).

The exclusion criteria includes participants with acute medical conditions, mental retardation, cognitive impairment, or linguistic limitations preclude understanding the research questions.

Participants will complete a comprehensive assessment battery (T1) and download the iFeel app using a random app-generated code. Once downloaded, the app will gather relevant information from the mobile phone for the next 6 months and prompt participants to respond to weekly brief questionnaires, including STB measurements and main risk factors. Research assistants will train the participants on the weekly survey protocol and questions, emphasize the importance of adherence, provide examples, and instruct them on how to use the subjective rating scales. Research assistants will contact participants during the follow-up period in cases of missing active or passive data collection and assist with technical or adherence issues. Participants will be invited for extended follow-up evaluations at 1 (T2), 3 (T3), and 6 months following the initial assessment (T4; see Figure 1). These will include in-person or remote video clinical assessments and self-report assessment scales administered via secured web-based surveys.

XSL•FO
RenderX

Figure 1. Illustration of study assessments. Initial and 1-, 3-, and 6-month extended assessments; 25 weekly digital self-report assessments over 6 months; and continuous passive mobile data usage monitoring (including mobility, activity, communication, and sleep patterns).

Real-Time Mobile Data Collection via the iFeel App

iFeel is an innovative digital health research platform that enables passive and active digital monitoring and provides continuous objective measurements for any given disorder. iFeel will harness mobile phone data to find associations between digital markers and STB ratings obtained via weekly self-reports and clinical assessments during study visits. The data will be collected using the iFeel mobile phone app. The information to be measured via mobile phones using the app will consist of the following:

- Communication patterns: number of phone calls (without phone numbers), duration of incoming and outgoing phone calls, communication app usage duration
- Activity patterns: accelerometer data and total distance accumulated
- Device usage: number of devices and screen opens and locks, time of screen active, Wi-Fi connections, Bluetooth connections, data usage (bits), battery usage, log of app usage, luminosity, device positioning (horizontal or vertical), and screen touch parameters (strength and frequency of touch)

All the collected information has no identifiable information and no intention to change the patient's treatment in this study.

Weekly Data Collection for STB

A brief self-report questionnaire will be generated by the iFeel app using push notifications once a week. Three items were selected to assess the main risk factors for STB based on the presuicidal mental state–specific diagnoses (ie, acute suicidal affective disorder and suicide crisis syndrome). These include general mood ("In general, how was your mood this week?"), entrapment ("Did you feel like there was no way out?"), and social isolation ("Did you feel isolated?"), rated on a visual analog scale between 1 and 5. The STB items are adapted from the C-SSRS [34] and include assessing suicidal ideation intensity (rated on a visual analog scale between 1 and 5), intent, plan, behavior, attempt, and nonsuicidal self-injury. If a participant indicates yes to a suicidal plan, current intent, or behavior, a safety protocol will be initiated whereby crisis and community services are made available to the adolescent, and contact is made with a parent (see the Ethics Approval and Adverse Events and Safety Procedures section).

In-Person Visits Measures (T1-T4)

The in-person visits measures include the following:

1. The Mini International Neuropsychiatric Interview for Children and Adolescents (MINI-KID) [35] will be administered at the initial assessment.
2. C-SSRS (Child Version) [34]: Evidence-based and commonly used suicidality scale.
3. Youth Suicide Crisis Inventory (Y-SCI) [36]; patient, parent, and clinician reports. The Y-SCI includes items derived, abridged, and adapted for adolescents from the original scale [37].
4. Strengths and Difficulties Questionnaire (SDQ) [38]: A 25-item questionnaire for assessing the psychological adjustment of children and youth, including 5 subscales—emotional symptoms, conduct problems, hyperactivity or inattention, peer-relationship problems, and prosocial behaviors.
5. Mood and Feelings Questionnaire (MFQ) [39]: A 13-item scale assessing depressive symptoms.
6. Social Adjustment Scale-Self-report (SAS-SR) [40]: A measure of social functioning in the family, school, and peer group domains.

XSL•FO
RenderX

7. Affective Reactivity Index (ARI) [41]: A 7-item parent- and self-reported concise dimensional measure of irritability.
8. Athens Insomnia Scale (AIS) [42]: An 8-item scale rated on a 0-3 scale for insomnia symptoms.
9. Sociodemographic and clinical information: Data will be collected on demographics, household composition, place of birth, parental employment, and religiosity. Information on medications, psychotherapy, ED visits, psychiatric hospitalizations due to STB, and other causes will be recorded.
10. Satisfaction survey: A 5-question (Likert-scale and open-ended) patient- and parent-satisfaction survey questionnaire about their experience and concerns about the monitoring app and procedures. A compatible, adapted version of the patient satisfaction survey will be used to capture clinicians' experiences with ease of use and perceived utility.

Data Analysis

Missing Data

While we will attempt to minimize missingness, missing data is typical and expected. Missing data will be examined for their possible clinical meaning by attrition and compliance analyses (eg, comparing completers to noncompleters and clinical correlations with missingness rate). We will investigate the pattern of missingness and use recommended methods [43] that consider the temporal nature of the data while constructing embedded, dense representations for sparse input data. We will adjust for the influence of the missingness rate on the prediction models.

Aim 1

We will conduct a descriptive analysis of the sample and compliance rate (mean, SD, frequency, and within-person correlations for the primary study variables). Given the expected low base rate of different suicidal behaviors, we will group the responses of the adapted C-SSRS into high-risk STB presence (Yes or No) based on their frequencies. We will assess the prediction of STB using logistic regression analyses and machine learning models (eg, random forest) for high-risk STB and nonhigh-risk STB group classification as the outcome. We will conduct multilevel modeling with a random intercept and random slope model (linear or logistic models). Predictors will be person-centered to compute within-person weekly fluctuations compared to an individual's mean. Level 2 predictors will include the corresponding individual mean level. Sociodemographic effects and treatment intervention type and duration will be examined for their effect on the results and adjusted for. The predictive accuracy of STB by weekly surveys will be estimated by a receiver-operating characteristic curve, the generalized area under the curve, precision, recall, and F_1 score [44]. We aim to identify the optimal prediction model by comparing different prediction models. The results of the satisfaction questionnaires will be analyzed using descriptive statistics and qualitative processing of open-ended text answers.

Aim 2

The analyses will include feature extraction, scaling, selection, embedding, and dimensionality reduction [22]. Our modeling approach uses unsupervised methods to learn useful representations using, for example, variational autoencoders [45] and underlying structures (eg, classical clustering methods). Multimodality will be handled using classical ensemble methods and the more advanced attention mechanism [46]. Similarly, sparsity will be handled using classical imputation methods and embedding (learned representation) processes [43]. Next, we will train and validate predictive models to infer higher-level activities (eg, conversation, activity and social media use) from raw sensor data. The labels will be used to train and validate the predictive models. A major challenge stems from the fact that the number of available labels is relatively small, while there is much more unlabeled (digital) data captured (continuously and passively) from the mobile phone. To use both labeled and unlabeled data, we will use semisupervised methods in conjunction with a novel method that is based on anomaly detection notions. The data will be split into training and test (holdout) data sets. Digital markers and predictive models are trained and cross-validated with k-fold cross-validation using the training set. Next, we use the test set (hold out data) to perform statistical validation and get an unbiased evaluation of the final model. The data split is stratified and performed at the patient level into 75% train and 25% test. Prediction models with STB as the outcome will adjust for potential confounders such as missingness rate, between-subject variability, diurnal and seasonal effects, and interventions. We will use classification modeling approaches (eg, random forest) appropriate for the sparsity of the data and relatively small sample size [28,47]. The performance of the machine learning methods using different data sources will be tested and compared using the generalized area under the curve, precision, recall, and F_1 score [44].

Power Statement

For multilevel models, we considered an unconditional 2-level model of the within-person longitudinal data with repeated weekly assessments (Level 1) collected across subjects (Level 2). Assuming a 75% completion rate with a power of 80%, repeated measures=25 (ie, weekly entries over 6 months), and ICC=0.5 (based on prior longitudinal studies), we need a sample of 90 adolescents. For machine learning models, the sample size represents the data held out for validation. Based on our previous studies in this population [48], over 6 months of follow-up, we expect at least 15% of the patients will have one or more self-harm incidents and 10% will have repeated ED admissions and hospitalizations. For chi-square goodness of fit, a medium effect size (d=0.5), and a power of 80%, 55 incidents are needed for validation, which will be approximately 10 unique patients. A Mann-Whitney-Wilcoxon test with similar power, effect size, and alpha provides similar results.

Ethics Approval

Study procedures were approved by the Rabin Medical Center Institutional Review Board (ID #0433-20). Specific ethical considerations that were included in the study protocol are detailed below.

XSL•FO
RenderX

Data Management and Confidentiality

The study assessment battery, including demographic information and self-reported outcome measures, will be completed through a secured web-based survey. The iFeel app ensures user privacy and anonymity with proper security data server protection software (eg, no data could be paired to a specific user). Privacy and information security comply with the European Union's privacy requirements. The data will not include any other identifying information. The research coordinator will record the key to identifying details on a secured log, which will be kept separately and password protected.

Adverse Events and Safety Procedures

Study assessments are performed by clinical research staff trained in suicide risk assessment using the study scales. Senior clinical staff and principal investigators will be available to the research staff by cell phone. Patients and parents will be informed that confidentiality will be kept unless there is a serious and imminent safety concern. In such an event, the disclosure will be made to a licensed clinician on the study team, the principal investigators, and the child's therapist. The surveys will only be sent during regular business hours (8 AM-4 PM) to ensure the research team has the capacity to respond to weekly surveys that positively endorse STB. If a participant rates STB above the predefined clinical cut point, a follow-up question will be triggered to confirm their valid response. If they confirm active intent to self-harm, a text box will be prompted, providing information on emergent clinical services. Immediately following these endorsements, the principal investigators and study staff will receive an email regarding the participants' responses. The principal investigators or licensed clinicians will thoroughly assess the participant during the same business day and respond according to the clinical practice guidelines of the medical center. In the case of adverse events (suicide attempt or other health-risk behaviors such as substance use intoxication, as well as hospitalization for suicide risk), a full report will be submitted to the institutional review board, principal investigators, and directors of the depression clinic. Our approach is consistent with expert consensus statements on ethical and safety practices for conducting digital monitoring studies with individuals at risk for suicide [49].

Results

We expect to find longitudinal, concurrent, and prospective associations between the digital markers and self-reported and clinical assessments of STB outcomes. Successful outcomes of the proposed study will: (1) develop the ability to predict imminent STB using mobile data in a real-time, real-world setting, (2) provide an innovative and robust methodology for future studies and clinical trials to examine mental states with minimal burden and self-report bias, and (3) provide a powerful tool to identify youth at risk for suicide. The technology for this project was developed and made available for participant recruitment. Participant recruitment and follow-up started in February 2021 and are expected to be completed by 2024. The digital monitoring and clinical follow-up assessments will continue until the last participant has finished enrollment in the study. The interim data analysis began after 6 months of recruitment, and the final data analysis will be done after recruitment and follow-up assessments are completed.

Discussion

This study aims to fill the knowledge gap in real-time predictors of STB using active and passive digital monitoring in a clinical setting. The study has 2 main objectives: (1) to demonstrate the clinical utility of weekly digital self-reports in identifying adolescents at risk for STB and (2) to develop an integrated prediction model using passive mobile sensing data for STB prediction. Based on the study hypotheses, the main anticipated findings of this study would be the significant associations between digital assessments and clinical assessments of STB, accurate classification of adolescents with high-risk STB using passive mobile usage data, and improved prediction of high-risk STB by integrating active self-reports and passive mobile sensing.

This study will contribute to the scientific and clinical efforts to understand, detect, and prevent STB in youth. While most previous studies used intensive self-reports, previous studies have also demonstrated the usefulness of predicting symptoms in patients with major depressive disorder and mood prediction in patients using machine learning algorithms with multimodal data collection from mobile devices [23-26,50]. However, this is one of the first studies to investigate proximal predictors of youth STB using real-time mobile passive sensing, including communication and activity patterns, and clinical and self-reported assessments over 6 months. Furthermore, this study will add to the limited body of literature providing results in a naturalistic setting, which is crucial to developing optimized prediction models for practical implementation in clinical settings [29].

This study has several limitations that are important to consider. As is common in intensive longitudinal studies, there are challenges in participant recruitment and retention, expected missing data due to equipment failures and nonadherence to study protocol, concerns about the power and limitations of weekly digital self-report assessments instead of daily assessments, disruptions in passive sensing information through mobile phones, psychometric validity concerns with digital self-reports, and concerns about overfitting and generalizability. To address these limitations, the study has developed a protocol for participant recruitment and retention, implemented reminder protocols and positive reinforcements, has backup systems for data, followed recommended practices for self-report reliability and validity, and will perform robust testing methodologies for working with small data sets and outcome points. The study will also adjust for mental health interventions received and document each contact.

While more intensive daily reports could better capture STB fluctuations and associations, we believe weekly assessments will be novel, feasible, and most generalizable for clinical settings. Moreover, the substantial reliance on daily self-reports requires greater compliance, which could burden patients, and weekly digital assessments of STB rather than daily could lead to greater satisfactory compliance, which can be translated to

XSL•FO
RenderX

clinical practice. The goal of the study is to provide proof of concept for using digital technology through mobile phones to identify the risk of youth suicidal behaviors more effectively. The results of this study will be the first step toward large-scale validation that may ultimately result in practical prediction models and immediate interventions to prevent suicide.

The results of this study can have a significant impact on developing future technology-based projects for suicide prevention. To ensure that the findings reach a wider audience, we plan to disseminate the study results through multiple channels, including manuscripts, social media, webinars, and conferences. The aim is to reach a broad audience of health care professionals, researchers, and policy makers. By disseminating the study's results through multiple channels, we hope to maximize its impact and ensure that it reaches a broad audience, including clinicians, researchers, policy makers, and advocacy groups. Future investigations have the potential to expand upon the findings of this study and contribute to the development of more advanced prediction models for STB in adolescents. Due to the relatively rare occurrence of suicidal behaviors, it may be beneficial to conduct a large-scale study or engage in collaborative research efforts focused on digital monitoring and prediction of STB. In addition, by combining physiological measurements obtained through wearable devices, valuable information on activity and arousal can be incorporated, validating the smartphone-based digital markers and addressing certain limitations. Therefore, the combination of these approaches in future studies offers advantages. Moreover, future advancements may involve the inclusion of additional data sources such as acoustic features and natural language processing, which were not considered in this particular study. By expanding the scope of data collection, a more comprehensive understanding of STB prediction can be achieved. Finally, to accomplish the goal of prevention, future studies should also concentrate on developing and evaluating adaptive interventions that take into account individual circumstances indicated by digital monitoring. These interventions should be informed by data obtained through both active and passive monitoring, allowing for effective responses to digital prompts and the provision of timely support.

Defining proximal risk factors in youth may significantly improve the clinical evaluation of imminent suicide risk. Relying more on passive sensing than self-reported data to identify the risk for suicidal behavior will make interventions more scalable and effective. With minimal assessment burden and reliance on patient disclosure of suicidal intent, digital markers can inform different interventions and provide an objective means to measure psychosocial or pharmacological treatment efficacy. Integrating multiple self-reported and passive data sources into a validated prediction model can improve the identification of adolescents at risk for STB. The ability to predict STB using mobile data in real-time, real-world settings has tremendous potential for suicide risk identification and prevention. It can enable personalized and just-in-time interventions triggered based on passive mobile usage and self-reported data, preventing adolescent injury and mortality.

Abstract

Background: Chronic insomnia is one of the most common health problems among veterans and negatively impacts their health, function, and quality of life. Although cognitive behavioral therapy for insomnia (CBT-I) is the first-line recommended treatment, sedative-hypnotic medications remain the most common. Sedative-hypnotics, however, have mixed effectiveness, are frequently prescribed longer than recommended, and are associated with numerous risks and adverse effects that negatively impact veteran function. Meeting the treatment needs of veterans impacted by insomnia requires delivering gold standard behavioral care, like CBT-I, and the reduction of sedative-hypnotics through innovative methods.

Objective: The objective of this feasibility clinical trial is to test a digital CBT-I approach combined with deprescribing to improve the success of sedative-hypnotic reduction among veterans. The intervention combines Noctem Health Clinician Operated Assistive Sleep Technology (COAST), an effective and efficient, scalable, and adaptable digital platform to deliver CBT-I, with clinical pharmacy practitioner (CPP)–led deprescribing of sedative-hypnotic medications.

Methods: In this nonrandomized single-group clinical trial, 50 veterans will be recruited and enrolled to receive CBT-I delivered via Noctem COAST and CPP-led deprescribing for up to 12 weeks. Assessments will occur at baseline, posttreatment, and 3-month follow-up. The aims are to (1) assess the feasibility of recruiting veterans with chronic sedative-hypnotic use to participate in the combined intervention, (2) evaluate veterans' acceptability and usability of the COAST platform, and (3) measure changes in veterans' sleep, sedative-hypnotic use, and function at baseline, posttreatment, and 3-month follow-up.

Results: The institutional review board approved the study in October 2021 and the trial was initiated in May 2022. Recruitment and data collection began in September 2022 and is anticipated to be completed in April 2024. Aim 1 will be measured by tracking the response to a mail-centric recruitment approach using electronic medical records to identify potentially eligible veterans based on sedative-hypnotic use. Aim 2 will be measured using the Post-Study System Usability Questionnaire, assessing overall usability as well as system usefulness, information quality, and interface quality. Aim 3 will use the Insomnia Severity Index and sleep diaries to measure change in insomnia outcomes, the Patient-Reported Outcome Measurement Information System Profile to

XSL•FO
RenderX

measure change in physical function, anxiety, depression, fatigue, sleep disturbance, participation in social roles, pain, cognitive function, and self-reported sedative-hypnotic use to measure change in dose and frequency of use.

Conclusions: Findings will inform the utility of a combined digital CBT-I and CPP-led deprescribing intervention and the development of an adequately powered clinical trial to test the effectiveness in a diverse sample of veterans. Further, findings will help inform potential new approaches to deliver care and improve access to care for veterans with insomnia, many of whom use sedative-hypnotics that may be ineffective and increase the risk for negative outcomes.

Introduction

Background

Chronic insomnia is one of the most common health problems among veterans and has a significant negative impact on health, function, and quality of life [1-3]. Insomnia impacts over 50% of veterans [2,4] and contributes to functional impairment, fatigue, reduced alertness, and impaired memory, attention, concentration, and work performance [5-8]. Insomnia also negatively affects comorbid health problems and increases the risk of depression, anxiety, substance use, chronic pain, cardiometabolic disorders, and suicidal behaviors [9-11]. In the general population, COVID-19 pandemic continues to cause significant stress and worry about health and has been associated with increased rates of insomnia as high as 38% and concurrent increases in prescriptions for sedative-hypnotic medications (eg, non–benzodiazepine receptor agonists, such as zolpidem, eszopiclone, zaleplon], temazepam, trazodone) [12-14].

Nonpharmacological treatments of insomnia are the first-line recommended treatment for insomnia. However, sedative-hypnotics (eg, non–benzodiazepine receptor agonists known as z-drugs, such as temazepam and trazodone) are the most common treatment for insomnia, ranging from 5% to 14% in large cohort studies, and even higher rates in survey studies (upward of 25%) [15,16]. Sedative-hypnotic use is associated with increased risks, functional impairment, and negative quality of life and health outcomes [14-16]. Daytime fatigue, impaired cognitive and psychomotor functioning, falls and fractures [17], as well as rare, yet serious, events such as sleep-driving, are linked with the use of sedative-hypnotics [18]. Although considered effective for short-term treatment of insomnia, meaning a few weeks to months, these medications are often taken well beyond 1 year [19,20] despite epidemiological research indicating sleep medications taken for at least one year may be related to elevated incidence of cancer and an increased risk of death (controlling for prior cancer diagnosis) [19]. Use of sedative-hypnotics, especially benzodiazepines, can result in tolerance, dependence, or abuse [20]. Furthermore, these medications only treat insomnia symptoms rather than underlying causal factors, and discontinuation often results in rebound insomnia [20]. Importantly, many patients prefer to avoid sedative-hypnotics if an alternative treatment is available [21]. In sum, sedative-hypnotics are the most common treatment for insomnia by a wide margin, [16,22] but are not the recommended first-line treatment for chronic insomnia [3,23,24].

The state of the science specifies that behavioral interventions, like cognitive behavioral therapy for insomnia (CBT-I), are the first line treatment for chronic insomnia [3,23,24]. Studies within and outside the Veterans Health Administration (VHA) demonstrate that CBT-I significantly improves insomnia symptoms, nighttime sleep quality, and daytime function [25-27]. CBT-I is a multicomponent evidence-based psychotherapy that includes stimulus control [28], sleep restriction [29], cognitive therapy [30], sleep hygiene [31], and relaxation [32]. CBT-I is typically 5-8 sessions (face-to-face; in-person or telehealth) delivered by psychologists or other mental health providers [33]. Randomized controlled trials and meta-analyses have established CBT-I as effective for adults with primary insomnia [34] and those with comorbid insomnia [35], including psychiatric disorders (eg, depression and anxiety [35-37]) and medical disorders (eg, chronic pain [38]). A Veterans Affairs (VA) study with nearly 700 veterans found that 60% who completed CBT-I achieved a treatment response (ie, reduction ≥8 points per the Insomnia Severity Index; ISI). These veterans had a mean ISI change of 20.7 to 10.9, a large effect size (pre- to posttreatment Cohen *d*=2.3) [26]. In terms of long-term treatment gains, a recent review found 50% of patients responded to CBT-I and maintained treatment effects for 4-10 years [39]. CBT-I is also more effective than sedative-hypnotics at reducing sleep onset latency and is equally effective at improving wake after sleep onset and sleep quality [40]. It is important to note that combining CBT-I and sedative-hypnotics may not improve outcomes beyond CBT-I alone [41].

Considering the recommendation of behavioral interventions like CBT-I compared to the high use of sedative-hypnotics and risks involved, it is vital to consider methods to decrease sedative-hypnotic use and increase engagement in CBT-I. Deprescribing is the reduction or withdrawal of a medication managed by a health care professional that aims to reduce harm and improve outcomes [42,43]. Deprescribing interventions to reduce sedative-hypnotic use range from patient-centered approaches (eg, written instructions, relaxation strategies, therapy) to provider education and training [44,45]. A typical intervention will involve gradual dose reduction (GDR), or tapering, and is sometimes accompanied by psychological

XSL•FO
RenderX

treatment, like CBT-I [45]. GDR and tapering approaches, including the use of telehealth [46,47], often involve dose reductions of 25%-50% every 1-3 weeks until cessation is achieved [44]. Cessation, however, has varying rates of success (27%-80%). Adding psychological treatments (eg, CBT-I) helps to reduce rebound insomnia and improve cessation rates compared to routine care (odds ratios [OR] 3.38-5.96). However, the results of combining medication tapering and psychological interventions have been mixed [47-49]. Two key challenges to deprescribing sedative-hypnotics are rebound insomnia symptoms and the lack of personalized care (eg, educational brochures) [49]. Many individuals report being unaware of the risks associated with sedative-hypnotics, thus education and multidisciplinary collaboration are critical, especially as these factors are associated with enhanced deprescribing outcomes [50]. Considering these barriers and prior research on CBT-I and sedative-hypnotic tapering [46], a personalized approach that can effectively combine CBT-I and deprescribing has the promise to improve insomnia and sedative-hypnotic outcomes among veterans.

Access to both deprescribing and behavioral interventions would provide maximum impact for veterans; however, access to both interventions remains a barrier. Sedative-hypnotic use is highly prevalent, with many chronic users [16,19,49,51]. While medication prescribers and clinical pharmacists can provide patient education and lead tapering efforts, they do not have training in behavioral insomnia interventions. Despite strong evidence of improved sleep quality and daytime function and with minimal adverse effects and long-term treatment gains [3], CBT-I continues to have limited availability. Even with significant training dissemination efforts by the VA (>1100 trained since 2011), there is still a shortage of trained CBT-I clinicians, especially outside of urban VA medical centers. Additional barriers involve the location of CBT-I delivery, often in mental health clinics, which remains stigmatized for many veterans. Of note, many trained CBT-I clinicians are generalist therapists and insomnia care represents only a small portion of their caseload. CBT-I, like all evidence-based psychotherapies, requires regularly scheduled visits (in-person or telehealth), usually weekly or biweekly, which are not always possible for veterans who work, have caretaking responsibilities, or have transportation challenges.

Digital sleep therapeutics offer personalized, efficient, effective, and scalable treatment for insomnia treatment. Digital CBT-I mobile apps are available, including several developed by the VA, that have similar sleep outcomes as in-person CBT-I [52]. However, these mobile apps are self-management programs—patients do not engage with clinicians via the app—that focus only on improving insomnia symptoms. There are no remote or digital interventions that combine personalized sedative-hypnotic tapering with CBT-I. The Clinician Operated Assistive Sleep Technology (COAST) platform (Noctem Health) offers capabilities for supervised clinical care that allows clinicians to prospectively monitor patients' symptoms, progress, and adherence to clinician-driven treatment recommendations and to deliver personalized interventions remotely. Thus, COAST can fill the gap for veterans who can benefit from a combined approach of deprescribing and CBT-I with direct and just-in-time supervision, albeit remote, of their care management team.

The COAST platform, unlike other digital insomnia mobile apps, is a decision support tool for clinicians that offers personalized and responsive evidence-based recommendations for each individual patient [53,54]. Data from the initial validation trial and recent quality improvement data from military treatment facilities show that CBT-I delivered via COAST significantly decreases insomnia symptoms per sleep diaries and self-report measures (eg, ISI) to a greater extent than a recent in-person CBT-I trial with active duty military [55]. COAST has been iteratively refined through testing with military personnel, veterans, health care providers, and clinical partners in the Department of Defense Military Health System and academic medical settings [54]. While COAST's focus is on behavioral sleep assessments and interventions, the platform is flexible and can integrate additional interventions, such as clinical pharmacy practitioner (CPP)–led sedative-hypnotic deprescribing, unlike existing insomnia mobile apps. The COAST platform consists of a provider dashboard and a patient-facing mobile app. It offers a safe, no-contact, or remote, intervention. Assisted by the platform's technology, providers monitor patient-reported behaviors, while a Health Insurance Portability and Accountability Act (HIPAA)–secure messenger allows just-in-time communication between patients and their treatment team. The integrated secure communication feature is uniquely valuable during the deprescribing process as it promotes rapid feedback for potential adverse effects of GDR or tapering. COAST's algorithms facilitate the detection of disordered sleep patterns based on patient input, resulting in timely clinical decision-making and personalized sleep interventions based on the core components of CBT-I. COAST's efficiency helps to significantly reduce clinician time involved in treatment to as low as 10 minutes total per patient versus 30-60 minutes per session for in-person and telehealth modalities (typically 5-8 sessions). COAST also promotes participant engagement [56] and reduces burdensome aspects of face-to-face CBT-I by bringing tools and clinical expertise directly to the patient through their mobile device.

Specific Aims

Chronic insomnia is one of the most common health problems among veterans and negatively impacts their health, function, and quality of life. Although CBT-I is the first-line recommended treatment, sedative-hypnotic medications remain the most common despite mixed effectiveness and associated risks and adverse effects. To address this gap and reduce sedative-hypnotic use, we are conducting a nonrandomized, single-group pilot clinical trial with 3 aims:

1. To assess the feasibility of recruiting veterans with chronic sedative-hypnotic use to participate in a 12-week combined deprescribing and CBT-I intervention, delivered through the COAST platform
2. To assess veteran acceptability and usability of the COAST platform
3. To assess change in veteran sleep, sedative-hypnotic use, and function pre- to postintervention

XSL•FO
RenderX

The results will inform the design of a larger clinical trial to test the effectiveness of a combined deprescribing and CBT-I intervention delivered via COAST versus usual deprescribing care.

Methods

Ethics Approval

This study has been approved by the Institutional Review Board (IRB) of the VA Pittsburgh Health Care System (VAPHS) (1638783). It is registered at clinicaltrials.gov (NCT05027438) with methods reported following Standard Protocol Items: Recommendations for Intervention Trials (SPIRIT) guidelines [57]. All protocol changes and amendments have been reviewed and approved by the VAPHS IRB. Protocol deviations are documented in a deviation log and submitted to the IRB as part of the annual renewal. Any reportable events (eg, serious adverse events) are reported according to the VAPHS IRB and Office of Research and Development guidelines. An audit, independent of the principal investigator, study team, or sponsor, is conducted by the VAPHS Research Compliance Officer at least once every 3 years, or upon study closure if no audit has been completed yet.

All participants undergo the informed consent process prior to enrollment. The informed consent process is administered via video telehealth with the study coordinator. Informed consent documents and HIPAA forms are reviewed during the video consent process and then sent to veterans for completion using DocuSign; veterans are not considered enrolled until signed documents are returned to the study coordinator. veterans also have the option to opt-in for their study data to be included in a research repository, which will allow their deidentified data to be used in other research with appropriate approval of the VAPHS IRB; this is optional and does not impact their ability to participate in the clinical trial. Participants are compensated up to US $175 if they complete all study procedures including the baseline assessment (US $50), posttreatment assessment (US $50), 3-month follow-up assessment (US $50), and the brief interview (US $25).

All participant data are kept private and confidential. Data collection will occur through the COAST platform and stored on Noctem's Amazon Web Services GovCloud secure cloud-based server behind a firewall with a security policy that includes a dedicated server, regular backup of data, use of a monitored network with active security measures, and well-defined role-based access control. No protected health information (PHI) is stored on the COAST platform. After secure data transfer from Noctem to VA, security protocols in place include study data stored on secure dedicated study drives behind the VA firewall and only study team personnel with access to the data. Participants are assigned a unique identification number to ensure their study-related data are deidentified. While some PHI is collected as part of the informed consent process (ie, email address for DocuSign), no PHI will be included in the data analysis and dissemination of findings.

Participants and Eligibility

Participants will include 50 veterans recruited from VAPHS and affiliated community based outpatient clinics. See Textbox 1 for inclusion and exclusion criteria.

The medications and doses selected for inclusion were based on clinical practice guidelines and medications indicated for the treatment of insomnia (on or off label) [58]. Medications used to treat insomnia but also used to treat other disorders, such as benzodiazepines (eg, clonazepam) and sedating antidepressants (eg, amitriptyline) were not included. In addition, as this is a feasibility pilot trial, the medications were limited to the most commonly prescribed sleep medications [59].

The primary recruitment method will occur via mail. The study team will mail letters to potentially eligible veterans (see Textbox 1) identified from VA medical records. A prescreen list of potentially eligible veterans will be generated by the study's data analyst through the VA's corporate data warehouse. Participants with preliminary eligibility will be stratified by age (<65 or ≥65 years), sex (male or female), and race (White or non-White, including American Indian or Alaska Native, Asian, Black or African American, and Native Hawaiian or other Pacific Islander) with an equal number of letters mailed for each group, until a group's sample is depleted (see Table 1) and recruitment goals are met (n=50 enrolled). If feasible, depending on COVID-19 restrictions, secondary recruitment methods will be in-person (eg, flyers, clinician-assisted) at VAPHS clinics (eg, primary care, behavioral health, and sleep medicine).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- VA Pittsburgh Health Care System (VAPHS) veterans aged ≥18 years
- Medical record documentation and self-reports of active sedative-hypnotic use ≥3 days/week for ≥3 months, including zolpidem ≤10 mg immediate release, ≤12.5 sustained release; zaleplon ≤20 mg; eszopiclone ≤3 mg; trazodone ≤400 mg; temazepam ≤30 mg; and hydroxyzine ≤100 mg; veterans on higher doses may be eligible on a case-by-case basis
- A desire to reduce or stop using sedative-hypnotics
- Access to a mobile device

Exclusion criteria

- A self-report of a medical or psychiatric disorder that would significantly impair participation (eg, cancer, uncontrolled pain, severe depression)
- A self-report of a medical or psychiatric disorder that can be exacerbated by changes in sleep (ie, seizure disorder, psychotic disorders, bipolar I disorder)
- A self-report of an active substance use disorder
- High risk of suicide per the Columbia-Suicide Severity Rating Scale (C-SSRS)
- Currently engaged in an evidence-based, time-limited psychotherapy (eg, prolonged exposure, cognitive processing therapy, cognitive behavioral therapy for depression, and cognitive behavioral therapy for insomnia)

Table 1. Estimated initial recruitment sample (N=1435).

	White (n=1287), n		Non-White[a] (n=148), n	
	Age <65 years	Age ≥65 years	Age <65 years	Age ≥65 years
Female (n=142)	92	23	26	1
Male (n=1293)	405	767	63	58

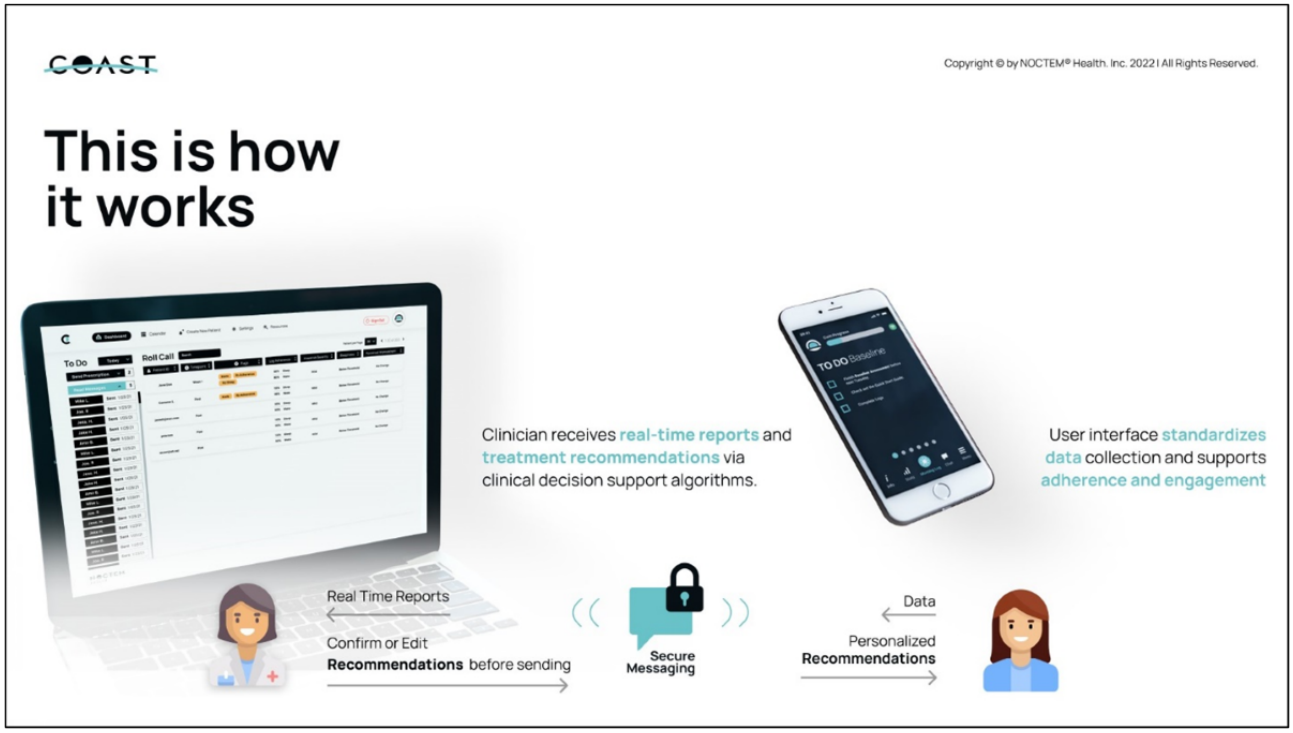
[a]Non-White included American Indian or Alaska Native, Asian, Black or African American, and Native Hawaiian or other Pacific Islander.

Interventions

Overview

This is a single-group, nonrandomized clinical trial lasting up to 12 weeks with assessments at baseline (T0), posttreatment (T1), and 3-month follow-up (T2). The intervention will combine CPP-led sedative-hypnotic deprescribing with CBT-I, delivered through the COAST platform and managed by a psychologist trained in CBT-I [53].

COAST Delivered CBT-I



The COAST algorithms, based on participant data (eg, sleep diary, self-report measures), will generate treatment recommendations after approximately 1 week of participant data entry [54]. COAST's treatment recommendations align directly with the core components of CBT-I—stimulus control, sleep restriction, cognitive therapy, and relaxation—with additional strategies targeting nightmares and daytime fatigue as needed. Weekly assessments and daily sleep diaries drive recommendations offered to the clinician. Because COAST is clinical decision support software, the study clinician (ie, a psychologist trained in CBT-I) must review and approve or change algorithm-generated recommendations before they are sent to the participant via the patient-facing mobile app (see Figure 1). This tailored approach allows for modification of COAST's recommendations based on clinician expertise and knowledge of the participant (eg, a recent stressor that indicates slowing or pausing treatment). To further enhance the treatment process, the clinician is available by secure message (ie, in-platform texting) during business hours to provide rapid support or schedule an appointment as needed (eg, phone, VA Video Connect). The messaging feature also allows for the study team to rapidly notify the participant if daily diaries are incomplete or assessments are missed. As needed, the study team will contact participants by phone or video telehealth for treatment adherence issues. These features offer personalization for each participant, consistent with a case-conceptualization approach based on the veteran's sleep needs. CBT-I via COAST is typically delivered over 4-6 weeks but has been adapted for this study to last up to 12 weeks as deprescribing can vary and ongoing COAST recommendations may further support deprescribing efforts.

The COAST recommendations are based on CBT-I and the rationale that modifying behaviors impacts the homeostatic and circadian drives. Modifying sleep and daytime behaviors helps regulate wakefulness, which can increase the homeostatic sleep drive and restructures and optimizes sleep and wake times to reinforce the circadian drive. Stimulus control limits the bed for sleep, sexual activity, and sickness, which strengthens the positive association between bed and sleep. Staying in bed while awake and engaging in nonsleep activities perpetuates the cycle of wakefulness, frustration, and arousal. When unable to sleep, it is recommended patients get out of bed and go to another room until sleepiness returns. Sleep restriction, or sleep efficiency training, matches the patients' sleep opportunity, or prescribed time in bed, to their average total sleep time. This

XSL•FO
RenderX

allows the homeostatic and circadian drives to become better aligned. A consistent wake time is (1) the most important cue for setting the biological clock, (2) regulates exposure to morning light, and (3) helps increase the homeostatic sleep drive for subsequent nights. Going to bed only when sleepy, but not before a prescribed bedtime, increases the sleep drive and the likelihood of falling asleep quickly. Intrusive thoughts and worry can result in wakefulness and can contribute to cognitive and physiological arousal. Reduction of intrusive thoughts and worry helps to reduce nighttime stress through the identification and challenging of dysfunctional beliefs. Targeted strategies can help to reduce intrusive thoughts at night and the wake or frustration cycle during awakenings. Relaxation exercises help reduce physical and cognitive arousal that can perpetuate wakefulness. Breathing exercises, guided imagery, and progressive muscle relaxation help to reduce arousal and increase readiness to sleep.

Figure 1. COAST features. COAST: Clinician Operated Assistive Sleep Technology.

CPP-Led Deprescribing

Approximately 1 week after CBT-I is initiated in COAST, participants will meet with a CPP to begin deprescribing. For the deprescribing intervention, the study CPPs will develop a personalized taper for each participant based on their medication, dosage, and factors such as anxiety about the taper, duration of use, comorbid disorders, and insomnia severity. The deprescribing plan will be communicated to each participant either through COAST's secure messaging or verbally (eg, phone, VA Video Connect). The study CPP will, as needed for the personalized taper, place appropriate orders for different doses or new medications in the VA's medical record system, the Computerized Patient Record System, concurrent with the scope of practice or for the participant's VAPHS prescribing provider to review or approve of a controlled substance. As needed, the taper can be extended to 12 weeks, and if necessary, participants can be referred to their VAPHS prescribing provider for further deprescribing assistance after the intervention and posttreatment assessment are complete (T1). At any point during the intervention, the taper can be paused if the participant is struggling to adjust or experiences withdrawal symptoms. All withdrawal symptoms will be self-reported through the COAST platform using the secure messaging or the daily sleep diary and will be responded to within 1 business day by a study team member. Outside of business hours (Monday-Friday, 8 AM-4:30 PM), if necessary, participants can contact emergency services.

Outcomes Measures

Demographics and VA Medical Record

On downloading the COAST app, participants will complete a demographic questionnaire recording their biological sex, gender identity, age, time served in military, and combat status. Psychiatric disorders and psychotropic medications will be collected from participants' VA medical records, as will their service connection—disabilities and disorders caused by military service (0%-100% [60]).

ISI Scores

The ISI will serve as the primary sleep outcome. The ISI is a brief measure of nighttime sleep disruption (eg, severity of sleep onset) and daytime impact (eg, interference with function) [61]. The ISI has 7 items scored 0-4, with higher scores indicating greater severity or impairment. The total score (0-28) is categorized as follows: no insomnia (0-7), subthreshold insomnia (8-14), moderate insomnia (15-21), and severe insomnia (22-28). A reduction pre- to posttreatment ≥8 points indicates a treatment response and a posttreatment score ≤7 indicates remission. The ISI demonstrates good psychometric properties, with validity endorsed by its correlation with sleep

XSL•FO
RenderX

diaries [62]. The ISI will be assessed at T0, T1, and T2 as well as biweekly during the intervention.

Self-Report of Sedative-Hypnotic Medication

Sedative-hypnotics will be measured by participant self-report, as part of a daily entry in COAST: "I took the following sleep medications: Zolpidem (Ambien), Eszopiclone (Lunesta), Zaleplon (Sonata), Trazodone (Desyrel), Temazepam (Restoril), or None." As medications will be reduced over the course of treatment, veterans will enter the dose of medication as free text. The daily COAST entry will also involve assessments for adverse effects and withdrawal symptoms (ie, the Clinical Institute Withdrawal Assessment–Benzodiazepines; CIWA-B [63]). Outcomes will include posttreatment (T1) and 3-month follow-up (T2) medication dosage relative to starting dosage at baseline (T0), and binary outcomes of a ≥50% reduction (yes or no) and total cessation (yes or no). Furthermore, medication information from participants' VA health records will be used to help validate their self-report of sedative-hypnotic use throughout the study.

Sleep Diary

Additional sleep outcomes will be measured with a daily sleep diary [64]. Sleep diaries provide information about participants' sleep behaviors, such as bedtime, rise time, total time in bed, total sleep time, sleep onset latency, number of nighttime awakenings, duration of wake after sleep onset, and sleep efficiency. The sleep diary exhibits good psychometric properties and significant correlations with objective data [65]. Sleep diaries will be completed daily from baseline (T0) through posttreatment (T1) and for 7-days at 3-month follow-up (T2). Daily sleep diary data are used by COAST's algorithms to generate personalized recommendations for each participant.

Patient-Reported Outcome Measurement Information System Adult Profile

Secondary clinical and functional measures will come from the Patient-Reported Outcome Measurement Information System Adult Profile (PROMIS) 29+2. This includes measures of physical function, social roles, anxiety, depression, fatigue, sleep disturbance, pain interference, pain intensity, and cognitive function. Each construct is scored individually (4 items scored 1-5 with a total score range of 4-20) except cognitive function (2 items scored 1-5 with a total score range of 2-10), with higher scores indicating more of the construct being measured. All constructs have high internal validity, with a ranging α=.86-.96. Raw scores are translated to a T-score with a mean of 50 and SD of 10. When all constructs are scored together, a preference score is calculated, representing health - related quality of life ranging from 0 (as bad as dead) to 1 (perfect or ideal health) [66].

Post-Study System Usability Questionnaire and Qualitative Interviews

COAST usability and acceptability will be measured with the Post-Study System Usability Questionnaire (PSSUQ) [67], which measures perceived satisfaction with systems such as websites or mobile apps. The PSSUQ has 16 items, scored 1-7 (1=strongly agree, 7=strongly disagree). The overall usability score is the average (total score divided by number of questions answered). The 3 subscales are usefulness (items 1-6), information quality (items 7-12), and interface quality (items 13-16). Lower scores (<3) indicate higher satisfaction and above-average usability. The measure has a high validity score (α=.94). The PSSUQ will be assessed at 2 time points. First, after the initial sleep or wake schedule recommendation is delivered (T0+1 week), as this will give participants a chance to learn the COAST platform and second, at posttreatment (T1), to measure change over time. To further assess usability or acceptability, 15 veterans will be interviewed (via phone or Microsoft Teams; Microsoft Corp) to gain additional context on their COAST user experience and potential changes or new features that could improve COAST. Veterans will be interviewed based on their PSSUQ scores to get a range of perspectives, if available, per score distribution (eg, 5 low, 5 medium, 5 high; see Table 2 for timeline of assessments).

Table 2. Timeline of assessments.

Data Collection, Management, and Quality Control

Primary data collection will be through the COAST participant-facing mobile app with additional data collected via the posttreatment qualitative interviews (phone) and VA medical records. All participants will be assigned a unique study identifier that is not related to any personal identifier such as social security or medical record number. During all phases of the study, participants will be encouraged to enter data in a timely fashion with reminders via the messaging feature on COAST as well as phone calls, as needed. Data submitted via COAST are not stored on participants' personal devices but directly stored on Noctem Health's NoSQL database, which is located on an Amazon Web Services GovCloud US-East region server. The database and servers adhere to US Government and Department of Defense security standards and use identity and access management (IAM) controls for its infrastructure services, which are limited to appropriate personnel and are continuously reviewed. Data quality control is enhanced by required responses to questions and limited data response ranges to enhance validity. Prior to secure data transfers from Noctem Health to VAPHS, all PHI will be removed from the data set and data will be reviewed for completion, redundancies, and quality. After data transfer, the study's VA data analysts will review deidentified data to ensure no PHI is included before data are available to the study team for review and analysis. Noctem and VA co-own all the data. The VAPHS study team will have access to the final data set used for analyses. Noctem will retain a copy of the deidentified data set. A limited data set will be created and shared pursuant to a data use agreement appropriately limiting the use of the data set and prohibiting the recipient from identifying or reidentifying (or taking steps to identify or reidentify) any individual whose data are included in the data set.

Analytic Plan

Power Analysis

Given the estimates from prior work on sedative-hypnotic deprescribing and digital insomnia interventions [46,68,69], we can expect an effect size (Cohen *d*) range for pre-post ISI between 1.09 and 2.26 with an average effect size of 1.73 (small, 0.3, medium, 0.5, large, 0.8) [70]. Given 50 enrolled participants and accounting for a 25% dropout (ie, 37 with pre-post data), we will still have 95% power to detect an effect size of 0.65.

Aim 1

To determine the feasibility of recruiting veterans to participate in this combined deprescribing and CBT-I intervention, a CONSORT (Consolidated Standards of Reporting Trials) diagram will be used to track the recruitment, enrollment of eligible participants, and their progression through treatment. During recruitment, the number of participants who contact the coordinator, undergo the study screen, and provide consent will be recorded relative to number of letters sent. To track treatment participation, the number of participants who download and activate the COAST app, complete baseline assessments, engage in treatment beyond the initial recommendation, and complete the intervention will be noted. Chi-square analyses will be used to determine group differences (age, sex, and race) in recruitment response and participation rates.

Aim 2

Usability and acceptability of COAST will be evaluated by the PSSUQ. Usability or acceptability will be measured early in treatment (T0+1 week) and at posttreatment (T1), as well as change over time (T1–T0+1 week). Change will be assessed using an intention-to-treat (ITT) approach and fitting mixed effects linear models that test change in usability or acceptability (change in PSSUQ scores over the course of treatment) and include a main effect of time (T0+1 week to T1) and random effects for the veteran.

Audio-recorded qualitative interviews will help to gain more nuanced information on COAST usability or acceptability. The interviews will be interpreted using rapid qualitative inquiry [71,72] to ensure that results are delivered in a timely manner to be meaningful to the study. Interviews will be summarized by the study's qualitative analyst into a template of categories that reflect topics of interest. The summaries will be coded by 2 analysts to develop the basis of content and thematic analyses.

Aim 3

Veteran clinical and functional outcomes will be evaluated using an ITT approach. We will fit mixed effects linear models that measure change over the course of treatment for our outcome measures (ISI, sleep diary, PROMIS) that includes a main effect of time (T0-T1, T0-T2, and T1-T2) and include random effects for the veteran (multiple measurements during treatment). Sedative-hypnotic change will be determined by an ITT approach and fitting a mixed methods logistic model that tests for medication dose reduction (≥50%, yes or no) and medication cessation (yes or no) over the course of treatment that includes a main effect of time (T0-T1, T0-T2, and T1-T2) and random effects for the veteran. Additional analyses will compare completers versus noncompleters and responders versus nonresponders.

Results

This study was approved by the VAPHS IRB in October 2021 with study initiation in May 2022. Recruitment and data collection began in September 2022 and is ongoing. As of June 1, 2023, there were 25 participants enrolled. The study is expected to be completed by summer 2024. Trial results will be posted on clinicaltrials.gov and disseminated through peer-reviewed journals. The study findings will be communicated to the study sponsor, but the sponsor will not be involved in the dissemination of findings.

Discussion

Sedative-hypnotic use, as a treatment for chronic insomnia, is highly prevalent among veterans and is associated with considerable health and safety risks. Importantly, use of sedative-hypnotics does not align with best practices for treating insomnia or veteran preferences per the VA/Department of Defense Clinical Practice Guidelines [3]. This pilot study offers deprescribing of sleep medications managed by experts (ie,

XSL•FO
RenderX

CPPs) while offering personalized, first-line insomnia treatment with CBT-I integrated and managed by a digital sleep platform. The COAST platform is unique, as it enables the efficient and effective delivery of CBT-I with the capability of integrating CPP-led deprescribing to combine these commonly siloed treatments. Patient-centered and personalized care is important to increase the likelihood of successful reduction or cessation of sedative-hypnotics. The combined and personalized care, from the CPP and psychologist, may result in better veteran outcomes compared to separate interventions, that is sedative-hypnotic deprescribing and CBT-I alone. Offering veterans a digital format of care reduces concerns regarding stigma and addresses barriers such as a lack of transportation and allows for the maintenance of social distancing. Notably, in the wake of COVID-19, older veterans (mean age 63.14 years) have demonstrated an increased preference for digital treatment over in-person treatment [73].

Focus on treating insomnia and reducing sedative-hypnotic use is of high value for veterans and their providers. Treatment response and remission of insomnia improve sleep quality, daytime function, and quality of life. Furthermore, treating insomnia reduces symptom severity in comorbid psychiatric disorders (ie, depression, anxiety, and posttraumatic stress disorder), reduces the risk of developing psychiatric disorders (ie, depression and suicidal behaviors), and reduces the risk associated with sedative-hypnotic use.

The long-term objective of this study is to inform the development of an adequately powered clinical trial to test the effectiveness of the combined deprescribing/CBT-I intervention in a diverse sample of veterans. Future clinical trials may also include a comparison of the combined intervention against treatment as usual or the combination of deprescribing and other digital insomnia platforms, such as the VA's Insomnia Coach. Beyond large-scale clinical trials, additional information is needed regarding cost and cost-effectiveness of using third-party software to support deprescribing and CBT-I delivery, like COAST, within the VA. In addition, implementation and dissemination are vital for success at scale in an integrated health care system like the VA and in the general community. If deemed cost-effective and if scaled appropriately, digital platforms like COAST can help reduce chronic sedative-hypnotic use, improve sleep quality, enhance functional outcomes for patients, and improve the access, efficiency, and effectiveness of delivering evidence-based care for veterans with insomnia.

Acknowledgments

The authors are greatly appreciative of the veteran participants for their service and willingness to volunteer for this research study and also thank Jennifer L McCoy, MA, for her assistance in data analytics. This study is funded by Veterans Affairs (VA) Rehabilitation Research and Development and Small Projects in Rehabilitation Research (1I21RX003732; ADB). Additional support was provided by VA Health Services Research and Development (award 1I01HX003096; ABD) and the VISN 4 Mental Illness Research, Education and Clinical Center (director David Oslin, MD; Pittsburgh director Gretchen Haas, PhD). The study sponsor, VA Rehabilitation Research and Development, had no role in the design of the study or the preparation of this paper. This is the sole work of the authors and does not represent the Department of Veterans Affairs or the US government.

Data Availability

Consistent with the VA Office of Research and Development Data Management and Access Plan, a limited and deidentified data set generated or analyzed during this study will be available from the corresponding author. Any available data set will be pursuant to a data use agreement appropriately limiting the use of the data and prohibiting the recipient from identifying or reidentifying any individual whose data are included in the data set.

Authors' Contributions

ADB conceptualized the study and was responsible for funding acquisition, leading the investigation, developing methods, obtaining resources, supervising staff, and writing the original draft. CEH was responsible for project administration and writing the original draft. AG contributed to project administration, obtaining resources and software, and writing and editing revisions. Other coauthors contributed to investigation, writing, editing, and revising.

Conflicts of Interest

Abstract

Background: Supracondylar humeral fractures (SCHF) are a common cause of orthopedic morbidity in pediatric populations across the world. The treatment of this fracture is likely one of the first procedures involving x-ray–guided wire insertion that trainee orthopedic surgeons will encounter in their career. Traditional surgical training methods of “see one, do one, teach one” are reliant on the presence of real-world cases and must be conducted within an operative environment. We have developed an augmented reality simulator that allows trainees to practice this procedure in a radiation-free environment at no extra risk to patients.

Objective: This study aims to examine whether training on a simulator in addition to traditional surgical training improves the in-theater performance of trainees.

Methods: This multicenter, interventional cohort study will involve orthopedic trainees from New Zealand in their first year of advanced training between 2019 and 2023. Advanced trainees with no simulator exposure who were in their first year in 2019-2021 will form the comparator cohort, while those in the years 2022-2023 will receive additional regular simulator training as the intervention cohort. The comparator cohort’s performance in pediatric SCHF surgery will be retrospectively audited using routinely collected operative outcomes and parameters over a 6-month period. Data on the performance of the intervention cohorts will be collected in the same way over a comparable period. The data collected for both groups will be used to determine whether additional training with an augmented reality training shows improved real-world surgical outcomes compared to traditional surgical training.

Results: As of February 2022, a total of 8 retrospective comparator trainees have been recruited by email. The study is financially supported through an external grant from the Wishbone Orthopaedic Research Foundation of New Zealand (September 2021) and an internal research grant from the University of Otago (July 2021).

Conclusions: This protocol has been approved by the University of Otago Health Ethics committee (reference HD21/087), and the study is due for completion in 2024. This protocol may assist other researchers conducting similar studies in the field.

Introduction

Background

Supracondylar humeral fractures (SCHF) of the elbow are one of the most common orthopedic causes of morbidity in children. SCHF represent 3.3% to 16.6% of all childhood fractures, 32.6% of upper extremity fractures, and 57.5% of elbow fractures across localities [1-4]. The Gartland classification system is used for characterizing the extension type of SCHF and is dependent on the degree of humeral fragment displacement [5]. The gold standard for the management of operative cases is closed reduction and percutaneous pinning (CRPP), unless severe neurovascular compromise or an open fracture is present [6-8]. CRPP is seen as a more effective and safer method for treating displaced SCHF than nonoperative and open reduction methods [9-12].

Current Training

The status quo of apprenticeship-style orthopedic training does not enable standardized hands-on skill practice outside of the operating room. The “see one, do one, teach one” methodology is becoming increasingly insufficient as trainees face a decrease in work hours for necessary well-being needs. This decrease in work hours means there are fewer opportunities for trainees to participate in and therefore learn from real cases. Limiting training to the operating room also incurs both financial and opportunity costs to the health care system as trainees require more time to complete procedures than consultants [13,14]. In addition to costs and reduced availability of the current method of training, there is also the question of whether apprenticeship-style teaching is really the most effective form of teaching available. Numerous studies on learning and teaching for adults have shown that independent, deliberate, and repeated practice is most effective for skill acquisition [15-18]. By nature, apprenticeship-style training allows for the repetition of individual case types but not a deliberate practice of certain aspects of the skills, such as only percutaneous pinning in CRPP.

An Alternative Training Method

Improvements in computer technology have afforded the development of a new method of surgical training—augmented reality (AR) simulation. Using AR technology, skill acquisition can take place before entering the operating room. CRPP requires a high level of hand-eye coordination, visuospatial reasoning to interpret the X-ray image, and haptic interpretation to be able to feel the wire entering or leaving the bone. One such example was developed by our research team. The “BoneDoc AR” simulator (University of Otago) that we have produced uses an iPad app to provide real-time simulated X-ray images, while trainees are drilling through a physical model of the elbow. This physical model is made of silicone soft tissue and 3D-printed plastic bones. In addition, the simulator can provide objective measures of proficiency, such as exact pin placement, which are not possible without the use of computed tomography scans. These objective measures may be of value in providing feedback on skills acquisition during surgical training.

Study Overview

Appropriate validation of the BoneDoc AR simulator is necessary to determine its usefulness in surgical training. Transfer validity, the ultimate test of a surgical simulator, is the transfer of skills acquired on a simulator into the real-world operating theater. Validity tests are necessary to ensure the efficacy of a simulator in a training environment [19]. There are few surgical AR simulators, which have shown positive transfer validity, and none on AR simulators of SCHF treatment [20]. There is a clear paucity in the literature of this field, and there is a need for further research. This pilot study aims to examine the transfer validity of orthopedic trainee practice on the BoneDoc AR simulator.

We hypothesize that training with the simulator will improve in-theater performance as defined by a reduction of theater time, number of fluoroscopy images taken, postsurgical complication rates, and an increase in pinning accuracy. In all metrics, intervention trainees will be compared with retrospective-matched comparator trainees.

Methods

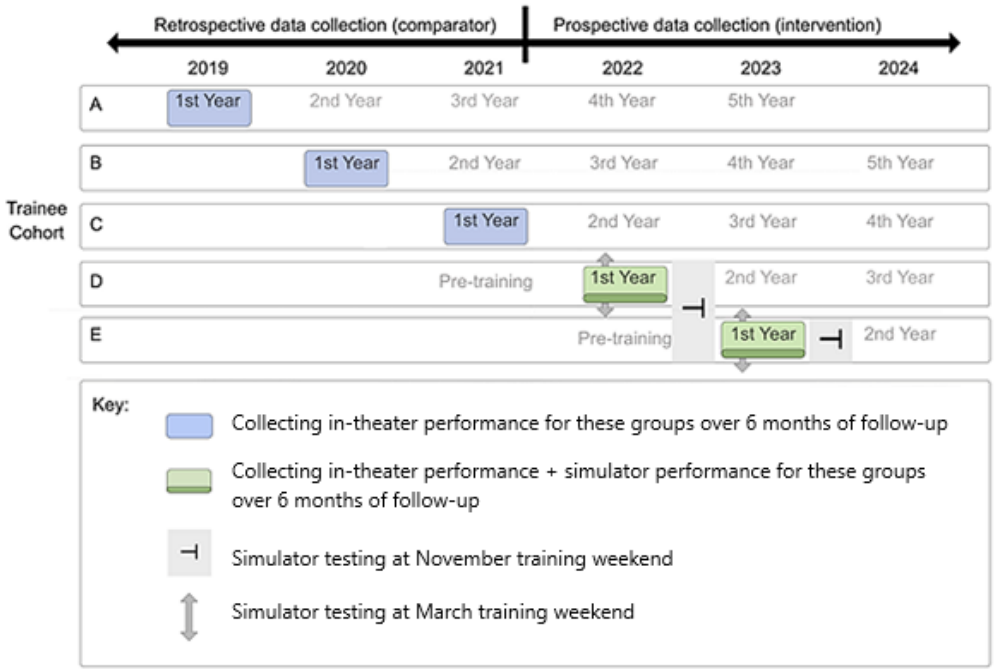
Study Setting

This multicenter, interventional cohort study will involve first-year orthopedic trainees stationed in New Zealand hospitals between 2019 and 2023.

Trainee performance will be collected across hospitals located in Invercargill, Rotorua, Timaru, Palmerston North, Whanganui, Taranaki, Tauranga, Christchurch, Waikato, and Auckland for 2022. The locations of first-year trainees in 2023 are yet to be determined. Retrospective comparator performances will be collected through training logbooks and electronic patient records.

Eligibility Criteria

The inclusion criterion was being a full-time registered first-year orthopedic trainee in New Zealand between 2019 and 2023.



Study Design

The intervention cohort is composed of trainees using the BoneDoc AR simulator at least once per month over a follow-up

XSL•FO
RenderX

period of 6 months (May to November) in the years 2022-2023 (Figure 1).

Figure 1. Schematic representation of the intervention and comparator data collection timeline.

Recruitment

Intervention group trainees will be approached at training weekends to inform them about the study, to assess eligibility, and to receive consent. Comparator group trainees will be identified from the New Zealand Orthopaedic Association trainee registry and approached via email for this process. Enrollment for comparator group trainees will begin in February 2022, and enrollment for intervention group trainees will occur in the March training weekends of 2022 and 2023.

We aim to include data for 14 trainees in 2022; however, the number of trainees in 2023 is not yet known. The comparator cohort data will be retrospectively audited from trainees who undertook traditional training without exposure to the simulator during their 6 months of follow-up in the years 2019, 2020, and 2021 (n=41). We expect a total sample size of approximately 65 trainees, given an average of 12 new trainees per annum. The comparator group is matched based on their length of registered training at the start of follow-up, that is, first-year trainees with 2 months of registered training.

The in-theater performances of the comparator and intervention groups will be compared using cumulative sum charts for each of the primary outcomes to determine any differences in trends of skill acquisition according to the method of training. The simulator performance of the intervention group will be used to establish a learning curve and compared with in-theater learning curves.

Retrospectively matched trainees have been chosen instead of prospective randomized ones for the comparison group in order to maximize sample size and to avoid contamination. New Zealand only introduces 10-15 trainees per year into the orthopedic training program, and thus a prospective randomized trial will greatly limit the statistical power. There is also the chance of cross-group contamination as there is no way of ensuring comparator trainees located in the same area as intervention trainees will not use the simulator.

Interventions and Comparators

Intervention

The simulator will be first administered at the March training weekends for each year. We will use these training weekends to test participants at baseline on the simulator and collect demographic data via survey. The simulator will be set up as one of the 15-minute assessment stations in the training weekend. Simulator sets will be distributed to individual trainees following the training weekend. Upon delivery of the simulator sets, the principal investigator will also provide aid to the trainee in identifying an appropriate environment for the simulator and address any setup issues.

It is then expected that trainees will undertake, at minimum, monthly 15-minute practices on the simulator for the next 6 months of training. These practice data are sent to a cloud server after each use. Note that the simulator training will be in addition to any routine training they will receive at their respective hospitals. Over this time, primary end points for each in-theater case will be taken over the course of follow-up through District Health Board (DHB) records, including patient picture archiving and communication system (PACS) records and trainees' logbooks.

We will request intervention trainees to write out relevant patient data and end point results as the cases present to maximize accuracy. Trainees will be reminded monthly by email to provide case data and practice on the simulator. Their simulator performance will be assessed again in a controlled environment during the November training weekend. At this point, secondary end points will also be collected via survey.

XSL•FO
RenderX

Comparators

The comparator cohort's follow-up will begin in February of each year. This is due to the change to the training schedule instated at the end of 2020 whereby trainees began their rotations in February instead of the prior December.

Primary outcomes will be collected retrospectively via trainee logbooks and patient PACS records for retrospective data. Secondary outcomes will not be collected for comparators.

Data Collection

Outcomes

Primary End Points—Collected for Each In-Theater Case Over Follow-up

- Theater time and radiation time in seconds (radiation time may not be available from retrospectively assessed notes but will be attained where possible)—collected from procedure reports from electronic patient records
- Number of fluoroscopy shots—collected from patient PACS records
- Pin accuracy—accuracy is defined based on procedural recommendation literature—analyzed from patient PACS records
- Complication/nonideal union incidence—stratified for types of complications (nerve injury, vascular injury, loss of reduction, compartment syndrome, and infection)—collected from reviews of medical records and letters of referral from electronic patient notes

These primary end points have been determined as measurements of trainee performance, which are relatively easily retrieved from patient records and trainee logbooks.

The number of fluoroscopy shots and radiation time can be used to approximate the amount of radiation patients and staff are exposed to. In particular, for patients, theater time and radiation exposure have been shown to correlate to a higher chance of complications and thus should be avoided [21]. Studies have shown a decrease in both measurements for SCHF treatments with increased trainee proficiency [22,23]. Pin accuracy affects the stability of union, and there are well-established guidelines for ideal position of pins.

Ultimately, postoperative complications and nonideal union are the most crucial outcomes the trainees should aim to avoid. We do not expect to see high rates of these for either group, but overall rates will be monitored for comparison.

Secondary End Points—Experience With the Simulator and Surgery—Collected at the End of Follow-up Training Weekend for Intervention Trainees

- Total number of times using the simulator over follow-up—collected from the BoneDoc AR app
- Frequency of using the simulator—collected from the BoneDoc AR app
- Perceived familiarity with SCHF by the end of the follow-up—determined from a 5-point Likert scale administered with a brief electronic survey:
  - Unfamiliar
  - Somewhat unfamiliar
  - Neither familiar nor unfamiliar
  - Somewhat familiar
  - Familiar
- Total number of SCHF treatments undertaken over follow-up—calculated using the entries from trainee logbook
- Number of mistakes while using the simulator—defined by the number of times the trainee reconsiders pin, collected from the BoneDoc AR app
- Pinning accuracy on simulator—final pin and range of mistakes as calculated by the simulator—collected from the BoneDoc AR app

Patient Data

Data such as the National Health Index (NHI) number and surgical details will be collected from trainee logbooks. The following data will be collected from the corresponding DHB records: NHI number; time and date of presentation to the emergency department; age; sex; ethnicity; side of fracture; Gartland classification of fractures—type I, type II, type III, and type IV; the presence of consultant or any other assistants in surgery.

Statistical Analysis

Operative outcomes using data taken before or without ongoing exposure to the simulator will be compared to outcomes using data from trainees who have used the simulator after 1 year. Comparisons will be performed using Student *t* tests or Wilcoxon Rank Sum tests (depending on the distribution of the data) for theater time and chi-square or Fischer exact tests (depending on the count of the outcome) for the number of complications, number of accurate pin placements, and number of mistakes.

Primary end points will be plotted on separate cumulative sum curves to show trends in performance over the course of follow-up by individuals and aggregated according to pre- and post–1-year simulator training. Control limits will be determined based on values identified in the literature and consultation with senior orthopedic consultants [22-24].

Accuracy of pin placements in subsets of images measured twice must be based on anterior-posterior, lateral, and oblique radiographs. Measurements taken will need to be compared for intra- and interobserver reliability using Bland-Altman plots and intraclass correlation scores.

The results from the familiarity questionnaire will be summarized as responses per category.

Univariable ordinary least squares regression analyses will be used to examine the association of theater time, number of complications (including nonideal unions), and number of x-ray shoots with independent variables. Logistic regression will be used to examine the association of accurate pin placement (yes or no) with independent variables. Independent variables will be the number of times the simulator is used, the number of SCHF procedures performed prior to intervention, Gartland classification, scores on tests of spatial awareness, and the number of SCHF procedures performed during the intervention. Independent variables that are significantly associated with a

XSL•FO
RenderX

primary end point ($P<.05$) will be included as covariates in multivariable analyses. Appropriate model diagnostics, and where required, data transformations will be used.

Software

All analyses will be performed using the statistical analysis software R (R Foundation) [25].

Data Management

Adverse events are unexpected with the use of the simulator, as trainees have operative experience and there is a low infection risk. Nevertheless, an independent data monitoring committee (DMC) has been setup consisting of 2 clinicians and will be reported to by a study researcher. Any adverse events will be reported immediately to the committee by trainees directly, and the committee may request an interim analysis of the data collected up to that point. The committee can request that the study be paused or discontinued based on the data they receive. The DMC will meet every 6 months to discuss this project.

Study researchers will ensure that the participants' anonymity is maintained. The participants will be identified only by a participant's ID number. Individual patients will not be contacted by a researcher. Identifiable patient and participant data will be anonymized and stored on secure University of Otago servers, and will only be accessible by the researchers directly involved with this data collection. Analysis will be performed only on anonymized data sets with an anonymous identifier instead of NHI numbers. The study will comply with the Data Protection Act, which requires all data to be anonymized as soon as it is practical to do so. Data will be stored for 10 years after the conclusion of the study and subsequently destroyed.

Ethical Considerations

The principal investigator will ensure this that study is conducted in full conformity with the current revision of the Declaration of Helsinki (last amended in October 2000, with additional footnotes added in 2002 and 2004). The principal investigator will ensure that this study is conducted in full conformity with relevant regulations and with the ICH Guidelines for Good Clinical Practice (CPMP/ICH/135/95) July 1996. Our study was approved by the University of Otago Health Ethics committee (reference HD21/087).

Any important protocol modifications will be communicated in a timely manner to trial participants already enrolled and the DMC in a timely manner.

The results of this study will be disseminated through peer-reviewed publications and conference proceedings. Trial participants will be provided with the option to receive notification of any disseminated results upon enrollment.

Results

As of February 2022, a total of 8 retrospective comparators have been recruited by email.

Discussion

Strengths and Limitations

This study is not a randomized trial and uses historical comparators, which may limit our ability to generalize the results due to confounding factors. We aim to mitigate the effects of potential confounding factors by matching comparators based on training experience. Potential confounding variables will be collected at baseline for both groups and explored for associations with our outcome measures. In monitoring the learning curves of both groups over time, a difference-in-difference analysis will be performed to explore simulator effects. The quality of patient data and logbook entries by historical trainees will determine the quality of our comparator data; however, we are confident that the primary outcomes we have chosen are sufficiently routinely collected for surgical cases.

This is the first surgical simulator validation study conducted across all New Zealand centers with early-stage trainees and will be invaluable for establishing a pathway for future New Zealand studies. In collaborating with the training organization at the early stages of testing, and continuous collaboration over the course of the project, the formal integration of this simulator into training can be streamlined. Collaborations for this study also exist with orthopedic surgeons in the United States. Successful multicenter testing in New Zealand is likely to lead to further testing in the United States, thereby improving the external validity of this simulator and possible integration into international training programs.

Conclusions

The results of this pilot study will show the feasibility and efficacy of simulator use within New Zealand's public health system. The long-term benefits to society will be both for the education of registrars and the health outcomes of patients. In particular, for trainees in localities with lower populations, this simulator can address the disparity in case volumes for those that would otherwise have been deprivileged by their location. Moreover, this simulator has been developed with minimizing costs and increasing accessibility as key objectives; it is cheaper than many currently available models and has low requirements for the environment. We envisage its frequent use as a valuable tool within hospital systems.

Acknowledgments

The authors thank Prue Elwood and Tim Gregg (New Zealand Orthopaedic Association) for organizing and allowing this project to be introduced in training weekends. This project is supported financially by The Wishbone Orthopaedic Research Foundation of New Zealand, the Dunedin School of Medicine Research Student Support Committee, and an internal research grant from the University of Otago.

Abstract

Background: Emergency department (ED) providers are important collaborators in preventing falls for older adults because they are often the first health care providers to see a patient after a fall and because at-home falls are often preceded by previous ED visits. Previous work has shown that ED referrals to falls interventions can reduce the risk of an at-home fall by 38%. Screening patients at risk for a fall can be time-consuming and difficult to implement in the ED setting. Machine learning (ML) and clinical decision support (CDS) offer the potential of automating the screening process. However, it remains unclear whether automation of screening and referrals can reduce the risk of future falls among older patients.

Objective: The goal of this paper is to describe a research protocol for evaluating the effectiveness of an automated screening and referral intervention. These findings will inform ongoing discussions about the use of ML and artificial intelligence to augment medical decision-making.

Methods: To assess the effectiveness of our program for patients receiving the falls risk intervention, our primary analysis will be to obtain referral completion rates at 3 different EDs. We will use a quasi-experimental design known as a sharp regression discontinuity with regard to intent-to-treat, since the intervention is administered to patients whose risk score falls above a threshold. A conditional logistic regression model will be built to describe 6-month fall risk at each site as a function of the intervention, patient demographics, and risk score. The odds ratio of a return visit for a fall and the 95% CI will be estimated by comparing those identified as high risk by the ML-based CDS (ML-CDS) and those who were not but had a similar risk profile.

Results: The ML-CDS tool under study has been implemented at 2 of the 3 EDs in our study. As of April 2023, a total of 1326 patient encounters have been flagged for providers, and 339 unique patients have been referred to the mobility and falls clinic. To date, 15% (45/339) of patients have scheduled an appointment with the clinic.

Conclusions: This study seeks to quantify the impact of an ML-CDS intervention on patient behavior and outcomes. Our end-to-end data set allows for a more meaningful analysis of patient outcomes than other studies focused on interim outcomes, and our multisite implementation plan will demonstrate applicability to a broad population and the possibility to adapt the intervention to other EDs and achieve similar results. Our statistical methodology, regression discontinuity design, allows for

XSL•FO
RenderX

causal inference from observational data and a staggered implementation strategy allows for the identification of secular trends that could affect causal associations and allow mitigation as necessary.

KEYWORDS

falls; emergency medicine; machine learning; clinical decision support; automated screening; geriatrics

Introduction

Falls are highly prevalent among older adults in the United States [1,2] and are a common reason for emergency department (ED) visits [2-4]. They often precipitate a decline in the patient's overall health and ability to perform activities of daily living, such as dressing, bathing, and toileting [3,5]. ED providers are important collaborators in preventing at-home falls because they are often the first providers to see a patient after a fall (secondary prevention) [1] and because outpatient falls are often preceded by previous ED visits (primary prevention) [6]. This phenomenon is especially true for patients being discharged from the ED [3].

Patients presenting to the ED are at higher risk of falls than the general population and are more likely to face barriers that limit their access to screening and interventions available in other health care settings [7-12]. While previous work has shown that ED referrals to falls prevention interventions can reduce the risk of an at-home fall by 38% [13], ED-based interventions to identify and refer high-risk older adults for falls prevention services have not been widely implemented [14]. Major barriers to fall risk screening in the ED include the additional time and resources necessary to perform in-person screening, but the integration of machine learning (ML) and clinical decision support (CDS) offers the possibility of automating the screening process, thereby making it feasible to incorporate in routine ED practice at scale without adding to provider cognitive burden [15-19]. However, it remains unclear whether the automation of such screening and referral systems can reduce the risk of future falls among older patients. The goal of this paper to is describe a research protocol for a study evaluating the effectiveness of an automated screening and referral intervention, both in terms of leading to evaluations at the Mobility and Falls Clinic and preventing future falls.

More generally, this study will provide data on the effectiveness of a model of an automated intervention to identify and refer patients during an ED visit. This model of care is extensible to many other conditions and situations in which ED patients would benefit from screening and primary or secondary prevention services.

Methods

Setting and Patient Population

This study takes place at 3 EDs, described in Table 1, within a health system in the Midwestern United States. All 3 EDs share an instance of the electronic health record (EHR) developed by Epic, though system configuration (eg, nursing flow sheets and order sets) is not identical at the 3 sites.

Table 1. Intervention settings.

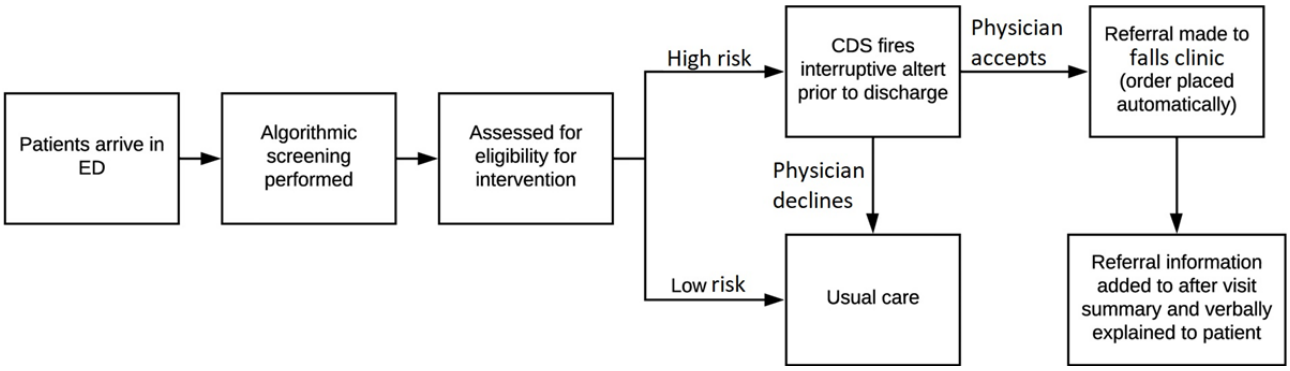
ED[a] site	Type	Intervention implementation date	Approximate annual volume of patients, n	Staffing
ED 1	Academic, level 1 trauma center	February 22, 2022	60,000 (25% geriatric)	Attending group 1, advanced practice providers, residents
ED 2	Community	September 27, 2022	22,000 (28% geriatric)	Attending group 1, advanced practice providers
ED 3	Community	Planned September 2023	65,000 (20% geriatric)	Attending group 2, advanced practice providers

[a]ED: emergency department.

The patient population for our study is individuals aged 65 years or older who present to participating EDs between February 22, 2022, and spring 2026, were discharged, and who had (at the time of ED visit) a primary care provider practicing within the health system in which this study is based. Because the ML-based CDS (ML-CDS) will be implemented in a rolling fashion at different EDs within the system, the start date for data will vary at different study sites. Dates were chosen to have at least two years' worth of index ED data for each site and an additional 6 months of follow-up ED visits to identify subsequent falls.

Intervention

These patients will be evaluated by our ML algorithm, and patients at high risk for an at-home fall within the next 6 months were flagged by our CDS when a provider documented a disposition of discharge from the ED [20,21]. The intervention, as well as training and validation of the algorithm, are limited to this in-system patient population for 2 reasons: first, these patients have a more complete patient history in the EHR for



XSL•FO
RenderX

the algorithm to draw on, and second, this restriction mitigates the possibility that access to care or insurance coverage network would be a barrier to patients being seen in the falls clinic.

The study intervention applies automation to harness existing data resources and information systems both to estimate risk at the patient level and to facilitate referral among high-risk patients. This risk estimate drives a CDS tool that presents a referral recommendation to the physician within the ED workflow. This selective application of automation is aligned with human factors principles [21-24] and allows busy clinicians to improve patient care without interruption to existing workflows.

To support efforts by ED providers to prevent falls among older adults, our team has developed an ML-based CDS algorithm to identify the risk of a return to the ED for a fall for discharged patients [20]. This algorithm was subsequently incorporated into the EHR (Epic Systems). When providers are preparing to discharge a patient, this CDS alerts the ED provider if the ML algorithm identified the patient as at high risk of an at-home fall in the next 6 months and recommends referral to an outpatient mobility and falls clinic [21]. This process is illustrated in Figure 1 [21]. The ML algorithm will be retrained with the same feature set for each site prior to implementation. Implementation at each site will be done in compliance with institutional practice for CDS changes, following human factors engineering principles [23,24], and using best practices for ML-based CDS implementations [25].

Figure 1. Operationalization of automated falls risk screening and referral process in the ED (adapted from Jacobsohn et al, reused with permission from Elsevier [21]). CDS: clinical decision support; ED: emergency department.

At the outpatient clinic, patients receive an evidence-based, multidisciplinary intervention to help them reduce their risk of a fall [13]. Together, the algorithm and associated CDS tool form a novel automated screening and referral intervention that was designed and implemented using a human factors engineering framework to ensure both usability and an emphasis on patient safety [21-23].

Outcomes

Our primary outcome is the rate of completed referrals to the Mobility and Falls Clinic among patients identified as high-risk. We define a completed referral as a patient completing an initial visit with a falls prevention specialist at the mobility and falls clinic.

Our secondary outcome is return visits to any ED for a fall within 6 months of the index ED visit, the outcome our ML algorithm was trained to predict. This outcome is meant to reflect the overall effectiveness of the intervention in preventing falls among patients identified as high-risk.

Additional process outcomes will be investigated to deconstruct steps from the identification of high-risk patients to completed referrals. These include whether a patient was referred to the outpatient mobility and falls clinic after being identified as high risk, whether referred patients were reached by schedulers, and whether referred patients scheduled an initial appointment, regardless of whether they attended.

Data Collection

Variables

Variables for analysis were selected conceptually based on the Andersen behavioral model of health services use, a well-established model that provides a context for characterizing the many factors which lead to health care use [26-29]. Within this model, both contextual and individual factors influence patients' initial ED visits and downstream health care use and outcomes. This model has been used to frame numerous prior studies involving ED use and falls among older adults [30,31], as well as the initial design and validation study of this intervention. During previous work, we have built a rich data set of covariates with over 700 potential EHR data features at ED 1 and will add data from ED 2 and ED 3 using the same data definitions [20]. These include patient factors, such as age, sex, race, ethnicity, and previous health system use; enabling factors, such as financial and physical availability of care; and ED encounter level factors, such as treatment team composition, ED length of stay, reason for visit, emergency severity index, diagnostic tests, and pharmaceutical and therapeutic interventions.

Data Retrieval Process

Data will be collected from the EHR in 4 steps. First, we will retrieve data about the patient, their index ED visit, and falls risk information—ML algorithm risk score, walking aids, history of falls, and acute care usage—from the EHR. Second, these data and information about referral orders and subsequent scheduled visits with the mobility and falls clinic will be

XSL•FO
RenderX

uploaded to a Health Insurance Portability and Accountability Act (HIPAA)-compliant database built in a Research Electronic Data Capture (REDCap; Vanderbilt University) database [32]. This REDCap database is needed so documentation about the reason a patient did not ultimately schedule or attend the clinic visit can be abstracted. Specific reasons for not completing the referral are not always documented discretely, so they will be abstracted from free-text scheduler notes by 2 trained reviewers. Specifically, the reviewers will look for reasons the patient was documented to be ineligible. Reasons include whether the patient is in other physical therapy, in hospice, or in memory care; is too advanced to benefit, immobile, or wheelchair-bound; and whether the patient or caregiver declined or was unreachable. Third, after verifying outcome variables and the reason for not scheduling a visit, the data on the clinic visit will be joined with the curated data described above into a limited data set for analysis. Finally, falls outcome data will be merged with Medicare claims data to determine if the patient was treated for a fall at an outside ED.

Statistical Analyses

Primary Outcome: Completed Referrals

The primary association of interest is whether an ED-based referral from an ML-based CDS can successfully cause patients to complete a specialist appointment. To assess the effectiveness of our program for patients receiving the falls risk intervention, our primary analysis will be to obtain point estimates and the 95% Wald CI of referral completion rate by site. We will perform a similar analysis to identify rates for prespecified process metrics, including referral orders placed among flagged patients and clinic appointments scheduled among at-risk patients. Further, we will perform a secondary analysis to identify subgroups at risk for lower odds of referral completion using a logistic regression model for each site to predict referral completion as a function of demography (sex, age, race, ethnicity, and education) and fall risk score. A model built for each site will account for site-level variability. Estimated coefficients and their 95% CIs will indicate risk factors for poor referral completion. This will help inform future implementation by, for example, identifying risk score thresholds for obtaining target rates of completed referrals for a given patient population.

Secondary Outcome: Return Visits to ED for a Fall

Although the intervention is not randomized, our study has a quasi-experimental design known as a sharp regression discontinuity with regards to intent-to-treat, since the intervention is administered to patients whose risk score falls above some threshold. This design allows for causal inference, provided that differences in outcomes for patients with similar risk scores can be attributed to the intervention (formally, expected potential outcomes are continuous in risk score). This occurs when patients are not manipulating their assignment to the intervention. Assuming this holds, we will primarily analyze only those patients whose risk scores fall within a band around the risk score threshold. Additionally, patients will be stratified by ED arrival date to account for changes to this threshold to be aligned with a sharp research continuity design. A conditional logistic regression model will be built to describe 6-month fall risk at each site as a function of the intervention, patient demographics, and risk score. The odds ratio of a return visit for fall and the 95% CI will be estimated by comparing those identified as high risk by the ML-CDS algorithm and those who were not but had a similar risk profile. Sensitivity analyses will be performed to examine the influence of bandwidth choice and key assumptions (ie, continuity of potential outcomes and linearity in risk score) on estimates. A secondary analysis will be to investigate the effect of covariates on completed referrals and falls using a stratified Cox proportional hazards model for time-to-fall events (right-censored by follow-up time).

Statistical Power

With the plan to flag 5 patients per week at each referral site, we plan to refer 520 patients per site, generating 1560 total patients referred. A sample size of 520 would lead to 95% Wald CI for referral completion rate by site that is 8.6% in width or smaller. This width provides sufficient precision for our study, considering that (1) a completion rate as small as 10% would be clinically meaningful and (2) we expect to observe a referral completion rate of 50% or higher—in which case, there would be nearly 100% power to reject a referral completion rate of 10% at a significance level of .05 when n=520.

For reference, very few patients were referred from the ED to the mobility and falls clinic prior to our intervention, and the clinic estimates that 80% of their patients referred from other providers visit the clinic. Power can be estimated for detecting a significant intervention effect on fall risk, provided additional covariates are ignored. In this case, a score test for this effect is equivalent to a Cochran-Mantel-Haenszel test of independence in a stratified sample. Such a test has 89.7% power to detect a difference in fall risk of 10% in a stratified sample size of 12 groups (in twelve 8-week periods over 2 years) assuming (1) a significance level of .05, (2) 40 patients receive the intervention and 40 patients do not who have similar risk scores, and (3) an average fall risk of 25%. For reference, our preliminary work predicted a number to treat of about 10 (ie, a fall risk difference of 10%) when setting the risk score threshold so that 5 persons per week receive the intervention (or 40 persons per 8 weeks) and an average fall risk of about 25% for individuals with a fall risk score above or near the fall risk score threshold. We plan on exploratory analysis of pooled data to evaluate the effect of specific covariates on rates of referral; in these cases, power will be lower based on the incidence of specific covariates in the data.

Data Protection

The major potential risk to subjects is that of loss of confidentiality. We have policies and procedures in place to protect the confidentiality and security of patient data, and our data protection measures (for protected health information) are consistent with HIPAA privacy and security rules. Only persons directly involved in the project will have access to patient data. Access to computer-stored information will be strictly controlled with data stored on servers physically sequestered and protected behind both physical and digital access controls. All servers are behind our organization's HIPAA firewall. All project personnel have successfully completed institutionally required human subjects training (required every 3 years) and HIPAA privacy and security training (required every year).

XSL•FO
RenderX

Dissemination

Our multidisciplinary team spans emergency medicine, engineering, health services research, and biostatistics, facilitating dissemination to a diverse and multidisciplinary audience. We will leverage institutional resources across the health system and university and capitalize on the breadth of professional networks offered by our interdisciplinary team to ensure broad dissemination. Dissemination of findings and of the final intervention will be accomplished through 2 channels. Academic dissemination will occur through publication in relevant peer-reviewed journals and presentations at national conferences focused on aging research, informatics, human factors, and emergency medicine. We will also share findings at end-user and EHR-focused conferences to reach potential adopters who might not be reached by more formal outlets.

Ethics Approval

This research plan was reviewed and approved by the University of Wisconsin Health Sciences Institutional Review Board (2021-0776). This observational quasi-experiment is registered with clinicaltrials.gov (NCT05810064).

Results

As of April 30, 2023, the CDS tool has been implemented at 2 of the 3 sites. Providers at ED 1 have written 303 referral orders for 260 unique patients, or 5 referrals per week on average, which is our goal. ED 2, the community ED, has not been live with the ML-CDS as long, and providers have written 91 referral orders for 86 different patients, or just over 3 referrals per week. Both EDs refer roughly 30% of patient encounters the algorithm identifies: 303 referrals for 1007 patients flagged at ED 1 and 91 referrals for 319 patients flagged at ED 2. The patient populations between these 2 EDs have substantial overlap, and 6 patients have received referrals from both EDs. After conversations with the mobility and falls clinic, we do not see repeat referrals as a problem unless the patient has already completed 1 of the referrals, so our ML-CDS tool was updated to exclude patients with a completed or scheduled appointment at the mobility and falls clinic. Notably, the patient uptake of the final intervention is about 15% of patients referred—45 patients of 339 unique patients; 1 patient was seen at and referred by both ED 1 and 2—which is less than the 80% that the clinic estimates for other referral sources. While not surprising that uptake would be lower from ED provider referrals than from primary care provider referrals, this conversion rate is lower than we anticipated, and we have taken steps to improve messaging, patient follow-up, and providers' ability to talk to patients about the program, and we have taken other steps that have shown some improvement appointment conversion in recent months. Additionally, waning concerns about COVID-19 have seemed to increase patients' willingness to consider completing the referral.

Discussion

Hypothesis and Expected Findings

We expect that this research will show the beneficial impact of automated screenings on both patients receiving recommended care (completed referrals) and preventing adverse outcomes (falls). Even for patients who are not referred, we anticipate providers having conversations with patients who are flagged as high risk for a fall, which could still lead to increased compliance with ongoing treatment or seeking falls prevention treatment outside our partner clinic (eg, physical therapy available at an assisted living facility). These findings will inform ongoing discussions about the use of ML and artificial intelligence to augment medical decision-making.

Significance of Principal Findings

Previous work with ML-CDS tools has focused on their implementation in a specific context [33] or on the predictive performance [34] of the underlying algorithm. Our unique data set will include information about patient's health history (eg, health care use) prior to the ED index visit, referral completion, and subsequent ED return visits for falls (either in the system or from Medicare claims), providing a more complete picture of a given patient's trajectory than most studies. We will use this unique data set to track not just ML-CDS performance in the context of its implementation, but in the context of larger patient health outcomes, which, to our knowledge, has not been done for this kind of long-term, preventative ML-CDS system. Similarly, the multisite implementation plan will demonstrate applicability to a broad population and the possibility to adapt the intervention to other EDs and achieve similar results.

Our statistical methodology (a regression discontinuity design) allows for an intent-to-treat causal inference about the impact flagging high-risk patients can have on patients' future falls. Conversations with patients about the referral, even if a referral is not written, could have impacts on patients' risk awareness and compliance with physical therapy, so ML-CDS flagging is the correct epidemiologic exposure to assess with respect to the outcomes of completed mobility and falls visits or return ED visits for falls. A staggered implementation strategy allows for the identification of secular trends that could affect causal association and mitigation as necessary.

Limitations

To achieve the desired number of clinic referrals per week, the falls risk threshold for the CDS identification will be changed over time. Because regression discontinuity designs typically assume a static threshold for analysis, we will need to approach the regression discontinuity analysis carefully and with sufficient sensitivity analyses to ensure that these threshold changes do not compromise the findings. Simulation studies will be conducted to ensure the assumptions of regression discontinuity analysis are met.

Clinically, our assumptions about the effectiveness of the mobility and falls clinic intervention are based on PROFET (Prevention of Falls in the Elderly Trial) [13], which specifically evaluated patients referred from the ED. The intervention is based on evidence from a randomized clinical trial, but the magnitude of the effect may be different in our patient population—for example, due to endogenous factors like demographic composition of the community or exogenous factors related to changes in care patterns during the COVID-19 pandemic. In addition to methodological concerns, there are

XSL•FO
RenderX

some pragmatic limitations. First, the intervention was implemented during the COVID-19 pandemic. During the study period and community, there were—and could continue to be—multiple waves of elevated SARS-CoV-2 infections and case counts that may dissuade some patients from scheduling an appointment at the mobility and falls clinic. Similarly, in order to maximize patient impact and to study the human factors inputs to this system, efforts were made to increase referral rates and referral completion with providers and patients. While these efforts will likely increase the statistical power over time, it is also likely that there will be secular effects in the imperfect compliance with referral rates and referral completion rates that are present in the data as a result of these efforts.

Acknowledgments

This work is supported by the Agency for Health Care Research and Quality (grant R18HS027735; BWP, PI) and by the National Institute on Aging of the National Institutes of Health (award K24AG054560; MNS). ALC receives additional funding from the American Psychological Association as a statistical editor for *The American Journal of Psychiatry*. This work is solely the output of the authors and does not represent the views of any funding agencies.

Authors' Contributions

DJH wrote and edited the manuscript and designed and built the data extraction and retrieval process. ALC performed substantial editing and review of the manuscript, is a coinvestigator on the Agency for Health Care Research and Quality R18 grant, and provided biostatistical expertise for the analysis plan presented in the manuscript, research plan, and R18 grant. APM and HJB reviewed and edited the manuscript, gave substantial feedback on data management processes, and helped manage the team. BWP is the principal investigator on this project and provided substantial manuscript editing and review and clinical expertise for the intervention design and implementation. MNS, DW, MAS, and FL provided manuscript review and substantial contributions to the study conception and design.

Conflicts of Interest

None declared.

Abstract

Background: By 2030, approximately 75 million adults will be living with Alzheimer disease and related dementias (ADRDs). ADRDs produce cognitive, emotional, and behavioral changes for persons living with dementia that undermine independence and produce considerable stressors for persons living with dementia and their spousal care-partners—together called a “dyad.” Clinically elevated emotional distress (ie, depression and anxiety symptoms) is common for both dyad members after ADRD diagnosis, which can become chronic and negatively impact relationship functioning, health, quality of life, and collaborative management of progressive symptoms.

Objective: This study is part of a larger study that aims to develop, adapt, and establish the feasibility of Resilient Together for Alzheimer Disease and Related Dementias (RT-ADRD), a novel dyadic skills-based intervention aimed at preventing chronic emotional distress. This study aims to gather comprehensive information to develop the first iteration of RT-ADRD and inform a subsequent open pilot. Here, we describe the proposed study design and procedures.

Methods: All procedures will be conducted virtually (via phone and Zoom) to minimize participant burden and gather information regarding feasibility and best practices surrounding virtual procedures for older adults. We will recruit dyads (up to n=20) from Mount Sinai Hospital (MSH) clinics within 1 month of ADRD diagnosis. Dyads will be self-referred or referred by their treating neurologists and complete screening to assess emotional distress and capacity to consent to participate in the study. Consenting dyads will then participate in a 60-minute qualitative interview using an interview guide designed to assess common challenges,

XSL•FO
RenderX

unmet needs, and support preferences and to gather feedback on the proposed RT-ADRD intervention content and design. Each dyad member will then have the opportunity to participate in an optional individual interview to gather additional feedback. Finally, each dyad member will complete a brief quantitative survey remotely (by phone, tablet, or computer) via a secure platform to assess feasibility of assessment and gather preliminary data to explore associations between proposed mechanisms of change and secondary outcomes. We will conduct preliminary explorations of feasibility markers, including recruitment, screening, live video interviews, quantitative data collection, and mixed methods analyses.

Results: This study has been approved by the MSH Institutional Review Board. We anticipate that the study will be completed by late 2023.

Conclusions: We will use results from this study to develop the first live video telehealth dyadic resiliency intervention focused on the prevention of chronic emotional distress in couples shortly after ADRD diagnoses. Our study will allow us to gather comprehensive information from dyads on important factors to address in an early prevention-focused intervention and to explore feasibility of study procedures to inform future open pilot and pilot feasibility randomized control trial investigations of RT-ADRD.

Introduction

Background

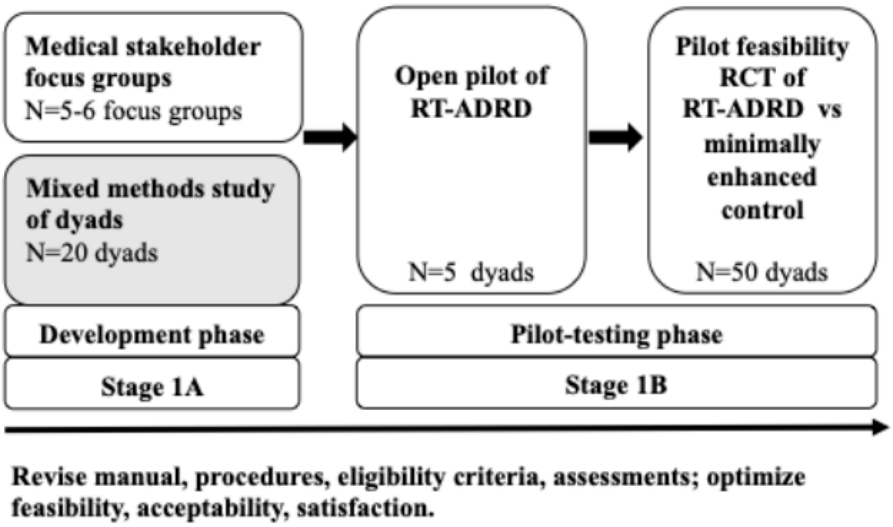
Alzheimer disease and related dementias (ADRDs) are already experienced by 55 million individuals worldwide, and this number is projected to increase to roughly 75 million by 2030 [1]. ADRDs produce early symptoms (eg, increased forgetfulness, communication challenges, loss of recognition of places, time, and routines) that progress over time and undermine the independence, health, well-being, and relationships of persons living with ADRDs and their family care-partners [2-4]. Over 11 million family members are primarily responsible for supporting persons living with dementia for activities of daily living, and many are romantic or spousal care-partners [1,5,6]. Spousal care-partners are often considered “the second patient” [1] due to their shared experience of the life disruptions and stress experienced as a result of ADRDs and their instrumental role in assisting in medical care, daily activities, and transitions in functional independence [7-9]. Among care-partners, spouses and romantic partners are recognized as an important group to target for early support given their role in at-home caregiving activities, experience of relational disruptions, and greater likelihood of experiencing mental and physical health consequences of caregiving [6].

From symptom onset to receiving a formal or suspected diagnosis, both persons living with dementia and their spousal care-partners experience substantial changes in roles, plans, and expectations [8,10,11]. While some adjust well to these disruptions, many individuals (23%-52%) and spousal care-partners (35%-50%) experience “clinically elevated emotional distress” (ie, depression and anxiety) in the weeks and months leading up to and after diagnosis [12-17]. Dyads’ distress amplifies amid the progressive symptoms and lack of sufficient treatments for ADRDs and the impact on their daily life and relationships [18-20]. Dyads’ distress is also interdependent (ie, mutually experienced and bidirectional) and interferes with their ability to effectively communicate and problem-solve challenges [12,18,21,22]. Without adequate support or treatment, emotional distress is likely to become chronic and negatively impact dyads’ relationship functioning, mental and physical health, and quality of life [12,22,23]. At present, individuals living with ADRDs and their care-partners have little support available after diagnosis to manage stressors, cope with distress, communicate effectively, and collaboratively plan for the future [22,24]. There are no established treatments to date that substantively alter the course of ADRDs and no available psychosocial interventions to promote positive dyadic adjustment to challenges experienced early after diagnosis [11,25].

Both individuals living with ADRDs and their spousal care-partners describe having insufficient support and a lack of resources to assist them in managing early symptoms, expressing personal needs, and learning to address shared challenges together [26,27]. Dyads each express an interest in participating in psychosocial interventions together in order to learn skills to cope with the diagnosis and symptoms and prepare for future challenges [27-31]. Dyadic interventions exist for early-late stage ADRDs that demonstrate promise in reducing dyads’ emotional distress and neuropsychiatric symptoms in the person living with ADRD [32]. However, no available interventions target the period early postdiagnosis, thereby missing the window of opportunity to meaningfully include persons with ADRDs in collaborative treatment and planning before symptoms progress [11,33,34].

Dyadic interventions delivered early after ADRD diagnoses may be an optimal avenue for promoting adjustment to the challenges experienced by persons living with dementia and their spousal care-partners while they are still able to engage collaboratively in treatment and care planning. Such approaches are capable of simultaneously providing both partners with individual and interpersonal skills training to (1) effectively cope with adversity, thereby reducing emotional distress, and (2) preserve the quality of life by maintaining identity and normalcy, preserving social connections, and communicating to better navigate shared challenges and long-term care plans

XSL•FO
RenderX



[35]. Dyadic interventions are more effective and economical than those focused on patients or care-partners alone [36] and are feasible and demonstrate some positive effects on the dyadic relationship in the context of early-stage ADRD [26]. Recent advances in telehealth approaches also allow these interventions to be delivered via live video telehealth (eg, Zoom), which can increase access and equity in care and allow for the personalization of skills-based interventions. Dyads coping with ADRD report similar preferences for telehealth and in-person visits, with fewer barriers using telehealth technology [37-39].

This Study

Early dyadic interventions have the potential to promote positive adjustment to ADRD by improving dyads' individual and interpersonal resiliency (ie, the ability to adjust effectively to significant adversity) [40] and provide skills and support to actively contribute to care-planning, preserve their autonomy, and express needs and preferences [41,42]. Many dyadic interventions include resiliency skills linked to positive adjustment after stress and trauma, including (1) mindfulness—staying present and deferring judgment in the face of adversity [43], (2) coping—building and applying cognitive, behavioral and emotional strategies to navigate challenges [44], (3) dyadic coping—open dialogue about stressors, preferences, and needs; approaching challenges as a unit [45,46], (4) social support—engaging social resources to meet needs [47], and (5) general self-efficacy (GSE)—perceived resourcefulness to adapt to adversity [48].

Members of our team developed Recovering Together, a brief dyadic resiliency intervention that prevents chronic emotional distress in patients and informal care-partners shortly after intensive care unit admission for acute neurological conditions (eg, traumatic brain injury, stroke) [49,50]. This study is part of a larger 5-year study that aims to use the prior research, methodology, program content, and procedures of the Recovering Together program as a basis for developing the novel Resilient Together for Alzheimer Disease and Related Dementias (RT-ADRD). RT-ADRD will be developed sequentially using the National Institutes of Health stage model and prior research to guide intervention development [9,51]. The purpose of this paper is to describe the protocol for a mixed methods study involving patient and spousal dyads early after ADRD diagnosis that will inform the development of the first version of RT-ADRD (Figure 1). Through this study, we hope to gather comprehensive information on dyads' challenges, needs, and intervention preferences to develop a program that is feasible, acceptable, and capable of meaningfully improving target outcomes for persons living with dementia and their spousal care-partners early after ADRD diagnoses.

Figure 1. Proposed iterative development of RT-ADRD. RCT: randomized controlled trial; RT-ADRD: resilient together for Alzheimer disease and related dementias.

Methods

Ethics Approval

This study was approved by the Mount Sinai Hospital (MSH) Independent Review Board (22-01623).

Study Design

We are currently conducting a mixed methods investigation involving persons living with ADRD and their romantic or spousal care-partners (target N=up to 20 dyads; recruitment scheduled to begin April 2023). This study is designed to (1) gather impressions of dyads' challenges and needs early after ADRD diagnosis, and (2) obtain feedback on proposed RT-ADRD program procedures (eg, screening, recruitment, consent, intervention delivery, survey assessment) and intervention content. Quantitative assessment measures will be used to explore the feasibility of assessment procedures and gather data to explore preliminary associations among hypothesized intervention mechanisms and target outcomes (see Figure 2 and Table 1).

Figure 2. Study conceptual model.

Table 1. Study measures.

Construct	Measure or description and type
Covariates	
Demographics	• Medical chart review and participant self-report: gender, age, race, ethnicity, marital status, education level, employment (status, occupation, and income), mental health history
Clinical characteristics	• Medical chart review and participant self-report: type of ADRD[a] diagnosis, age at diagnosis, date of diagnosis, symptoms
Primary outcomes	
Emotional distress	• Hospital Anxiety and Depression Scale (14 items) (depression and anxiety subscales)–emotional distress • Geriatric Depression Scale–Short Form (15 items)–depression • Perceived Stress Scale (4 items)–stress
Quality of life	• World Health Organization Quality of Life–Short Form (26 items)–quality of life
Relationship satisfaction	• Couple Satisfaction Index (16 items)–relationship satisfaction and communication
Primary intervention targets	
Mindfulness	• Cognitive and Affective Mindfulness Scale–Revised (12 items)–mindfulness skills
Individual coping	• Brief Coping Orientation to Problems Experienced (28 items)–adaptive and maladaptive coping strategies
Dyadic coping and communication	• Dyadic Coping Inventory–common dyadic coping subscale (5 items) and negative dyadic coping (4 items) subscale–dyadic stress management • Dyadic Relationship Scale (10 items for patients, 11 items for caregivers)–relationship strain
Social support	• Social Support Questionnaire-Short Form–Revised (12 items)–social support availability and satisfaction
Self-efficacy	• General Self-Efficacy Scale (10 items)–self-efficacy
Caregiver readiness	• Preparedness for Caregiving Scale (8 items; caregiver only)–preparedness for caregiving

[a]ADRD: Alzheimer disease and related dementias.

Inclusion and Exclusion Criteria

We will recruit dyads with English fluency and literacy who are willing to participate and comply with the requirements of the study (including surveys and an interview). Eligible persons living with ADRD will be individuals aged 65 years or older who have a chart-documented ADRD diagnosis within the past month, ADRD symptom onset after the age of 65 years, and cognitive assessment scores and symptoms consistent with early-stage dementia (as determined by provider impressions and test scores such as the Clinical Dementia Rating Scale [52] scores of 0.5 or 1.0 or Montreal Cognitive Assessment [53] scores between 18-21). To be included in the study, they will also be required to (1) demonstrate cognitive awareness of their problems (as determined by the treating providers), and (2) capacity to understand the study and research protocol (confirmed during study screening using scores >12 on the University of California Brief Assessment of Capacity to Consent [UBACC] 10-item scale [54], described in detail

XSL•FO
RenderX

below). In addition, at least 50% of dyads will exhibit clinically elevated emotional distress (as determined by self-report measures listed below) in order to compare dyads' responses by level of distress and inform future selection criteria. Exclusion criteria for persons living with dementia are (1) a diagnosis of frontotemporal dementia-behavioral variant or other ADRD variant that would interfere with the ability to meaningfully participate, (2) inability to provide informed consent due to cognitive or behavioral impairments, and (3) being deemed inappropriate to participate by the referring providers. Additional exclusion criteria for dyads are comorbid terminal illness diagnosis in either partner. Both dyad members must be eligible and provide informed consent in order for either member of the dyad to participate.

Recruitment and Screening

Dyads will be recruited via the MSH dementia care clinical infrastructure, including the departments of neurology, psychiatry, and geriatrics. The recruitment team will present the aims to medical staff in department clinics, explain the purpose and potential benefits of participation, and discuss ways to best facilitate referrals. As part of routine procedures, treating providers conduct assessments of each patient's understanding (knowledge of facts) and appreciation (recognition of factors that apply to that person) of the presence and severity of cognitive impairment. Results of these assessments are included in patient's medical records, and can be used as a metric for facilitating appropriate referrals. Treating providers will confirm diagnoses of ADRDs and clear patients for participation in the study before facilitating referrals. Potential participants will first hear about the study from their treating providers, who will introduce the study around the time of diagnostic disclosure and provide interested dyads with a study flyer. Providers will also obtain permission for the dyad to be contacted by the research team for recruitment purposes.

With dyads' permission, providers will refer potentially eligible patients by sharing relevant dyad information with the study team, including (1) patient and spouse names and contact information, (2) medical record numbers, (3) diagnosis, and (4) date of diagnosis. Dyads can also contact the study team directly via a screening survey accessed through the study flyer on the Research Electronic Data Capture (REDCap) program. The research team will contact dyads via email to complete screening procedures using the REDCap survey and a screening call (Zoom video or telephone). The screening call will be used to provide dyads with more information about the study, answer questions, and assess eligibility. A member of the research team will speak with persons living with ADRD and spousal care-partners individually while administering initial screening measures to ensure privacy. Once determined eligible on these initial measures, dyads will have the option to complete the remaining screening and consent procedures individually or together according to preference. If either dyad member is deemed unable to meaningfully participate in the study based on screening procedures (eg, assessment of capacity to consent, described below) but is eligible based on the remaining criteria, the study staff will provide the dyad with a resource sheet containing local and national resources for ADRDs. If eligible, a member of the research team will document informed consent for dyads using an e-consent feature on REDCap.

Assessment of Capacity to Consent

Individuals' ability to understand the study and research protocol will be determined by a standardized teach-back method. Research staff will receive extensive training and supervision to administer the assessment, which will consist of the 10-item UBACC scale [54]. Scores >12 indicate ability to consent. After reviewing the consent form, individuals will be asked to repeat aspects of the consent back to the research staff. We will ask 4 questions about the expectations and risks of the study for participants, which have predetermined acceptable answers. Individuals who respond with 100% accuracy will be eligible to consent to the study, whereas individuals who do not achieve 100% accuracy will be prompted to reread the consent form and will be reasked the questions. If the individual does not achieve 100% accuracy a second time, they will not be eligible for the study.

Qualitative Data Collection

After both dyad members consent to participate in the study, a member of the research team will schedule a 60-minute joint interview with a PhD-level clinical psychologist with expertise in conducting dyadic interviews. In advance of the interview, we will send dyads an interview guide with potential discussion topics and tips for using the secure live video software. A member of the research team will also be available to provide technology support and orientation to Zoom before and during the scheduled interview session. During the 60-minute interview, the clinical psychologist will follow a semistructured interview guide (see Multimedia Appendix 1). Another member of the study team will attend the interview to complete a rapid data analysis template developed by the research team. The rapid data analysis template will be used to inform formal coding and will capture observations within key interview domains, poignant participant quotes, researcher reflexivity, and important notes and observations (see Multimedia Appendix 2). During the interview, the clinical psychologist will work to generate information from dyad members on their convergent and divergent perspectives regarding their early experiences after ADRD diagnoses and unmet support needs and to gather feedback surrounding the proposed intervention content and procedures. Following the completion of the joint interview, dyad members will have the opportunity to participate in optional 15-minute individual interviews to share anything that they would prefer to discuss with the research team without their partner present.

Quantitative Data Collection

Overview

Following the completion of the qualitative interviews, we will send each dyad member a quantitative survey to complete individually via the web-based REDCap platform which will take approximately 30-50 minutes to complete. Dyad members will have the option to complete the survey independently or over Zoom with assistance from a member of the research team. If completing the survey over Zoom, the research team member will use the "Share Screen" feature to gather responses to survey

XSL•FO
RenderX

items and progress through the questionnaires. Questionnaires were selected to gather additional information surrounding the hypothesized intervention targets (ie, mechanisms of change), and outcomes, as well as selection criteria for individuals to target in the context of an early dyadic intervention. We selected questionnaires for the survey that each have strong psychometric properties and were feasible and acceptable in prior dyadic studies. Survey responses will be stored on the REDCap platform and accessed via password-protected laboratory computers. Paper data files (with coded subject identification) will be stored in a locked filing cabinet accessible only to the research team.

Demographics

We selected demographic variables to assess factors that may impact dyad experiences and adjustment to ADRD diagnoses. We will collect information on participants' gender, age, race, ethnicity, marital status, education level (number of years in school), employment (status, occupation, and income), and mental health history.

Clinical Characteristics

We selected clinical characteristics to assess dyads' experiences in the context of their ADRD symptoms and medical care. For the person living with dementia, we will collect information on their ADRD diagnosis and symptoms via electronic medical records, including clinical characteristics, type of diagnosis, age at diagnosis, and date of diagnosis.

Proposed Outcomes

We selected proposed outcomes based on prior research documenting the prevalence and correlates of emotional distress and low quality of life among dyads experiencing dementia and recent calls for interventions to promote positive adjustment early after diagnosis. We will use the 14-item Hospital Anxiety and Depression Scale (HADS) [55] total score to assess emotional distress. Scores range from 0-42 with higher scores indicating more emotional distress. We will also examine the 7-item depression and anxiety subscales of the HADS (HADS-D and HADS-A, respectively). Scores range from 0 to 21, with higher scores indicating more depression or anxiety. We will also use the 15-item Geriatric Depression Scale (GDS)–Short Form [56] to assess the past week depression symptoms. Scores range from 0-15, with higher scores indicating more depression. We will assess perceived stress over the past month using the perceived stress scale (PSS-4) [57]. Scores range from 0-16, with higher scores indicating greater perceived stress. To assess perceived quality of life, we will use the 26-item brief World Health Organization Quality of Life (WHOQOL-BRIEF) assessment [58]. The WHOQOL-BRIEF assesses quality of life across 4 subscales (physical health, psychological, social relationships, and environment). The first 2 items provide a global assessment of the quality of life, and subscale scores are calculated by summing items and transforming scores to a 0-100 point interval, with higher scores indicating greater perceived quality of life. To assess dyadic relationship satisfaction, we will use the 16-item Couple Satisfaction Index (CSI) [59]. Total scores range from 0-81, with higher scores indicating greater relationship satisfaction.

Treatment Targets

We selected treatment targets assessing individual and dyadic coping and relationship functioning based on our hypothesized mechanisms underlying changes in proposed outcomes (ie, emotional distress, quality of life). We will use the 12-item Cognitive and Affective Mindfulness Scale, Revised (CAMS-R) [60] to assess mindfulness. Total scores range from 12-48 with higher scores indicating greater engagement in mindfulness practices. We will use the 28-item Brief Coping Orientation to Problems Experienced (Brief COPE) [61] to measure ways of individually coping with stressful events. The Brief COPE includes 3 subscales that assess coping styles: (1) problem-focused (8 items), (2) emotional-focused (12 items), and (3) avoidant coping (8 items). Scores for each subscale are calculated with the sum of item scores divided by the number of subscale items, which higher scores indicating a greater degree of using the subscale coping style. To assess perceptions of dyadic coping, we will use the items from the Dyadic Coping Inventory [62,63] subscales: common dyadic coping and negative dyadic coping. The common dyadic coping subscale includes 5 items that assess dyads' ability to cope with problems together and search for solutions. Scores range from 5-25, with higher scores indicating greater perceptions of the dyad's use of common coping. We will also use the 4 items of the negative dyadic coping subscale of the Dyadic Coping Inventory to assess negative coping interactions. Scores range from 4-20, with higher scores indicating greater perceptions of the dyad's use of negative dyadic coping. In addition, we will assess dyadic relationship strain in the context of caregiving using the dyadic strain subscale of the Dyadic Relationship Scale (DRS) [64], which has a 10-item patient version and an 11-item caregiver version. Subscale scores range from 1-10 and 1-11 for DRS-Patient and DRS-Caregiver, respectively, with higher scores indicating greater relationship strain. We will use the 12-item brief Social Support Questionnaire (SSQR) [65] to assess social support availability and satisfaction. The SSQR consists of 2 subscales: support network availability (SSQR-N) and overall satisfaction (SSQR-S). Each item assesses support availability and satisfaction in separate parts; participants will be asked to (1) indicate how many people they can count on for various types of support, and (2) indicate how satisfied they are with the support. The SSQR-N subscale composite is calculated by adding the total number of people for all items and dividing it by the total number of items for an average support number. For the SSQR-S subscale total scores are calculated by adding subscale items and range from 6-36, with higher scores indicating greater social support satisfaction. We will assess perceived self-efficacy with the 10-item GSE [66] scale. Total scores range from 10-40, with higher scores indicating greater perceived self-efficacy. Finally, for spousal care-partners we will use the 8-item Preparedness for Caregiving scale to evaluate readiness for caregiving in relation to their spouse. Total scores range from 0-32 with higher scores indicating greater preparedness for caregiving.

Qualitative Analyses

Audio data from dyadic and individual interviews will be transcribed verbatim using a transcription service and then deidentified. We will upload and analyze deidentified transcripts

XSL•FO
RenderX

using the Dedoose qualitative analysis software [67]. Our approach to data analysis will involve a hybrid deductive-inductive approach that will allow us to explore our key research aims surrounding experiences and treatment preferences of spousal dyads early after ADRD diagnosis. Specifically, our approach will be deductive, in the sense that our interview guide, rapid data analysis template, and codebook domains will be influenced by (1) prior research on early psychosocial challenges following ADRD diagnosis, (2) prior studies focused on dyadic intervention development and adaptation, and (3) theories of dyadic adjustment to chronic and progressive illness. For example, our interview guide will include questions surrounding dyads' perceptions of available psychosocial supports, which we will explore further using a-priori defined rapid data analysis template and codebook domains. The remainder of our approach will be primarily inductive in nature, in the sense that our research team will document observations during rapid data analysis in a generative manner based on dyads' discussion. We will refine our initial codebook using these observations and assess when thematic saturation is reached for key aims. Formal qualitative data analysis will then be guided by the framework method. Members of the research team involved in qualitative analysis will begin with line-by-line review of 1-2 dyadic interview transcripts and open code poignant observations, which we will organize into the a-priori deductive domains and revise our initial codebook through team discussion. Next, 2 members of the research team will code 25% (approximately 5/20) of the interview transcripts (n=5) in the Dedoose software package [67] during the initial codebook. Coders will resolve discrepancies through discussions in weekly meetings with the larger research team. We will ensure high agreement between coders before they code transcripts individually. We will then refine coded data into themes and subthemes within each domain through team discussion.

Quantitative Analyses

We will use descriptive statistics to characterize the number and proportion of individuals approached, screened for eligibility, screened eligible, consented, and retained through interviews and surveys. For proposed outcome measures and treatment targets, we will calculate means and standard deviations of scores for each dyad member, and average scores of each dyad member to assess average responses across dyads. We will examine preliminary associations between treatment primary targets and emotional distress and quality of life outcomes using bivariate correlations. In addition, we will conduct a preliminary assessment of dyadic interdependence (similarity in patterns of responses) by calculating bivariate correlations of dyad members' scores on survey composites.

Comparison and Combined Interpretation of Qualitative and Quantitative Findings

We will use a convergent parallel mixed methods approach to evaluate and interpret qualitative and quantitative findings simultaneously [68,69]. This design involves concurrent, separate collection and analysis of qualitative and quantitative data followed by a detailed examination of convergence or divergence between qualitative and quantitative findings. Specifically, we will examine whether qualitative themes surrounding couples' perception of psychosocial stressors correspond with perceptions on relevant quantitative measures (described as triangulation of findings; eg, with survey constructs such as emotional distress, quality of life, individual and dyadic coping). We will also examine whether correlations between quantitative measures are explained by qualitative descriptions of underlying processes. If observed, divergent findings will be further explored by examination of dyads' demographic and clinical characteristics as well as through the integration of knowledge from prior research, consistent with guidelines for mixed methods research [70].

Results

This study is funded by the National Institute on Aging grant 1K23AG075188 to SMB, who recently moved to MSH. This study was approved by the institutional review board of MSH. Recruitment started in April 2023. Data collection is anticipated to be completed by September 2023, and data analysis is anticipated to be completed by November 2023.

Discussion

Receiving a diagnosis of ADRDs can have a devastating impact on individuals and their care-partners given the lack of available ameliorative interventions or cures and insufficient support early postdiagnosis [18,34]. Prior research suggests that (1) dyads of individuals and their care-partners are interested in participating in early psychosocial interventions together, and (2) that it is feasible to adapt existing dyadic interventions to effectively and efficiently address early challenges to dyads following an ADRD diagnosis [26,32,51]. Comprehensive feedback from dyads can facilitate the development of such programs, and be used to promote alignment between patient, caregiver, and health care system perspectives on ways of optimizing ADRD clinical care.

This paper describes a mixed methods study design that is part of the development phase of a larger study that aims to develop a novel postdiagnosis dyadic resiliency intervention for couples facing ADRDs. We describe the study aims and details of the procedures for recruitment, screening, data collection, and data analysis. This description is valuable for future studies focused on the adaptation and tailoring of dyadic interventions for ADRDs as well as other chronic and progressive conditions. Results of this trial will critically support the development of the first version of the proposed RT-ADRD intervention content and procedures. In addition, findings can be used in conjunction with our prior study of ADRD medical stakeholders to elucidate ways of integrating the RT-ADRD intervention and other supports within existing clinical infrastructures, and to navigate barriers and facilitators to dyads' recruitment and participation in the RT-ADRD intervention. Our approach is consistent with National Institutes of Health stage model recommendations [9] to leverage findings to guide the development and refinement of program content and procedures prior to further testing.

This mixed methods study aims to gather comprehensive information from persons living with dementia and their spousal

XSL•FO
RenderX

care-partners surrounding their experiences, unmet support needs, and feedback on proposed intervention content and procedures for a postdiagnosis dyadic intervention. The overarching goal is to inform the design, procedures, and content of the novel RT-ADRD program prior to subsequent pilot testing, clinical trials, and implementation efforts. Findings from this study also have the potential to increase available information surrounding dyads' experiences following ADRD diagnosis and perceptions of helpful supports, which has implications for ADRD clinical care and can extend to other chronic and progressive neurological conditions.

Acknowledgments

We would like to thank the members of the Massachusetts General Hospital (MGH) Center for Health Outcomes and Interdisciplinary Research lab members and the MGH K club led by AMV for their feedback on the proposed study procedures. This study was funded by grants from the National Institute on Aging (1K23AG075188-01A1) to SB, and grants from the National Institute of Nursing Research (R01NR019982-01) and National Center for Complementary and Integrative Health (1K24AT011760-01) to AMV.

Abstract

Background: Electronic health record (EHR)–integrated digital personal health records (PHRs) via Fast Healthcare Interoperability Resources (FHIR) are promising digital health tools to support care coordination (CC) for children and youth with special health care needs but remain widely unadopted; as their adoption grows, mixed methods and implementation research could guide real-world implementation and evaluation.

Objective: This study (1) evaluates the feasibility of an FHIR-enabled digital PHR app for CC for children and youth with special health care needs, (2) characterizes determinants of implementation, and (3) explores associations between adoption and patient- or family-reported outcomes.

Methods: This nonrandomized, single-arm, prospective feasibility trial will test an FHIR-enabled digital PHR app's use among families of children and youth with special health care needs in primary care settings. Key app features are FHIR-enabled access to structured data from the child's medical record, families' abilities to longitudinally track patient- or family-centered care goals, and sharing progress toward care goals with the child's primary care provider via a clinician dashboard. We shall enroll 40 parents or caregivers of children and youth with special health care needs to use the app for 6 months. Inclusion criteria for children and youth with special health care needs are age 0-16 years; primary care at a participating site; complex needs benefiting from CC; high hospitalization risk in the next 6 months; English speaking; having requisite technology at home (internet access, Apple iOS mobile device); and an active web-based EHR patient portal account to which a parent or caregiver has full proxy access. Digital prescriptions will be used to disseminate study recruitment materials directly to eligible participants via their existing EHR patient portal accounts. We will apply an intervention mixed methods design to link quantitative and qualitative (semistructured interviews and family engagement panels with parents of children and youth with special health care needs) data and characterize implementation determinants. Two CC frameworks (Pediatric Care Coordination Framework; Patient-Centered Medical Home)

XSL•FO
RenderX

and 2 evaluation frameworks (Consolidated Framework for Implementation Research; Technology Acceptance Model) provide theoretical foundations for this study.

Results: Participant recruitment began in fall 2022, before which we identified >300 potentially eligible patients in EHR data. A family engagement panel in fall 2021 generated formative feedback from family partners. Integrated analysis of pretrial quantitative and qualitative data informed family-centered enhancements to study procedures.

Conclusions: Our findings will inform how to integrate an FHIR-enabled digital PHR app for children and youth with special health care needs into clinical care. Mixed methods and implementation research will help strengthen implementation in diverse clinical settings. The study is positioned to advance knowledge of how to use digital health innovations for improving care and outcomes for children and youth with special health care needs and their families.

Introduction

Background

Care coordination (CC) is an essential intervention for children and youth with special health care needs that involves clinicians and patients or families collaborating to coordinate numerous health and related services across multiple service sectors within the "complex care ecosystem" of each child and youth with special health care needs [1]. Children and youth with special health care needs are children and youth aged 0-21 years that "have or are at increased risk for chronic physical, developmental, behavioral, or emotional conditions and who also require health and related services of a type or amount beyond that required by children generally" [2]. Among children and youth with special health care needs, family-centered CC is associated with better outcomes (eg, fewer emergency visits and missed school days) [1,3-6]; however, many children and youth with special health care needs receive inadequate CC [7,8] and 86% of children and youth with special health care needs lack a well-functioning system of services [2]. These critical CC gaps contribute to higher health care usage and parental stress and isolation [9] as parents and caregivers (referred to as families) of children and youth with special health care needs are forced to primarily manage their child's CC needs in the absence of a well-functioning system of care [10].

To fill CC gaps, some families of children and youth with special health care needs have developed strategies to organize details of their child's lifelong health records (eg, longitudinal care plans, manual notebooks, or binders) [11,12]; however, better solutions are needed because these approaches have limitations. For example, manually curated records by families are labor-intensive, not synchronized with electronic health records (EHRs), and largely invisible to clinicians, thereby limiting their impact and obscuring family insights into their child's health progress at home. Digital health innovations offer promising solutions for children and youth with special health care needs and families to manage CC needs at home. In particular, digital personal health records (PHR) [13] enabled by Fast Healthcare Interoperability Resources (FHIR) for secure data access and sharing between mobile apps and EHRs [14,15] could assist families of children and youth with special health care needs to directly manage health information and facilitate family-centered CC [16]. FHIR-enabled digital PHRs accomplish this by synchronizing EHR and family-reported information with a personal mobile device, sharing family-reported insights longitudinally with providers (eg, care goals), and facilitating family and provider communication.

Despite their potential as digital health innovations and the clinical need for solutions for children and youth with special health care needs, FHIR-enabled digital PHRs have not yet been broadly adopted due to logistical and research challenges. Key logistical challenges include technical barriers, funding and infrastructure support, and lack of end user engagement in co-design [17]. In the research domain, as adoption of digital health innovations (eg, telehealth, mobile apps, and remote monitoring) accelerates, early phase pragmatic clinical research is needed [18] to elucidate implementation outcomes (eg, feasibility and acceptability) [19] and identify implementation barriers and facilitators that can inform future larger scale implementation efforts [20]. Methodologically, mixed methods research (MMR) is well-suited for pragmatic studies [21] but under-used in digital health research. MMR could be particularly valuable for digital health research because integration of multiple data sources can augment understanding of implementation more than quantitative or qualitative data alone [22,23]. As such, MMR provides an approach to achieve nuanced understanding of how, why, and for whom a digital health innovation might work best in real-world settings.

Objectives

The objectives of this study are to (1) evaluate the feasibility of a digital PHR mobile app with FHIR-enabled EHR integration to coordinate care for children and youth with special health care needs, (2) identify and describe barriers and facilitators (determinants) of mobile app implementation, and (3) explore associations between mobile app adoption and patient or family-reported outcomes.

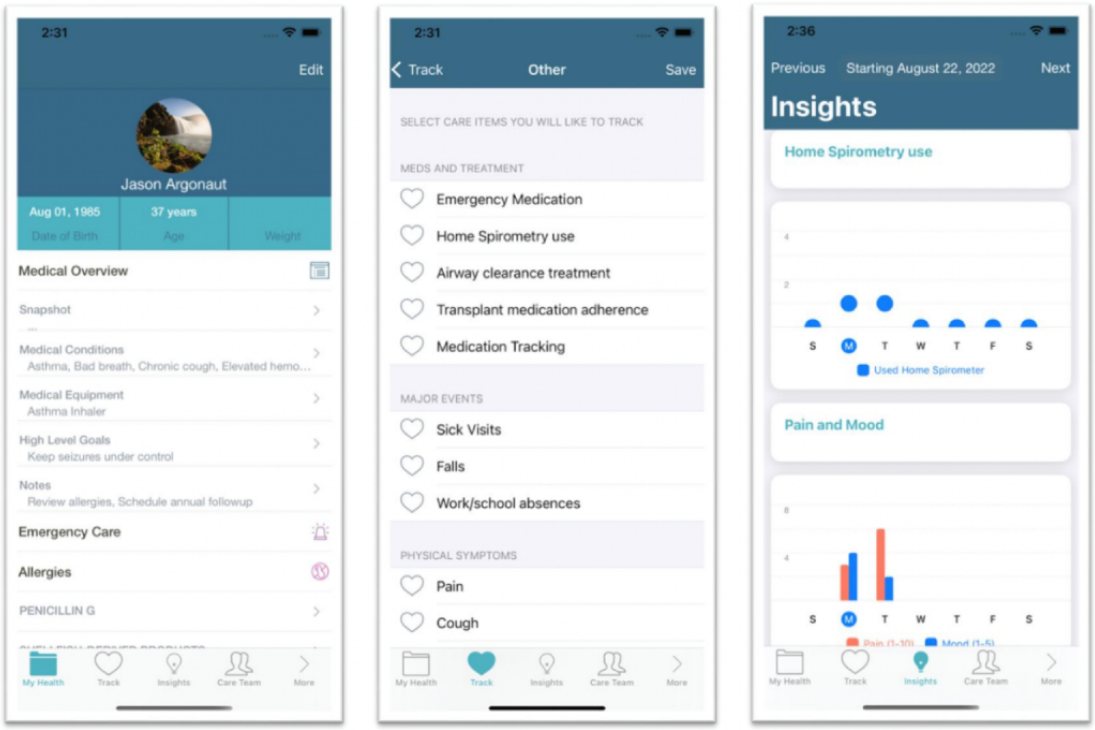
Methods

Study Design

This study protocol describes a nonrandomized, single arm, prospective feasibility trial of a FHIR-enabled digital PHR mobile app used as a CC tool by families of children and youth with special health care needs in primary care settings for a 6-month period. We will apply an intervention MMR study design [24] within the clinical trial to link quantitative and qualitative data collection and analysis at multiple points in order to characterize implementation determinants (Figure 1).

Figure 1. Overview of mixed methods study design and data integration method. CYSHCN: children and youth with special health care needs; EHR: electronic health record; FHIR: Fast Healthcare Interoperability Resources.



Intervention Description and Preliminary Proof-of-Concept Testing

The intervention under evaluation in this study is a FHIR-enabled digital PHR mobile app (Caremap). The app is a digital health innovation designed to facilitate family-centered CC for children and youth with special health care needs through several key features. One key CC feature of the app is FHIR-enabled access to structured data elements from the child's EHR chart (eg, medication list, allergies, and problem list), thereby allowing families to view health information as seen by their child's primary care provider (PCP) in the EHR (Figure 2, left). A second key app feature is that families can track self-selected patient or family-centered care goals (eg, fewer missed school days due to illness and adherence to routine medications; Figure 2, middle) and graphically display progress over time (Figure 2, right) that is visible within the EHR to their child's PCP via a clinician dashboard.

Core app features were developed to maintain the locus of control for the child's health information with their families; development of the clinician dashboard involved input from practicing clinicians. After initial app development was completed, parents of children and youth with special health care needs with established pediatric specialty care within our health system and a sample of parents of children and youth with special health care needs with care external to our health system tested an early app prototype [25]. These early experiences of family users provided proof-of-concept for the app's core features and laid the groundwork for this study protocol's evaluation of the app in real-world settings.

Figure 2. Caremap mobile app screenshots.

Study Setting and Population

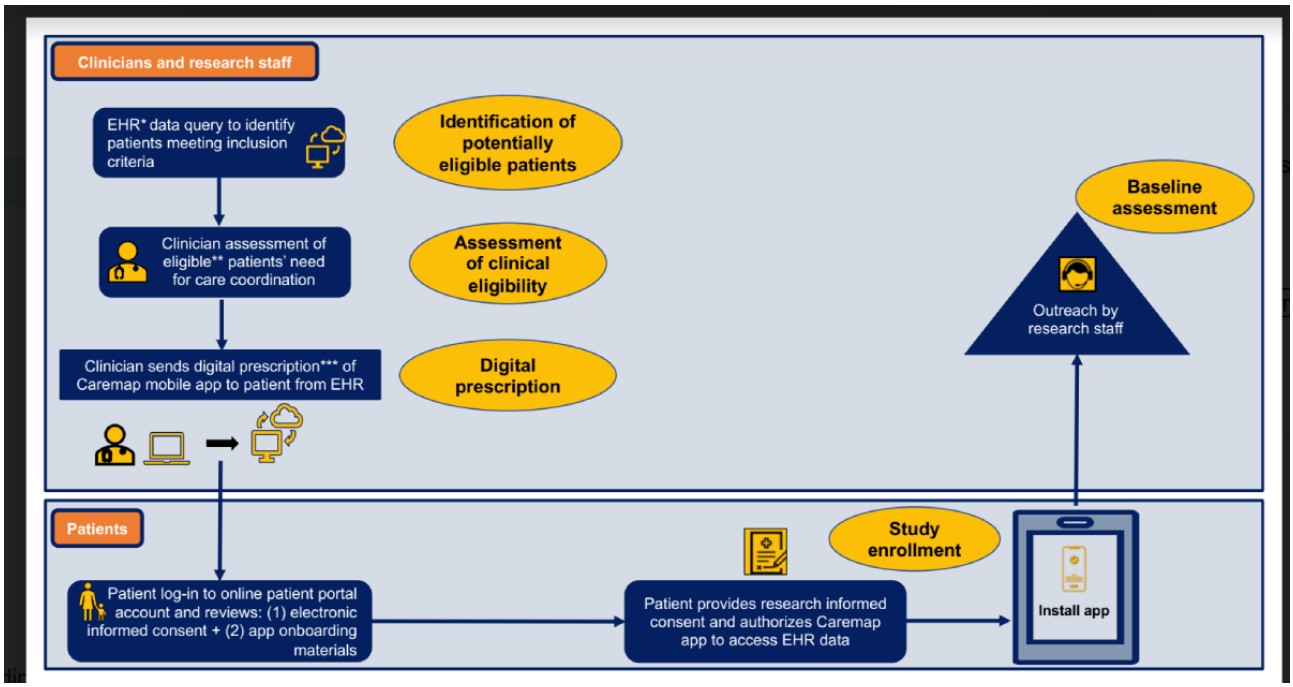
This study will be conducted at a large health system in the southern United States that includes a tertiary care children's hospital and multiple primary care pediatric practices using an enterprise-wide EHR system (Epic). The study will recruit adult parents or guardians of children and youth with special health care needs aged 0-16 years old with primary care established within a network of pediatric primary care sites that are academically affiliated with our institution.

PCPs will be recruited as study participants in order to include clinician perspectives on the feasibility of a dashboard as a companion to the mobile app. The clinician dashboard is accessible from within the EHR and includes a summary of information recorded by families on their personal device and synchronized with the EHR, thereby providing PCPs with view-only access to family-reported longitudinal health insights at the point-of-care during clinical visits.

Eligibility Criteria

Eligibility criteria for study participation will include (1) patient age of 0-16 years, (2) primary care attribution to a participating site, (3) PCP clinical determination that the child has complex needs that can benefit from additional CC support, (4) child is at high-risk for hospitalization in the next 6 months defined using a novel EHR-based machine learning clinical predictive model [26], (5) English-speaking, (6) family has requisite technology at home (internet access and Apple iOS mobile device), and (7) an active web-based EHR (Epic) patient portal account to which parent or caregiver has full proxy access. An active web-based EHR portal account with parental proxy access is required at our institution for FHIR-enabled data access and sharing between the app, the child's EHR chart, and the clinician dashboard within the EHR.

Recruitment Procedures



A 3-step process (Figure 3) will be used to recruit and enroll the planned sample of 40 study participants. The first step—identification of potentially eligible patients—will be an EHR data query to identify patients meeting inclusion criteria identifiable within health system data (ie, 0-16 years old, primary care attribution to a participating site, active web-based portal account with full proxy access, English-speaking, and high-risk for future hospitalization).

The second step in recruitment—assessment of clinical eligibility—will be an assessment by each potentially eligible child's PCP to determine whether the child has complex needs that can benefit from additional CC support. If the PCP determines that more CC support would be beneficial, the study will be introduced to parents of children and youth with special health care needs during an upcoming PCP office visit or via a mailed recruitment letter.

The third, final step of recruitment will be direct delivery of detailed study materials (eg, recruitment letter, study flyer, links for downloading the app, and tutorial videos and instructional guide for how to use the app) as a digital prescription (Figure 3). The digital prescription will be transmitted to parents of eligible participants via the patient's web-based portal account. Transmission of digital prescription study materials will be facilitated by a digital health platform (Xealth) for prescribing and monitoring digital health tools within EHR workflows. After parents of children and youth with special health care needs review all materials, they will be able to consent or decline study participation from within the app (Apple Research Kit); those who consent will be contacted by research staff for baseline study assessment.

Theoretical Frameworks

Guiding this study are 2 categories of extant theoretical frameworks focused on CC and evaluation (Table 1). The 2 CC frameworks central to this research are the Patient-Centered Medical Home (PCMH) and the Pediatric Care Coordination Framework [5,6]. The standard for longitudinal care of children and youth with special health care needs is the PCMH [27]; and CC is a core pillar of PCMH. The Pediatric Care Coordination Framework specifies functions and competencies for systems of care to meet patient or family needs across the ecosystem of essential services for children and youth with special health care needs (eg, medical, social, community, and schools).

To complement these 2 CC frameworks, in this study we are also applying 2 theoretical frameworks focused on evaluation: the Technology Acceptance Model (TAM) and the Consolidated Framework for Implementation Research (CFIR). The TAM is a theoretical model widely applied in digital health research to explain adoption and use of new technologies by end users [28]; the TAM proposes that technology use is mediated by users' perceptions of usefulness and ease of use, leading to acceptance and actual use [29,30]. CFIR is an implementation framework [31,32] developed to comprehensively evaluate implementation barriers and facilitators (referred to as "determinants") within and across multiple domains (process, individuals, intervention, inner setting, and outer setting) [33]. CFIR has been applied in combination with other frameworks [34] and across all phases of implementation research [35]. The combination of TAM and CFIR has been proposed to be complementary [36] and together are well-positioned to guide implementation of digital health innovations.

Despite potential for integration of CFIR with the TAM within digital health research [37], we are unaware of previously published examples. Our approach was to map core components of the Technology Acceptance Model (version 3; TAM-3) [38] and CFIR frameworks with one another to facilitate application of both in an integrated, parsimonious manner (Figure 4). An example of how these 2 theoretical frameworks can be integrated is that multiple CFIR-defined implementation determinants can be mapped to key TAM domains—for example, the CFIR-defined construct of compatibility aligns with perception of external control, which is a TAM-3-defined determinant of perceived ease of use [39]. The recently published CFIR Outcomes Addendum [40] provides additional theoretical foundations to inform this study's conceptual framework. As defined by the CFIR Outcomes Addendum, the mobile app in this study is an example of an innovation and this study's planned primary outcomes are "innovation outcomes." These CFIR-defined innovation outcomes map to TAM-3–defined constructs (eg, behavioral intention to use, perceived usefulness, and perceived ease of use) that function as determinants of actual use of the innovation. Measurement of these innovation outcomes are then interrelated to CFIR implementation determinants and implementation outcomes (Figure 4).

Selection of primary and secondary study outcome measures was guided by operationalizing the TAM-3 and CFIR theoretical frameworks as a study-specific logic model of hypothesized associations between mobile app use and process, proximal, and distal outcomes (Figure 5). Our study logic model was informed by a combination of published studies from the pediatric complex care and CC literature, our prior research, and clinical experience caring for children and youth with special health care needs.

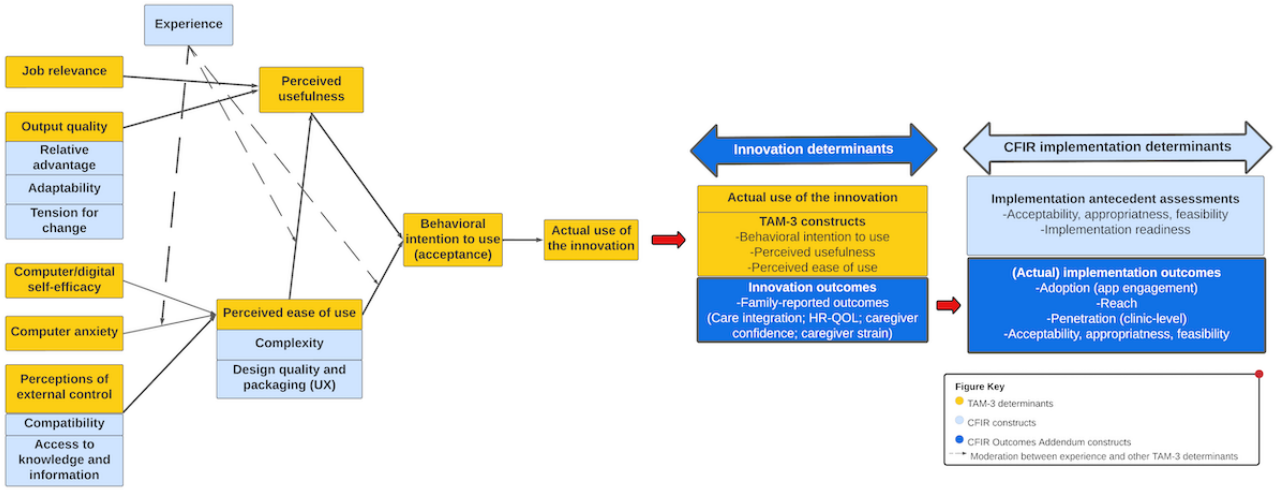
Table 1. Overview of guiding theoretical frameworks.

Framework	Category	Purpose
Patient-Centered Medical Home	Care coordination	Gold-standard ambulatory care model with 5 core functions: accessible, comprehensive, patient or family-centered, coordinated, and high-quality or safe care
Pediatric Care Coordination Framework	Care coordination	American Academy of Pediatrics' framework outlining purpose, scope, and features of care coordination
Technology Acceptance Model	Evaluation	Approach to understand reasons for acceptance and use of new technologies
Consolidated Framework for Implementation Research	Evaluation	Framework for assessing determinants (barriers and facilitators) of effective implementation of interventions

Figure 4. Applied conceptual framework: integration of CFIR, TAM-3, and CFIR Outcomes Addendum frameworks. CFIR: Consolidated Framework for Implementation Research. TAM-3: Technology Acceptance Model (version 3). CFIR Outcomes Addendum: adapted from from: Damschroder, et al [32] (CFIR), Venkatesh, et al [38] (TAM-3), and Damschroder, et al [40].



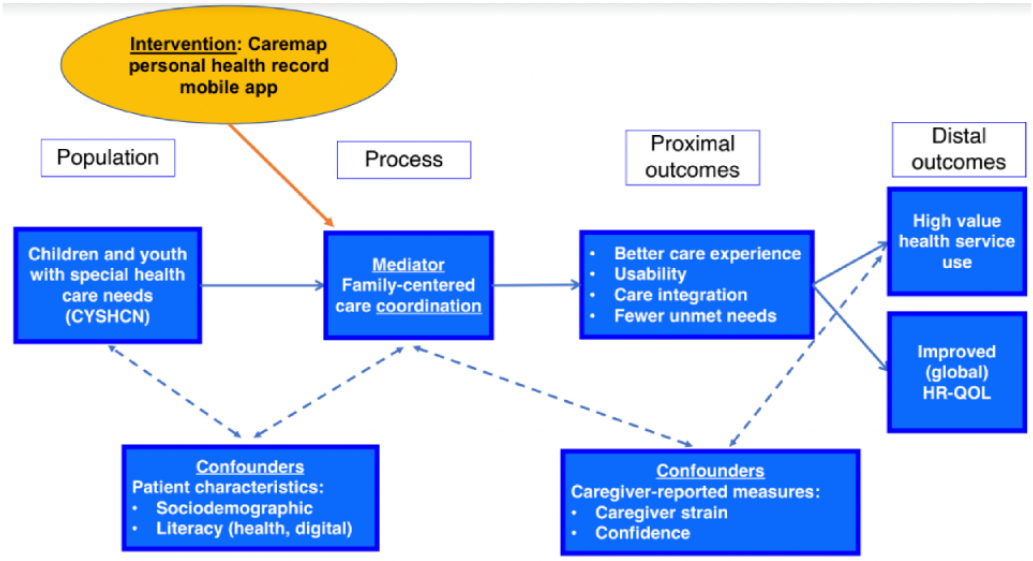


Figure 5. Study logic model. CYSHCN: children and youth with special health care needs; HR-QOL: health-related quality of life.

Quantitative Measurement and Outcomes

A summary of quantitative measures is shown in Table 2. Feasibility is the primary outcome and will be measured as technical and implementation feasibility. Secondary outcome measures will be adoption (app log-ins by families and EHR dashboard use by clinicians) and parent-reported outcomes (eg, care integration and health-related quality of life) measured by parent-reported surveys.

XSL•FO
RenderX

Table 2. Summary of quantitative measures.

Measure name	Definition or approach	Frequency	Source
Primary outcomes			
Technical feasibility	Measurement of key technical processes: (1) success rate of FHIR[a]-enabled data transfer from EHR[b] to app and (2) success rate of FHIR-enabled transfer of parent-reported health insights from app to clinician dashboard	Weekly	Mobile app and EHR
Implementation feasibility	Parent and clinician report of mobile app feasibility based on 4-item Feasibility of Intervention Measure	End of study (6 months)	Parent and provider surveys
Secondary outcomes			
Adoption	Measurement of: (1) app engagement (number of log-ins), (2) clinician engagement (view of EHR clinician dashboard), and (3) number of times mobile app digitally prescribed to families by clinicians	Weekly (parents), monthly (clinician)	Mobile app and EHR
Care integration	Parent report of degree of care integration using 19-item Pediatric Integrated Care Survey	Baseline, 6 months	Parent survey
HR-QOL[c]	Parent report of HR-QOL for child using 9-item PROMIS[d] global HR-QOL survey (parent-proxy)	Baseline, 3 months, 6 months	Parent survey
App usability	Parent and clinician report of app usability based on 10-item System Usability Scale	Baseline, 6 months	Parent and clinician survey
Caregiver strain	Parent report of degree of strain experienced by providing care for their child's health conditions using the 7-item Caregiver Strain Questionnaire-Short Form 7	Baseline, 3 months, 6 months	Parent survey
Parent confidence	Parent report of level of confidence in avoiding hospitalization using single item	Baseline, 3 months, 6 months	Parent survey
Net promoter score	Parent report of likelihood of recommending the (Caremap) app to others using single item	End of study (6 months)	Parent survey
Global health status	Parent-reported global assessment of child's general health status	Weekly	Parent survey
Implementation outcomes	Parent and clinician report of mobile app acceptability and appropriateness based on 4-item Acceptability of Intervention Measure and 4-item Intervention Appropriateness Measure	End of study (6 months)	Parent and provider surveys

[a]FHIR: Fast Healthcare Interoperability Resources.

[b]EHR: electronic health record.

[c]HR-QOL: health-related quality of life.

[d]PROMIS: Patient Reported Outcomes Measurement Information System.

Qualitative Measurement and Outcomes

Qualitative measures, data collection, and analytical procedures are summarized in Table 3. The primary objective for qualitative data collection will be to identify and describe key implementation determinants (study aim 2). One source of qualitative data will be semistructured interviews with a nested purposive sample of 8-12 parents of children and youth with special health care needs and 8-12 PCPs participating in the study; we expect that this interview sample size will be sufficient to reach information saturation and information power [41,42]. The approach for participant interviews will be qualitative description [43]; interviews will be recorded and analyzed using rapid and value-adding qualitative analysis [44,45].

A second source of qualitative data will be family engagement panels (FEP) with a group of parents of children and youth with special health care needs purposively sampled to reflect a diversity of lived experiences. FEPs are modeled after Community Engagement Panels, a consultative model that engages patients, families, and other community stakeholders for project-specific input [46]. Rooted in principles of community-engaged research, these panels emphasize the importance of bidirectional communication, colearning, flattening of the hierarchy between researchers or project leaders and community stakeholders, and identifying mutual benefits of the project [47]. An initial FEP was conducted in fall 2021 prior to trial launch to gather formative feedback. A second FEP after completion of data analysis will be conducted to return findings to community partners and gather recommendations for future directions with an emphasis on enhancing inclusion and access with future app iterations.

XSL•FO
RenderX

Table 3. Summary of qualitative measures.

Qualitative data type	Approach	Timing	Analyses
Semistructured interviews (parents)	In-depth interviews with nested convenience sample of parents of children and youth with special health care needs (n=8-12) participating in the study; interview guide mapped to TAM[a] and CFIR[b] framework constructs	End of study	Rapid qualitative
Semistructured interviews (clinicians)	In-depth interviews with identical samples of primary care pediatricians (n=8-12) caring for study participants; interview guide mapped to TAM and CFIR framework constructs	End of study	Rapid qualitative
Family engagement panels	Small group discussions with purposive sample of 4-6 parents of children and youth with special health care needs to gather stakeholder input on study design or procedures and future direction	Baseline (prestudy), end of study	Qualitative description

[a]TAM: Technology Acceptance Model.

[b]CFIR: Consolidated Framework for Implementation Research.

Integration of Quantitative and Qualitative Data

To address the study aim of identification and description of implementation determinants, we will use the MMR data integration method of embedding to link quantitative and qualitative data collection and analysis at multiple points within the intervention MMR study design [24] Consistent with an embedded data integration method, we will also apply other data linking strategies [24]. For example, we will use building to link pretrial FEP qualitative data with quantitative counts of eligible patients identified in EHR data to inform study recruitment procedures; and we will use merging to link collection and analysis of quantitative and qualitative data (feasibility data, surveys, and interviews) after the trial period. An overview of the intervention mixed method study design and embedded data integration methods is shown in Figure 1.

Ethics Approval

The study protocol has been reviewed and approved by our institutional review board Duke Health (Pro00109514). Informed consent for eligible parents or caregivers will occur on their personal device. Eligible participants will review and sign the written electronic informed consent form prior to beginning the study. Participant confidentiality will be protected by collecting only information needed to assess study outcomes, and study data used for final summative quantitative analyses will be deidentified. All qualitative interviews will be conducted by a trained interviewer from the study team on the telephone, via video call (Zoom), or in-person. Interviews will be video-recorded or audio-recorded and transcribed; if an interviewee wishes to not be recorded, detailed notes will be taken instead. Parent or caregiver participants will receive US $50 compensation for completion of surveys (US $25 at baseline, US $25 at 6 months); participants who complete an interview will receive an additional US $50 compensation.

Results

Participant recruitment began in October 2022. We expect that data analyses will be completed by early 2024. We anticipate that quantitative and qualitative findings will address primary and secondary outcomes outlined in Table 2.

Analyses of pretrial quantitative and qualitative data gathered to-date have informed study procedures and design. A pretrial FEP was conducted in fall 2021 with 4 parents of children and youth with special health care needs. Formative qualitative feedback gathered during this first FEP informed changes to app design and user-facing materials, monetary incentives for study participation, and recruitment procedures. An initial EHR data analysis was conducted in January 2022 to estimate the size of the eligible population for the study. From a population of >40,000 children with primary care attributed to the 3 participating PCP sites, our preliminary analysis identified 317 patients who met all inclusion criteria based on available EHR data; it is expected that this sample will be of sufficient size to enroll the goal of 40 study participants to use the mobile app.

We have used these preliminary quantitative and qualitative findings to refine study recruitment procedures. Specifically, based on feedback from parents of children and youth with special health care needs during the first FEP, recruitment procedures were revised to introduce the study to eligible patients directly during a PCP office visit instead of via automated web-based patient portal electronic messaging. Additionally, detailed patient-facing videos and written tutorials were developed in response to family requests for user-friendly onboarding materials. Quantitative estimate of the potentially eligible patient population led to procedural revisions so that PCPs will be familiar with study aims (to facilitate introduction of the study during office visits) and study materials can be delivered via digital prescription in order to better align with real-world clinical workflows.

Discussion

Anticipated Principal Findings

Findings from this study will characterize the feasibility and implementation barriers and facilitators (determinants) for a digital PHR mobile app used by parents of children and youth with special health care needs for CC in primary care settings. Novel study procedures that can contribute to the digital health literature include the protocol's use of digital prescriptions for participant recruitment. Additionally, application of MMR and implementation research methods offers a novel methodological approach that could address recent calls for innovative and pragmatic evaluation of digital health solutions [48].

This study protocol describes a pragmatic approach for integrating theory into digital health study design by combining

XSL•FO
RenderX

the established CFIR and TAM-3 frameworks [28,32,33,38], thereby facilitating application of implementation science methods within early phase clinical studies. It is recognized within the implementation research field that earlier phase research—for example, pilot and feasibility studies [20]—presents opportunities to establish foundations for future intervention dissemination and to test promising implementation strategies within the context of implementation determinants. Additionally, available implementation science models, theories, and frameworks [31] provide a strong theoretical basis for digital health intervention studies to integrate implementation science and digital health research frameworks.

Similar to implementation science, methodological approaches from the MMR field that systematically integrate quantitative and qualitative data [21,22] can generate insights needed to understand how best to implement, evaluate, and improve digital health innovations. In our preliminary work to-date, use of the MMR analytical technique of building to integrate pretrial quantitative and qualitative data informed improvements in study procedures that would have been challenging to identify without mixed methods data integration. We anticipate that continued collection of both forms of data with embedded data linking at multiple points in the trial will deepen understanding of the feasibility and implementation of the digital health mobile app. These methodological approaches are well-positioned for exploration and adoption by other digital health researchers.

In addition to integrating MMR and implementation science methods into digital health research, there are opportunities to streamline study procedures. For this protocol in particular, the use of digital prescriptions will be used to facilitate dissemination of study materials directly to eligible participants via existing web-based patient portal accounts. This approach may help improve study workflow efficiency and mitigate infectious risk in the face of the ongoing COVID-19 pandemic by reducing study personnel's reliance on in-person recruitment. Digital prescriptions are also positioned for future studies where they could facilitate scaled recruitment via automated delivery of study materials to large numbers of eligible patients identified by EHR data. Although a digital prescription-based approach is promising for study recruitment, caution should be exercised. More efforts are needed to close the digital divide [49], mitigate inequitable access to web-based patient portals [50], and provide tailored support for historically marginalized populations (eg, instructions for web-based portal access and use in multiple languages; interpreter access for patients with limited English proficiency).

This study has several limitations that should be acknowledged, including the study's single center design and limited size and scope. Smaller scope is necessary at this early stage to focus on feasibility and to gather in-depth feedback from participants that can inform subsequent app improvements. Additionally, our inclusion criteria that study participants have existing internet access, a digital device, and an active web-based patient portal account may introduce barriers to research participation. Factors that could mitigate these barriers include national-level data that demonstrated that 81% of US adults own a smartphone [51] and data from our previously conducted digital health trial when parents were successfully recruited using similar technology requirements [52]. Finally, this study's lack of randomization and effectiveness evaluation will limit the strength of conclusions. Although evaluation of effectiveness of the mobile app on health outcomes is beyond the scope of this study, we will systematically explore family and clinician-reported data by including validated measures of health-related quality of life and perceptions of care integration [53,54].

Digital health tools have the potential to improve care and outcomes for children and youth with special health care needs; however, the evidence base is early in development. The methodological rigor of early phase digital health studies could be enhanced by incorporating novel study procedures and methods from research fields outside of traditional pediatric clinical trials. By doing so, strengthened conclusions from early phase digital health studies will be positioned to serve as foundations for future multisite prospective trials that measure effectiveness for health and implementation outcomes. Ultimately, these future directions can serve to accelerate the pace of investigation so that clinicians and families of children and youth with special health care needs will have the evidence base needed to determine the impact of new digital health tools on patient and family-centered outcomes.

Conclusions

This study will evaluate the feasibility of integrating a FHIR-enabled digital PHR mobile app as a CC tool for children and youth with special health care needs into clinical care. Application of MMR and implementation science methods is anticipated to facilitate understanding of implementation determinants in primary care settings. The findings of this study are positioned to inform future pragmatic trials that can further advance knowledge of how to use digital health innovations for improving care and outcomes for children and youth with special health care needs.

Acknowledgments

The authors acknowledge the following sources of support for this research: (1) Health Resources and Services Administration Maternal and Child Health Bureau for their support of early phases of this work while the team participated in the Maternal and Child Health Bureau Grand Challenge for Digital Care Coordination Solutions for Children with Special Health Needs, (2) The Duke Institute for Health Innovation for their support of technical development and implementation planning efforts at Duke Health, (3) Duke Clinical and Translational Science Institute's Community Engaged Research Initiative (CERI) for their support and facilitation of family engagement panel discussions, and (4) Dr Gordon Worley for his support of presentation of this work at the Pediatric Academic Societies meeting in April 2022 (Denver, Colorado).

Abstract

Background: Diabetes impacts nearly 25% of veterans. Many veterans do not engage in recommended physical activity and other diabetes self-management behaviors. Type 2 diabetes is generally asymptomatic; as such, the long-term consequences of inadequate self-management and benefits of consistent self-management are not salient in the short term. Furthermore, self-management behaviors typically take place outside of medical visits; however, self-management–related factors are only assessed during medical visits, likely missing large amounts of variability. Thus, ambulatory assessment methods such as ecological momentary assessment (EMA), accelerometry, and continuous glucose monitoring are needed to understand the dynamics of daily self-management and identify potential intervention targets.

Objective: The overarching goal of this study is to understand daily, time-varying factors (comorbid affective symptoms and social context) that influence physical activity, diabetes self-management, glycemic management, daily functioning, and quality of life in participants' natural environments.

Methods: We are recruiting veterans with type 2 diabetes (target N=100). Participants are required to complete a battery of baseline assessments related to mental health, psychosocial factors, and self-management behaviors. Participants then receive 5 momentary EMA surveys and 1 daily EMA survey per day, in which veterans report comorbid affective symptoms (mood, stress, and pain), social support, social interactions, physical activity, and other self-management behaviors. Momentary surveys are delivered randomly during daily preprogrammed intervals over a 14-day sampling period. Accelerometry and continuous glucose monitoring are also used to assess physical activity and blood glucose, respectively. The first 6 participants also completed interviews assessing their experience in the study and barriers to participation. These test participants informed modifications to the protocol for the remaining participants.

Results: The project received funding in April of 2023. Enrollment began in March of 2023 and is planned to be completed in April 2025. Among the 6 test participants, the overall EMA response rate was 87% (range 74%-95%). The response rate for the EMA survey including daily items (67%, range 21%-93%) was lower than the earlier shorter EMA surveys (89%, range 81%-96%). The mean rate of valid accelerometer wear of at least 20 hours per day was 93% (SD 11%), and continuous glucose monitoring data were available for 91% (SD 17%) of days on average. Participants reported few barriers to completing EMA surveys but noted the random timing of questions made it difficult to plan around, and the end-of-day survey was long. Two participants reported survey items reminded or motivated them to engage in diabetes self-management behaviors.

Conclusions: Assessment tools developed from this study can inform clinical decision-making by considering barriers to self-management that occur in daily life. Clinical applications include tailored, adaptive technology–supported interventions to improve self-management that provide the right type and amount of support at the right time by adapting to an individual's changing internal and contextual state.

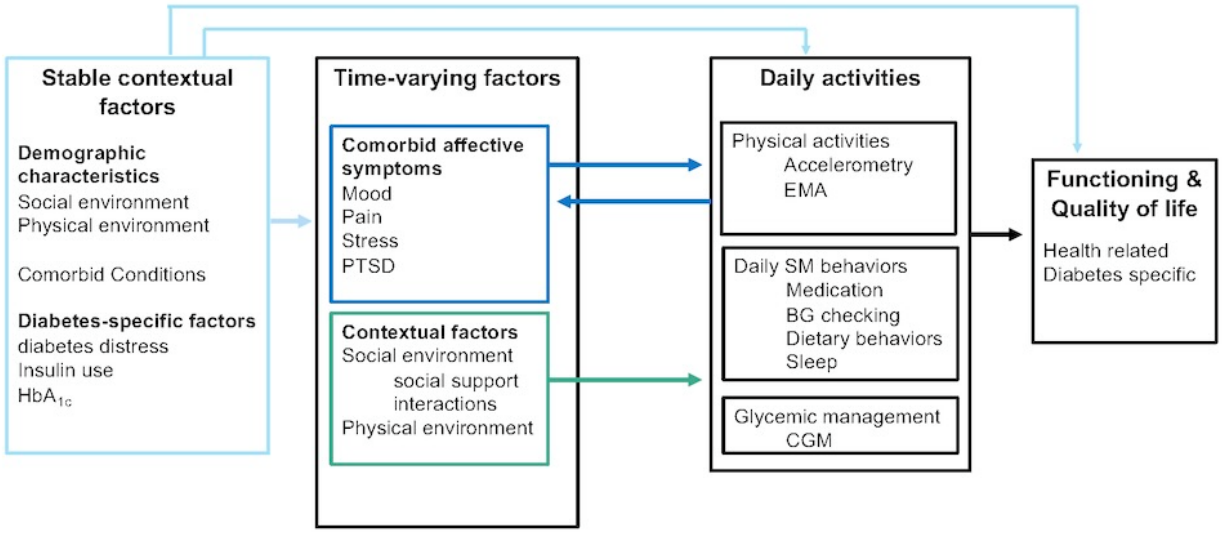
Introduction

Background

Almost 1 in 4 veterans have type 2 diabetes (T2D), which is over double the prevalence of the general population [1]. Engaging in regular diabetes self-management behaviors, including physical activity, medication taking, following dietary recommendations, and monitoring blood glucose, greatly improves diabetes outcomes [2], but many veterans with T2D do not consistently engage in these behaviors [3]. A more nuanced understanding of veteran-specific barriers to daily engagement in self-management behaviors is needed to develop personalized and impactful interventions to improve self-management.

This study is informed by temporal self-regulation theory, a framework for explaining individuals' health behaviors, which accounts for temporal dynamics, context (eg, social contact, mood, and pain), and individual factors (eg, beliefs and executive functioning) on health behaviors [4]. Specifically, one of the temporal self-regulation theories posits that engagement in health behaviors is more contingent on immediate outcomes (eg, convenience and discomfort) and less contingent on long-term outcomes (eg, improved health status) and that social, internal, and environmental contexts can influence these temporal contingencies. For individuals with T2D, the long-term consequences of suboptimal self-management may not be immediately salient, as suboptimally managed T2D is often asymptomatic but can lead to several long-term complications [5]. However, other daily experiences, including comorbid affective symptoms and social contextual factors, may have a stronger proximal impact on diabetes self-management behaviors. Comorbid conditions with affective symptoms such as depression, anxiety, stress, and pain are common among veterans with T2D [6-8] and may influence their engagement in self-management behavior. Additionally, veterans' social context, especially social support, plays a crucial role in daily diabetes self-management [9]. Research suggests that high social support is associated with engagement in diabetes self-management behaviors, which contribute to improved glucose levels, mood, and quality of life [10], while low social support is linked to depression symptoms and functional disability [11], all of which may impede engagement in diabetes self-management behaviors.



Prior research on such influences on diabetes self-management behaviors has mostly relied on cross-sectional studies, which examine static between-person relationships. Few studies have explored within-person variability over time, specifically the moment-to-moment associations between comorbid affective symptoms, psychological states, social support, and daily engagement in diabetes self-management. Intensive longitudinal studies are needed to capture and model fluctuations over short periods of time, context-specific fluctuations, person-specific patterns in behavior [12], interactions between processes at different time scales [13], and both concurrent and lagged temporal dynamics. This study uses ecological momentary assessment (EMA), a real-world ambulatory assessment method that allows for the assessment of mood, behavior, and contextual factors in participants' own physical and social environments combined with accelerometry and continuous glucose monitoring to continuously assess physical activity behavior and blood glucose levels, respectively. These intensive longitudinal methods can provide valuable insights into these dynamics and help tailor interventions to the specific needs of veterans.

Aims

The overarching goal of this study is to understand daily, time-varying factors (comorbid affective symptoms and social context) that are particularly relevant to veterans and that influence physical activity, diabetes self-management, daily functioning, and quality of life (Figure 1). The specific aims of the study are to (1) use EMA to examine how daily and within-day fluctuations in comorbid affective symptoms influence engagement in physical activity, other diabetes self-management behaviors, and glycemic management; (2) examine social support as it relates to physical activity, diabetes self-management, and glycemic management; (3) capitalize on the advantages of intensive longitudinal data by exploring relationships among other within-person time-varying factors, social contextual factors, between-person demographic and T2D-specific characteristics, and T2D self-management behaviors that may impact daily functioning and quality of life; and (4) leverage intensive longitudinal data to explore temporal relationships among study variables using network analysis. We hypothesize that (1a) greater comorbid affective symptoms will be associated with less concurrent and future engagement in physical activity, diabetes self-management behaviors, and glycemic management; (1b) time-varying within-person factors will predict physical activity, diabetes self-management behavior, and glycemic management even after accounting for stable between-person factors; and (2) daily social support and social interactions will each independently attenuate the association between daily comorbid affective symptoms and subsequent physical activity, diabetes self-management behaviors, and glycemic management. Aims 3 and 4 are exploratory.

Methods

Overview of Study Design

Participants use a smartphone app to report comorbid affective symptoms (mood, stress, and pain), social support, social interactions, physical activity, and other self-management behaviors, multiple times per day randomly, during preprogrammed intervals in their natural environment over 14 days. Participants also wear accelerometers and continuous glucose monitors (CGMs) to passively assess physical activity and glycemic management, respectively. The first 6 participants were interviewed about their experience in the study and barriers to responding to EMA items and wearing study devices as well as their understanding of the EMA items. Interview responses in combination with the data collected were used to refine study procedures for the remainder of the participants.

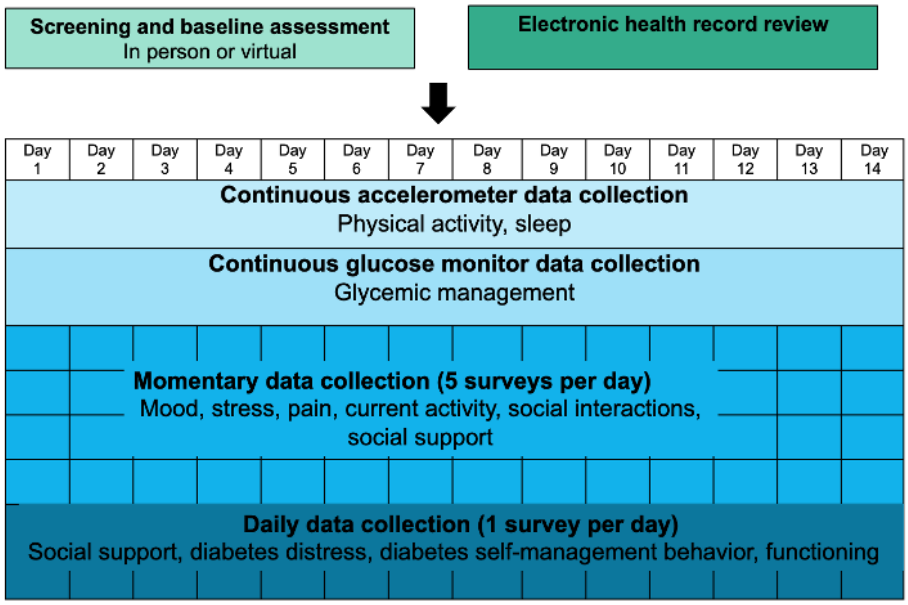
Target Population and Eligibility

Participants are included if they are users of the VA health care system, diagnosed with T2D, older than 18 years, ambulatory with or without a cane, able to stand without a cane, able to read and understand English, and able to provide informed consent. Participants are excluded if they do not meet the aforementioned criteria or if they are diagnosed with serious or unstable psychiatric illness (ie, unmanaged psychosis, manic episode, or substance use within the past 6 months), psychosocial instability (eg, homelessness) that could compromise study participation, serious or unstable medical illness (eg, dialysis and terminal illness), active suicidal ideation or history of suicide attempt within the past 3 years, concurrent and ongoing engagement in treatment specifically targeting diabetes management, self-reported illness or conditions that would impair the cooperation with the study team or the ability to complete the study, use of a walker, wheelchair, or other assistive devices that will interfere with accelerometry or a score of < 22 on the Montreal Cognitive Assessment (MoCA) or <18 on the MoCA blind [14].

Recruitment

Participants are recruited using flyers and advertisements posted in the local VA hospital common areas and in clinic spaces likely to serve individuals meeting the eligibility criteria. Additionally, targeted recruitment letters are sent to potentially eligible veterans inviting them to participate in the study, and participants are recruited from lists of veterans who participated in other research studies and expressed interest in being contacted for future studies.

Ethical Considerations



All participants provide informed consent, and the protocol was approved by the VA San Diego Health Care System institutional review board and R&D Committee (protocol 1227858). Data are deidentified, and key linking participant identifying information to data is kept on a secure server that is only accessible by the research team. Participants receive up to US $200 compensation for participation in the study based on EMA survey response rates and accelerometer wear rates. Specifically, participants receive US $15 for completing the baseline assessment, US $15 for returning devices at follow-up, US $2 for each end-of-day survey, and US $1 for each in-the-moment survey. Participants also receive an additional US $15 for completing 75% (52/70) of EMA questions, an additional US $20 for completing 100% (70/70) of EMA questions, an additional US $15 for wearing their accelerometer for at least 20 hours a day for 75% (10/14) of days, and an additional US $22 for wearing their accelerometer at least 20 hours a day for 100% (14/14) of days. Finally, participants receive a copy of their blood glucose data report collected from the CGMs worn during the study.

Procedures

An overview of data collection procedures is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Overview of data collection procedures.

Prescreening

Initial screening for interest and eligibility takes place in person or via telephone by the study coordinator. Participants are given an overview of the study and, after providing verbal consent, are screened with a questionnaire covering the inclusion and exclusion criteria. The study coordinator also reviews the veteran's electronic health record for eligibility criteria. Veterans who are not excluded based on the initial screen and who express interest in participating in the study are invited for continued evaluation of eligibility and the baseline assessment either in person or via a video call.

Baseline Assessment Visit

Participants provide written informed consent and Health Insurance Portability and Accountability Act (HIPAA) authorization, followed by the Mini International Neuropsychiatric Interview [15] and the battery of baseline assessments. Participants download the *RealLifeExp* app (LifeData, LLC) to their phones or are provided with EMA devices with the app already downloaded. Participants are trained in the EMA procedures, including how to operate the application, the meaning of all questions and response choices, the timing of the prompts, and procedures for responding to prompts. Each participant is provided with written information on responding to EMA surveys and contact information for crisis lines and all study staff. We also provide participants with an Actigraph wGT3X-BT (Actigraph, LLC) accelerometer and instructions for use. Participants are asked to wear the accelerometer for 14 consecutive days during the EMA period. Participants are also provided 2 CGMs (G6pro, Dexcom) that each last for 10 days, the first of which is placed by the research coordinator on the participant's right abdomen. Participants are instructed to place the second CGM on their left abdomen on day 9 of the study and remove the first CGM on day 10. CGM data are blinded to participants. Participants already using a CGM will also be asked to wear the study CGMs. Following the baseline assessment visit, participants practiced with the EMA device and accelerometer at home independently for 24 hours. The study team will be available to help the participants in problem-solving any barriers to participation identified during the 24-hour training period.

Ambulatory Assessment Procedures

After the 24-hour training period, participants complete 14 days of EMA data collection in which they respond to a set of questions on comorbid affective symptoms, social context, and daily activities 5 times throughout the day, including 1 longer end-of-day survey that also contains questions pertaining to social support and daily T2D self-management behaviors. Prompts are delivered randomly within 2-3–hour time windows. Participants choose between 3 response window options: early (prompts delivered approximately between 7 AM and 7 PM), standard (prompts delivered approximately between 8 AM and 8 PM), and late (prompts delivered approximately between 10 AM and 10 PM). Research staff contact participants after 24 hours, 7 days, 9 days (day of CGM switch), and on day 14 to check in about any issues. Additionally, research staff continually monitor participants' response rates to EMA survey questions and accelerometry wear time using remote dashboards.

Follow-up Visit

Participants return their accelerometer and CGM sensors to the research team after the 14-day data collection period and complete forms for compensation. The first 6 participants completed brief interviews about their experiences in the study, experiences with the EMA platform, completing EMA items, and wearing the accelerometer and CGM.

Measures

Baseline Assessment

Participants complete standardized measures of stable contextual factors including social support, diabetes-specific factors, mental health symptoms, self-management behaviors, functioning, and quality of life. Participants also complete a 24-hour diet recall interview and physical functioning assessment. The full baseline assessment battery is shown in Multimedia Appendix 1 [14-36].

XSL•FO
RenderX

Ecological Momentary Assessment

EMA items are shown in Multimedia Appendix 2 [34,37-45]. Items were adapted from existing standardized measures or prior EMA studies when possible. Items were refined based on performance in terms of within-person versus between-person variability and interviews conducted in our pilot study and the initial 6 participants of this study.

Actigraphy

Actigraph wGT3X-BT accelerometers assess time spent in light, moderate, and vigorous activities as well as total physical activity counts between each within-day assessment interval and averaged across each day [46]. Total activity counts will be computed for the 60 minutes before and after each prompt, and total activity counts will be computed for each day. Accelerometers will also assess sleep including total sleep time, sleep efficiency, and sleep latency. Accelerometer recordings are time stamped to be combined with EMA data at each prompt. A minimum of 20 valid hours a day will be considered as a valid day for both activity and sleep. A minimum of 10 hours a day will be considered a valid day for activity only.

Continuous Glucose Monitoring

Blinded Dexcom G6pro CGMs are used to assess the measures of glycemic management including glycemic management indicator, glycemic variability, percent time in range, percent time in low, percent time in very low, percent time in high, and percent time in very high blood glucose ranges.

Analytic Plan

Protocol Refinement

Data from the initial 6 participants along with their interview responses were used to inform modifications to the protocol. Interview responses were summarized in a table and reviewed with the study team. Response rates for EMA surveys and the number of valid accelerometer and CGM wear days were computed. Intraclass correlations (ICCs) were computed for all EMA items to examine the proportion of the total variance in each EMA survey item attributable to between-person differences versus within-person (ie, day to day) variability.

Data Cleaning and Preliminary Analyses

EMA data will be included for all participants completing at least 30% (21/70) of programmed EMA assessments. Additionally, the pattern of missing data will be examined to determine whether missing values are random or systematic omissions. The proportion of participants who complete >80% (56/70) of assessments (including momentary and daily assessments) and the overall dropout rate will be computed. We will examine data completeness using a paired *t* test to evaluate whether participants completed fewer EMA surveys during the second half of the study than during the first half.

We will examine descriptive statistics for all study variables as well as inspect scatterplots subject by subject. Continuous outcome variables will be screened for normality. We will examine bivariate relationships between a set of potential covariates (eg, gender, age, race, comorbid conditions, and diabetes-specific factors) and the primary outcomes. These significant covariates will be included simultaneously in multilevel models (MLMs).

Primary Analyses

Overview

For aims 1-3, we will estimate MLMs [47]. Models will be estimated with up to 3 levels (prompt, day, and person) with the full-information maximum likelihood method, the between-within method for the denominator degrees of freedom option, and the unstructured variance-covariance matrix for the random effects and residuals. For aim 4, we will use network analysis.

Aim 1: Use EMA to Examine How Daily and Within-Day Fluctuations in Comorbid Affective Symptoms Influence Engagement in Physical Activity, Other Diabetes Self-Management Behaviors, and Glycemic Management

To examine the concurrent association between within-day comorbid affective symptoms and engagement in physical activities, we will use MLM to test whether comorbid affective symptoms (depressed mood, stress, and pain) are associated with concurrent (ie, from the same prompt) engagement in physical activity. Physical activity will be assessed using both EMA-reported engagement in physical activity at each prompt (EMA survey) and accelerometer-assessed minutes spent performing physical activity at each prompt interval (total activity counts). The within-person (level 1, prompt-level) version of each comorbid affective symptom predictor variable (ie, depressed mood, stress, and pain) will be entered into each model to partition the variance allowing for the interpretation of within-person results. The within-person terms will be centered on the person-mean, or the participant's mean value of each comorbid symptom predictor across all prompts for that day, and represent the deviation in each prompt's comorbid affective symptoms as compared to that individual's mean value. Within-person comorbid affective symptoms averaged across each day will be included in level 2 (day level). To examine the direction of the association between daily comorbid affective symptoms and daily engagement in future physical activities (EMA survey and accelerometry), we will test multilevel autoregressive cross-lagged path models. These cross-lagged models will examine whether EMA measurements of each comorbid symptom will predict time spent in physical activities the following day while controlling for the effects of time spent in physical activities the previous day, and also whether time spent in physical activities predicted subsequent comorbid affective symptoms after controlling for previous symptoms. In both concurrent and cross-lagged models, we will include covariates in level 3 (person level) to control for between-person differences in these characteristics. We will use an analogous approach for other diabetes self-management behaviors (medication taking, blood glucose monitoring, and diet behavior) and glycemic management (time in range and glycemic variability).

XSL•FO
RenderX

Aim 2: Examine Social Support as it Relates to Physical Activity, Diabetes Self-Management, and Glycemic Management

Similar to aim 1, we will examine whether social interactions (ie, alone or with someone else; level 1), companionship or emotional social support (level 2) and instrumental or informational social support (level 2) obtained from EMA surveys are each associated with time spent in concurrent and future physical activity (EMA survey and accelerometry) using MLM. We will include covariates in level 3 (person-level) to control for between-person differences.

Aim 3: Capitalize on the Advantages of Intensive Longitudinal Data by Exploring Relationships Among Other Within-Person Time-Varying Factors, Social Contextual Factors, Between-Person Demographic and T2D-Specific Characteristics, and T2D Self-Management Behaviors That May Impact Daily Functioning and Quality of Life

We will examine the relationship between the between-person demographics and diabetes-specific characteristics that may impact daily activities and quality of life using the statistical approaches described above. We will examine the relationship between time-varying comorbid affective symptoms (depressed mood, stress, and pain) and social context (social support and social interactions) with other diabetes self-management behaviors including exercise, diet behaviors, blood glucose monitoring, and medication taking from EMA questions modified using the same statistical approaches described above. We will also examine whether social contextual factors moderate the relationships between comorbid affective symptoms and each outcome variable (physical activity, diabetes self-management behaviors, and glycemic management).

Aim 4: Leverage Intensive Longitudinal Data to Explore Temporal Relationships Among Study Variables Using Network Analysis

Network analysis will be conducted to visualize, understand, and compare the associations and covariances among time-varying study variables (eg, comorbid affective symptoms and social contextual factors), physical activity, other diabetes self-management behaviors, and glycemic management. We will estimate within-person networks and between-person networks based on variables in our conceptual model [48]. We will estimate and graph network models in which associations between variables included in the network are drawn if they correlate after controlling for all other variables in the network. Networks will be computed based on partial correlation methods [48]. We will create between-person networks by averaging values from each participant for each physical activity variable, each self-management behavior, and each time-varying factor across the 14 (daily) or 70 (momentary) time points. We will create within-person networks by subtracting the mean of each participant's score across all time points, such that we estimate a network of interrelationships, centered on each person's average value during the study. This will allow us to test whether deviations from the mean level for a given variable are associated with variations from the mean of other variables. We will also explore whether network patterns differ based on between-person characteristics (eg, sex and insulin use) that could influence the associations between factors in the network.

Sample Size

To estimate the sample size needed to detect statistically significant effects for the outcomes outlined in aim 1, we used a power program *EMAtools*, a software specifically designed for EMA data, prior research, and estimates of response rates from our pilot data. There is little prior research with similar populations in terms of examining within-person variability of diabetes self-management behaviors and glycemic management. In terms of physical activity, prior research suggests that we should expect medium effect sizes for aim 1 and small-to-medium effect sizes for aim 2 [37,49]. ICCs for physical activity in similar populations range from 0.12 to 0.34 [49,50]. Specifying 14 days of data collection, and 5 momentary prompts per day, showed that with 100 participants, we are adequately powered to detect the expected effect sizes for aim 1 and small-to-medium effect size for any given outcome (ie, aims 2-3) at 80%. Additionally, we are powered to detect small-to-medium effect sizes with response rates as low as 75%. Network analysis (aim 4) is a relatively new field and research on power requirements is ongoing, but prior studies have found that as few as 30 participants are needed for adequate power to detect variability in network structures [51]. Taken together, the target sample size for this study is 100, with a maximum of 7000 EMA survey responses. Conservatively estimating a 75% response rate, this target would produce 5250 completed EMA surveys that can be combined with corresponding accelerometry and CGM data points. Data from this study can be used in a Monte Carlo simulation to more precisely determine the most appropriate sample size for future studies.

Results

The study was funded by the Department of Veterans Affairs Rehabilitation Research and Development Service for 5 years. Enrollment began in September of 2022 to collect a sample of 6 test participants which informed subsequent modifications to the protocol. Enrollment restarted in March of 2023 and is planned to be completed in April 2025. Results are planned to be analyzed and published in March 2026.

Among the 6 test participants, the overall EMA response rate was 87% (range 74%-95%). The response rate for the EMA survey including daily items (67%, range 21%-93%) was lower than the earlier shorter EMA surveys (89%, range 81%-96%). The mean rate of valid accelerometer wear of at least 20 hours per day was 93% (SD 11%; range 71%-100%), and CGM data were available for 91% (SD 17%) of days on average (range 57-100). Participants generally reported few barriers to completing EMA surveys but noted that the random timing of questions made it difficult to plan around, and the end-of-day survey was long. Two participants reported accelerometers were uncomfortable at times and 1 participant's second CGM did not collect data. Two participants reported that survey items reminded or motivated them to engage in diabetes self-management behaviors.

RenderX

Discussion

Summary

There are very few EMA studies examining physical activity and other self-management behaviors in T2D, and there are no studies that we are aware of that examine daily objective physical activity, EMA-assessed self-management behaviors, and CGM-assessed glycemic management among veterans with T2D. Furthermore, the combination of accelerometry and EMA provides both objective and subjective assessments of overall physical activity levels while also distinguishing among activity types.

Methodological Challenges and Decisions

Modifications to the design of this protocol were made based on a prior pilot study and our test participants [52,53]. Based on response rates lower than 80% and participant feedback from our test participants, we reduced the number of questions delivered at each EMA to 1 per construct. Given our interests in within-person variability, we examined ICC values, representing the amount of within-person versus between-person variability of each item, to inform decisions about which items to drop. Items with lower ICC values, representing greater within-person variability, were favored. Participants in our target population vary in terms of occupational and retirement status and thus participants varied in terms of what times during the day were most ideal for having EMA prompts delivered. To balance variability among participants and capture participants' typical waking hours and response rates, we decided to offer 3 time window options. Participants also requested to know the exact time EMA prompts would be delivered; however, we decided to keep prompt delivery within random time windows to best capture participants' experiences across the day.

Social desirability and measurement reactivity pose challenges to assessing daily diabetes self-management behaviors. We initially adapted the Summary of Diabetes Self-Care Activities Assessment scale [16] for daily use but found little variability in responses from participants, and found that most participants endorsed engaging in all self-management behaviors. With our initial test participants, we tried including a response option "this survey reminded me to complete *X* behavior" to gauge reactivity bias; however, no participant selected this option. Additionally, participants reported in interviews that they found the assessment helpful to their diabetes management. We added a component to our instructions emphasizing that we are not intending to change their behaviors in this study. We also modified dichotomous rating scales to be continuous (0-100) to capture variability in behaviors and added new dietary items that included representative food groups without labeling the nutritional value of the food to reduce social desirability biases. We also adapted much of our protocol for remote delivery; however, to date, many participants choose to complete baseline assessment in person.

Significance

Diabetes is a significant and drastically growing problem among veterans [54] and is related to disability, poor quality of life, and substantial health care costs. Most diabetes self-management activities take place outside of medical visits; however, factors related to self-management are only assessed at the time of medical visits, likely missing large amounts of variability. This study targets this problem by examining time-varying influences of daily diabetes self-management behaviors and daily life functioning, in real-time, in veterans' own environments.

Results will identify barriers and facilitators of diabetes self-management that when intervened may unleash a cascade of improvement through their interrelationships with other factors. For example, if comorbid affective symptoms are important predictors of physical activity or other self-management behaviors, interventions for T2D management that include additional evidence-based strategies for targeting comorbid symptoms, such as pain management, may need to be evaluated. Adaptive just-in-time interventions can be developed to deliver personalized patient-centered feedback in real time. For example, an intervention could deliver a behavioral activation strategy when a veteran reports high levels of depression. Interventions can be designed to include appropriate timing of prevention strategies or the use of supportive services to help break self-sustaining cycles of poor functioning. Furthermore, assessment tools developed from this study could inform clinical decision-making and treatment planning that considers barriers to self-management that occur outside of medical visits.

Abstract

Background: Varenicline is a pharmacological intervention for tobacco dependence that is safe and effective in facilitating smoking cessation. Enhanced adherence to varenicline augments the probability of prolonged smoking abstinence. However, research has shown that one-third of people who use varenicline are nonadherent by the second week. There is evidence showing that behavioral support helps with medication adherence. We have designed an artificial intelligence (AI) conversational agent or health bot, called "ChatV," based on evidence of what works as well as what varenicline is, that can provide these supports. ChatV is an evidence-based, patient- and health care provider–informed health bot to improve adherence to varenicline. ChatV has been programmed to provide medication reminders, answer questions about varenicline and smoking cessation, and track medication intake and the number of cigarettes.

Objective: This study aims to explore the feasibility of the ChatV health bot, to examine if it is used as intended, and to determine the appropriateness of proceeding with a randomized controlled trial.

Methods: We will conduct a mixed methods feasibility study where we will pilot-test ChatV with 40 participants. Participants will be provided with a standard 12-week varenicline regimen and access to ChatV. Passive data collection will include adoption measures (how often participants use the chatbot, what features they used, when did they use it, etc). In addition, participants will complete questionnaires (at 1, 4, 8, and 12 weeks) assessing self-reported smoking status and varenicline adherence, as well as questions regarding the acceptability, appropriateness, and usability of the chatbot, and participate in an interview assessing acceptability, appropriateness, fidelity, and adoption. We will use "stop, amend, and go" progression criteria for pilot studies to decide if a randomized controlled trial is a reasonable next step and what modifications are required. A health equity lens will be adopted during participant recruitment and data analysis to understand and address the differences in uptake and use of this digital health solution among diverse sociodemographic groups. The taxonomy of implementation outcomes will be used to assess feasibility, that is, acceptability, appropriateness, fidelity, adoption, and usability. In addition, medication adherence and smoking cessation will be measured to assess the preliminary treatment effect. Interview data will be analyzed using the framework analysis method.

XSL•FO
RenderX

Results: Participant enrollment for the study will begin in January 2024.

Conclusions: By using predetermined progression criteria, the results of this preliminary study will inform the determination of whether to advance toward a larger randomized controlled trial to test the effectiveness of the health bot. Additionally, this study will explore the acceptability, appropriateness, fidelity, adoption, and usability of the health bot. These insights will be instrumental in refining the intervention and the health bot.

KEYWORDS

evaluation; health bot; medication adherence; smoking cessation; varenicline; artificial intelligence; AI

Introduction

Medication adherence presents a significant and pressing challenge worldwide across health care systems [1]. This problem spans across various medical conditions, from chronic illnesses such as hypertension, diabetes, and cardiovascular disease to acute infections [2]. Nonadherence to medication regimens can lead to a cascade of problems, including decreased treatment effectiveness, a higher risk of disease progression or complications, medication resistance, increased health care costs, and a reduced overall quality of life for patients [3]. It also places an additional burden on health care providers, who must constantly navigate the complexities of patient adherence to optimize treatment outcomes. Addressing medication adherence is not only a matter of improving individual health but also a vital step toward more efficient health care systems and improving population health.

One notable area where medication adherence could have a significant effect on public health is with smoking cessation medications. Tobacco smoking is not only extremely addictive [4], but it also damages almost every organ in the body [5] and is a leading cause of health inequalities [6]. Despite decades of efforts to reduce the smoking prevalence in Canada [7], over 4 million (15%) Canadians smoked in 2020 [8]. Tobacco use remains the leading cause of preventable death in Canada [9], and following smoking cessation, the risk of developing tobacco-related diseases gradually decreases over time [10].

Varenicline, a partial agonist of the α-4 β-2 nicotinic receptor, is one of the most effective smoking cessation medications associated with a doubling of long-term quitting with 12 weeks of continuous treatment [11]; however, adherence is a major barrier to achieving and maintaining abstinence [12-14]. Among those who take varenicline for smoking cessation, over one-third stop taking the medication by the second week of treatment, and these patients are significantly less likely to quit smoking [15-18]. In addition, several studies that have examined the correlation between sociodemographics and adherence to varenicline have found male sex [15,19], older age [15,19-21], White race [21,22], and higher education to be associated with better adherence [21]. Conversely, 1 study found that greater age was associated with poorer adherence [21].

One of the most effective strategies to improve adherence to medication is tailoring behavioral interventions [23]. Research has also shown that the use of technological solutions is crucial to providing personalized, cost-effective, and evidence-based interventions [24]. One such digital health solution is a web-based program integrating artificial intelligence (AI) conversational agents, or "health bots," that can be helpful in improving adherence to medication [25]. Health bots have greater functionality compared with applications providing simple text message reminders since they can track medication intake, provide information about side effects, and answer medication-related questions [26,27].

The "ChatV" health bot is an example of such a digital health solution that we developed to improve adherence to the smoking cessation medication varenicline [28]. We used a theory-based, patient-centered approach through the Discover Design Build and Test framework [29] to design the health bot; we conducted a rapid review to explore the barriers and facilitators to varenicline adherence and interviewed 20 patients and 19 health care providers to understand similar barriers and facilitators as well as features to be included in a health bot that may improve varenicline adherence. The data from these sources were analyzed using the capability, opportunity, motivation-behavior change (COM-B) [30] model of behavior change and its associated framework (theoretical domain framework) [31] and taxonomy (behavior change techniques taxonomy) [32] to identify the features to be included in the health bot. We used the Wizard of Oz methodology [33] to build a library of responses that were programmed in the health bot to answer users' questions. We are currently beta testing the minimal viable product that has the following features: (1) scheduling and receiving reminders for varenicline dosing; (2) setting a smoking quit date; (3) answering questions related to varenicline (eg, guidance for missed doses) and smoking cessation (eg, strategies to reduce cravings); (4) providing information and strategies to manage side effects [12,15,18]; (5) tracking medication use and smoking; and (6) encouraging participants to increase their motivation to maintain medication intake and continue their quit attempts. Throughout the development of the health bot, a health equity lens was adopted to address any disparities in varenicline use and health bot features between different demographic characteristics.

In this protocol, we detail our plans to examine the uptake, usability, acceptability, and appropriateness of ChatV (ie, feasibility) [34] and to determine whether progression to a fully powered randomized controlled trial (RCT) is warranted.

Methods

Design

We will conduct a nonrandomized, single-arm feasibility study.

Participant Recruitment

We will recruit 40 participants. In order to ensure diversity with respect to age, gender, race, and socioeconomic status, we will purposefully recruit participants through a variety of methods, including the research boards of Centre for Addiction and Mental Health (CAMH), where recruitment flyers are posted for patients to explore research opportunities; health care providers at CAMH programs (eg, Smoking Treatment for Ontario Patients [STOP] program, Aboriginal services, and Rainbow services) and partnering organizations (Rainbow Health Ontario); the STOP program's list of people who are seeking treatment for smoking and who have consented to be contacted for future research studies; and social media and community boards. Research staff members will conduct a prescreening for those who are interested, and if eligible, participants will be enrolled in the study.

Inclusion Criteria

The inclusion criteria include individuals who are seeking treatment for their tobacco use who smoke 10 or more cigarettes a day, are willing to set a quit date in the next 30 days, are willing to take varenicline for 12 weeks, are aged 18 years, speak and read English, have a smartphone with a data plan, report being committed to answering questions during follow-up, and live in Ontario.

Exclusion Criteria

The exclusion criteria include having contraindications to varenicline use, being pregnant, planning to become pregnant, breastfeeding, or participating in the co-design phase.

Ethical Considerations

The CAMH Research Ethics Board (REB #050/2022) has provided approval to conduct the study, and all participants will provide written informed consent before participation. It has been registered at ClinicalTrials.gov (NCT05997901). Any amendments to the protocol are noted, and substantial changes will be reported to the ethics committee. All interested participants will receive an information sheet and a consent form describing the study and providing sufficient information for the participant to make a decision regarding study participation. A research staff member will arrange a personal meeting with the prospective participants and inform them again about all study procedures, benefits, risks, and their rights regarding study participation. Afterward, the consent form is signed by both the participant and the research staff before the participant undertakes any study procedure. The informed consent process is documented in Research Electronic Data Capture (REDCap; Vanderbilt University).

All study-related documents and data will be held in strict confidence and stored on CAMH servers that will follow CAMH policies and procedures to ensure participant privacy and confidentiality. Any data collected as part of the participants' completion of the electronic consent form will be securely stored in REDCap, a CAMH-approved data collection tool.

In addition to free medication (for 12 weeks), participants will receive an honorarium in the form of a CAD $30 (US $22) gift card after completion of the 4-week follow-up survey and a CAD $40 (US $30) gift card after completion of the 12-week interview.

Procedures

The research team will inform potential participants about the study and evaluate if they meet the inclusion criteria. If they qualify, participants will receive a consent form and arrange a phone-based discussion to obtain consent. After obtaining consent, participants (n=40) will complete an internet-based questionnaire covering sociodemographic characteristics, nicotine dependence [35], and an adapted scale to measure varenicline adherence self-efficacy [36-38]. After completing the questionnaire, participants will have an internet-based or in-person visit with a health care provider for eligibility confirmation and to obtain a prescription for varenicline for the first 4 weeks (1 tablet [0.5 mg] daily for the first 3 days, 1 tablet [0.5 mg] twice daily for the next 4 days, and 1 tablet [1 mg] twice daily for 3 weeks). In addition, research staff will show participants how to use the health bot on their phones. Medication will be provided in person or, in the case of internet-based contacts, mailed to the participants. A follow-up visit will be scheduled at 2 weeks, where health care providers will assess the participant's tolerance of varenicline and provide a prescription for the remaining 8 weeks (1 tablet [1 mg] twice daily or a different dose depending on the tolerance of each participant). Any unanticipated problems (ie, adverse events that are unexpected in terms of severity, nature, or frequency; are related or possibly related to participation in the research; and suggest that the research places other research participants at greater risk of harm) will be documented and reported to the research ethics board, and adverse drug reactions will be reported to the market authorization holder (Apotex) as applicable.

Participants will be required to complete surveys at 1, 4, 8, and 12 weeks. When participants join the study, they will be able to opt to respond to these questions using either the health bot or an internet-based platform. Those who do not complete the internet-based or health bot follow-up within the designated time frame will receive a phone call from our research staff. Additionally, after 12 weeks of joining the study, participants will be invited to participate in a 1-hour semistructured phone interview.

Measures

Overview

The taxonomy of implementation outcomes of Proctor et al [39] guides our selection of implementation outcomes (Table 1).

[a]Acceptability of Intervention Measure.

[b]Intervention Appropriateness Measure.

[c]System Usability Scale.

[d]Timeline Followback.

Acceptability

Acceptability is the extent to which an innovation is agreeable, palatable, or satisfactory to a stakeholder [39]. In order to measure acceptability, we will use the Acceptability of Intervention Measure (AIM) in the follow-up surveys as well as in the semistructured phone interviews.

Appropriateness

Appropriateness is the perceived fit or compatibility of an innovation with a practice setting or context [39]. In this study, appropriateness will be assessed on an individual basis, including factors such as alignment with users' attitudes, needs, and background, as measured in the 12-week survey with the Intervention Appropriateness Measure (IAM), a validated 4-item intervention appropriateness scale [40], and explored in depth in the semistructured interviews.

Fidelity

Fidelity is the extent to which an intervention is used as intended [39]. For this study, in the semistructured interviews, we will investigate the functions of the health bot that participants used; the purposes for which they used it (such as answering questions or seeking support); the frequency of usage; and the quality, specifically whether the health bot provided accurate information.

Adoption

Adoption is the intention, decision, or initiation of use for an evidence-based practice, characterizing it at the level of the provider or organization [39]. Since the concept of adoption is closely related to the actual use of systems, researchers investigating behavioral intervention technologies, such as the health bot, have extended this level of analysis to include consumer behavior [41]. In this study, we will measure the adoption of the health bot by analyzing analytics data throughout the 12 weeks that the participant is scheduled to take varenicline. These data will allow us to evaluate the timing (day and time) of user interactions with the health bot, the specific features used, and the duration of engagement. Thus, we will have objective data on the actual adoption of the health bot by each participant. Additionally, during the semistructured interviews, we will probe for participants' subjective perceptions of their use of the health bot.

Usability

Usability will be assessed using the System Usability Scale (SUS) [42]. The SUS is a 10-item measure assessing usability and user satisfaction with technology.

The AIM, IAM, and SUS all have items that are rated on a 5-point Likert scale (1=completely or strongly disagree to 5=completely or strongly agree).

Medication Adherence and Smoking Status

Participants will be asked about their smoking status [43] and adherence to varenicline using the Timeline Followback (TLFB) [44] in the surveys collected at 1, 4, 8, and 12 weeks. Participants will report the number of pills taken since the previous assessment. Participants who log their varenicline use in the health bot will be able to refer to these data when filling out the TLFB. We chose the TLFB method for assessing adherence because the 12-week TLFB measure demonstrates a moderate correlation with saliva varenicline levels and is widely regarded as the most practical measure of varenicline adherence [16]. In order to assess the feasibility and accuracy of measuring adherence using TLFB, participants will also be asked to send pictures of their varenicline blister packs at 1, 4, 8, and 12 weeks. This additional measure will also help explore which method to assess adherence should be used for any future research studies (eg, RCT). Smoking abstinence will be defined by a negative response to the dichotomous 7-day point prevalence question, "Have you had a cigarette, even a puff, in the last 7 days?"

Analysis of Survey Data

We will calculate descriptive statistics, including means, medians, ranges, and SDs, for the demographic data as well as

XSL•FO
RenderX

for the AIM, IAM, and analytics data captured by the health bot internal logs. All scores will be analyzed using the appropriate guidelines provided by Weiner et al [40] (acceptability and appropriateness) and Brooke [42] (usability). Consistent with previous studies, adherence will be defined as taking ≥80% of the prescribed varenicline [45-48]. We will not treat adherence as a continuous variable because it is likely to be strongly bimodal and is not necessarily linearly associated with the cessation outcome. We will calculate the percentage of participants who were adherent at week 12 and who reported not having smoked in the last 7 days. These results will serve as progression criteria to determine whether a full-scale RCT is warranted. Although the sample size will be insufficient for meaningful regression analysis, especially given the potentially nonlinear effects of age, we will also test for differences across age and gender groups using 2-tailed *t* tests and chi-square tests. The power for these comparisons will be low; therefore, this analysis will be an exploratory evaluation of large adherence or outcome differences that may be important to future study design, and interpretation will focus on observed differences and CIs.

Analysis of Semistructured Interviews

We will use framework analysis [49] to analyze the data. Specifically, we will use the implementation outcomes of Proctor et al [39] with an intersectional lens as the a priori framework. Framework analysis is a method used to draw descriptive and explanatory conclusions from qualitative data and includes the following six steps: (1) verbatim transcription of interviews, (2) familiarization of interviews, (3) coding and labeling the data, (4) developing a framework by grouping and categorizing codes, (5) indexing transcripts using the developed framework, and (6) reducing and charting data into a matrix. Interview findings will help us contextualize the findings from the surveys and the information collected from the use of the health bot. For example, we will understand why the health bot was or was not used (adoption); if it was used as intended (fidelity), what about the health bot the participants found agreeable and what they did not (acceptability); what features, if any, aligned with participants' attitudes, needs, and background (appropriate); and how other features would need to change in order to align with their needs. In addition, we will be able to understand how social identity (eg, age and gender) and power structures (eg, ageism and sexism) played a role in these results. This will provide us with important information to improve the health bot through an equity lens.

Triangulation of Findings

Once the survey data and interviews are analyzed, we will triangulate the results by listing all the findings on the same page to identify instances where findings from each method align (convergence), provide additional insights on the same topic (complementarity), or seem to conflict with one another (discrepancy or dissonance) [50,51]. Triangulating the data will allow us to contextualize the quantitative findings and explore "intermethod discrepancy" that might lead to a better understanding of how the health bot works and the modifications needed.

Exploring the Feasibility of the Approaches on Recruitment, Retention, and Data Collection

This study, using "stop, amend, and go" progression criteria for pilot studies [51], will help determine if proceeding with an RCT is a logical next step and whether additional adjustments are necessary. We will only conduct a full-scale RCT if none of the criteria outlined in Table 2 meet the "stop" criterion (unless we see that there are contextual issues that can be modified to overcome the identified problems). If 1 or more of the concepts in Table 2 meet the "amend" criterion, the trial will proceed to an RCT only if the issues can be addressed. If all concepts in Table 2 satisfy the "go" criterion, we will proceed with planning an RCT.

Table 2. Criteria to decide if a randomized controlled trial is warranted.

Criteria	Stop	Amend	Go
Patient recruitment	If <30 patients are recruited within 12 months	If 30-40 patients are recruited within 12 months	If 40 patients are recruited within 12 months
Patient retention	If <25% of patients answer the 12-week survey	If 25.1%-79.9% of patients answer the 12-week survey	If ≥80% of patients answer the 12-week survey
Missing data, medication adherence, or smoking status	If >60% of adherence data and smoking status are missing	If 21%-59% of adherence and smoking status data are missing	If ≤20% of adherence and smoking status data are missing
Acceptability and appropriateness	If mean score for the AIM[a] or IAM[b] is ≤8	If mean score for the AIM or IAM is 9-12	If mean score for the AIM or IAM is ≥13
Usability	If mean SUS[c] score is ≤40	If mean SUS score is 41-67	If mean SUS score is ≥68
Adoption	If mean use is ≤ 20 times	If mean use is 21-79 times	If mean use is ≥80 times

[a]AIM: Acceptability of Intervention Measure.

[b]IAM: Intervention Appropriateness Measure.

[c]SUS: System Usability Scale.

Results

Participant enrollment for the study will begin in January 2024.

Discussion

Despite the proven effectiveness of varenicline in aiding smoking cessation [52], a significant number of individuals attempting to quit continue to smoke because they struggle with adhering to their varenicline regimen [12-14]. While there are proven strategies to help people adhere to their medications, they have been hard to implement. Digital technology for medication adherence has started to emerge [53,54]; whether these tools can be feasibly implemented and adopted, especially within diverse and disadvantaged populations, remains largely unknown.

In this protocol, we outline the methodology to assess the uptake, usability, acceptability, and appropriateness of ChatV and assist in determining whether it is appropriate to advance to an RCT to gauge the effectiveness of the intervention. This study will address many limitations of previous mobile health trials [55,56], including using an intervention that clearly outlines the behavior-change theory used and the intervention content. In addition, this study provides well-outlined a priori criteria for progressing to an RCT. This will enhance its replicability. Furthermore, this study will provide insights into potential mechanisms underlying the intervention's impact, shed light on the effectiveness, or ineffectiveness, of its various components, and offer possible explanations.

In summary, the results of this feasibility study will provide much-needed data and insight into the potential implementation of ChatV to augment adherence to smoking cessation medications. In addition, this project has the potential to increase our understanding of how digital tools can improve adherence to other medications in a cost-effective manner.

Acknowledgments

This research is funded by a Proof of Concept Intervention Grant in Primary Prevention of Cancer (action grant) of the Canadian Cancer Society and the Canadian Institutes of Health Research-Institute for Cancer Research (grant 707218) and a Canadian Institutes of Health Research Project grant (funding reference PJT 180405; Multimedia Appendix 1). The authors would like to thank MEMOTEXT for their contribution to the development of the ChatV health bot.

Data Availability

The data sets generated during this study will be available from the corresponding author upon reasonable request.

Authors' Contributions

NM conceived the study with the support of JR, PS, SV, LZ, and MR. NM (lead), KM, ME, SH, RTAK, and PS have shaped the intervention (health bot). NM (lead), KM, and ME were involved in gaining ethical approval. NM and KM wrote the first draft of the manuscript. All authors reviewed and edited the manuscript and approved the final version of the manuscript.

Conflicts of Interest

The authors declare that they have no conflicting interests with respect to this manuscript; however, some authors have general disclosures to report. NM reports receipt of funding from the Canadian Institutes of Health Research, the Canadian Cancer Society, and the discovery fund of the Centre for Addiction and Mental Health (CAMH). PS reports receipt of funding from the Canadian Institutes of Health Research, the Canadian Cancer Society, Pfizer Inc, Pfizer Canada, and the Ontario Lung Association. PS also reports that, through an open-tender process, Johnson & Johnson, Novartis, and Pfizer Inc are vendors of record for having provided smoking cessation pharmacotherapy for research studies at free or discounted rates. PS holds the Vice-Chair, Research, and Giblon Professor in Family Medicine Research, a university-named professorship at the University of Toronto. OCM reports receiving grant and salary support from the Centre for Addiction and Mental Health and the Department of Family and Community Medicine at the University of Toronto through the New Investigator Award.

Abstract

Background: Chronic musculoskeletal pain is prevalent and disabling among older adults in underserved communities. Psychosocial pain management is more effective than pharmacological treatment in older adults. However, underserved community clinics often lack psychosocial treatments, in part because of a lack of trained providers. Shared medical appointments, in which patients undergo brief medical evaluation, monitoring, counseling, and group support, are an efficacious and cost-effective method for chronic disease management in underserved clinics, reducing the need for specialized providers. However, shared medical visits are often ineffective for chronic pain, possibly owing to lack of inclusion of skills most relevant for older adults (eg, pacing to increase engagement in daily activities).

Objective: We have described the protocol for the development and initial pilot effectiveness testing of the *GetActive+* mind-body activity intervention for older adults with chronic pain. *GetActive+* was adapted from GetActive, an evidence-based intervention that improved pain outcomes among mostly affluent White adults. We aim to establish the initial feasibility, acceptability, fidelity, and effectiveness of *GetActive+* when delivered as part of shared medical appointments in a community clinic.

Methods: We conducted qualitative focus groups and individual interviews with providers (n=25) and English-speaking older adults (aged ≥55 y; n=18) with chronic pain to understand the pain experience in this population, perceptions about intervention content, and barriers to and facilitators of intervention participation and implementation in this setting. Qualitative interviews with Spanish-speaking older adults are in progress and will inform a future open pilot of the intervention in Spanish. We are currently conducting an open pilot study with exit interviews in English (n=30 individuals in total). Primary outcomes are feasibility (≥75% of patients who are approached agree to participate), acceptability (≥75% of patients who enrolled complete 8 out of 10 sessions; qualitative), and fidelity (≥75% of session components are delivered as intended). Secondary outcomes include physical function—self-reported, performance based (6-minute walk test), and objective (step count)—and emotional function (depression and anxiety). Other assessments include putative mechanisms (eg, mindfulness and pain catastrophizing).

Results: We began enrolling participants for the qualitative phase in November 2022 and the open pilot phase in May 2023. We completed the qualitative phase with providers and English-speaking patients, and the results are being analyzed using a hybrid, inductive-deductive approach. We conducted rapid analysis of these data to develop *GetActive+* before the open pilot in

XSL•FO
RenderX

English, including increasing readability and clarity of language, reducing the number of skills taught to increase time for individual check-ins and group participation, and increasing experiential exercises for skill uptake.

Conclusions: We provide a blueprint for the refinement of a mind-body activity intervention for older adults with chronic pain in underserved community clinics and for incorporation within shared medical visits. It will inform a future, fully powered, effectiveness-implementation trial of *GetActive+* to help address the chronic pain epidemic among older adults.

Introduction

Background

Chronic musculoskeletal pain (pain that persists for >3 mo [1]) is highly prevalent among older adults and is associated with substantial clinical, economic, and societal burden [2-4]. Chronic pain tends to be more complex in older adults, with approximately 60% to 70% describing pain in multiple sites alongside multiple comorbidities [5]. Among older adults, chronic pain leads to significant decline in physical and emotional function, with substantial disability from reduced mobility, avoidance of activity, falls, depression, anxiety, sleep impairment, and social isolation [2,3,6,7] regardless of the location and severity of pain [8,9]. Sedentariness, lack of engagement in activities of daily living, and impairments in balance and gait [10] are common in older adults with chronic pain and further increase the risk for morbidity and mortality [2].

For older adults, pain medications, including opioid analgesics, have limited efficacy [11,12], increase the risk for adverse events such as falls [13], and can lead to confusion and cognitive decline [14]. Nonpharmacological treatments for chronic pain such as cognitive behavioral therapy or mindfulness-based interventions are safe for older adults and can improve pain outcomes including physical and emotional function [15,16]. However, access to timely treatment is scarce [17], and treatments often fail to target physical function components that are critical in older adults, including walking and activities of daily living [18].

Importantly, treatment access is not evenly distributed. Older adults from communities of high socioeconomic status have substantially greater likelihood of receiving psychosocial pain management, whereas individuals from underserved communities often lack psychosocial treatment options, despite being at the highest risk for negative pain outcomes [19,20]. Disparities in chronic pain management are multidimensional, including divisions in patient and health care provider communication, variability in decision-making, and gaps in access to effective treatment [19,21]. Furthermore, older adults from underserved communities receive most of their care from primary care practitioners. However, many primary care practitioners do not have the time or training to provide psychosocial pain management and tend to primarily focus on pharmacological treatment. Access to nonpharmacological therapies is limited for many older adults from disadvantaged populations because therapies are not affordable, not recommended by providers, or not available in their community [22-25].

There is a need to implement psychosocial pain management interventions within primary care that are accessible to underserved older adults with chronic pain. Shared medical visits may be a viable model to overcome the many barriers to implementation in these communities [26,27]. Shared medical visits seek to improve patient health through a blend of medical care, education, and peer support [28]. They include group conversations, individual check-ins, and peer interactions as key elements [29]. Shared medical visits are often used to provide greater access to complementary and integrative health approaches to pain management, including mindfulness-based interventions [30]. Patients report that shared medical visits allow them to learn from peers' experiences and create a sense of connection [31,32], with many preferring them to individual primary care appointments [33]. There is evidence to suggest that pain management can be delivered successfully in shared medical visits [34,35], including with economically and ethnically diverse populations [36-38]. Patients qualitatively support shared medical visits and demonstrate increases in quantitative measures of quality of life [33,35,39]. However, pain outcomes, including pain interference and pain catastrophizing, are often not adequately targeted by existing shared medical visit interventions [34,39]. Existing interventions are often broad in their scope, including using mindfulness, guided imagery, health behaviors (eg, exercise and nutrition education), yoga, chiropractic education, and acupuncture [33,35,37,39], without enough attention to skill uptake and integration into daily life. Although experiential exercises are sometimes incorporated, less time is allocated for repetition and troubleshooting skills use to acquire mastery. Furthermore, many of these programs were developed for young populations; there is an absence of skills focused directly on activities of daily living, which is particularly important to older adults [40].

Objective

To address the need for accessible, psychosocial, group pain management for older adults, we are iteratively adapting our evidence-based chronic pain intervention, the GetActive program [41], for implementation in an underserved community clinic using shared medical visits performed in English and Spanish. GetActive uses cognitive behavioral therapy (eg,

XSL•FO
RenderX

identifying and challenging negative thoughts) and mind-body skills (eg, deep breathing and mindfulness) to promote engagement in physical activity [42]. Our team has previously reported on the development and testing of GetActive including (1) strong feasibility, acceptability, and credibility [43,44]; (2) moderate to large significant improvements in self-reported physical function, performance-based physical function (6-minute walk test; 6MWT), pain, and emotional function (depression and anxiety) [43,45]; and (3) improvements through the mechanistic intervention targets (pain catastrophizing, fear of pain, pain resiliency, mindfulness, coping, and self-compassion) [44,46-48]. However, the original >*GetActive* program was developed in a predominantly White and affluent sample and did not use the shared medical visit format.

Our new intervention, *GetActive+*, will be delivered within the shared medical visit format. Each group session will include both pain management skills and a medical check-in with a nurse practitioner, to monitor fall risk and ability to engage in the physical activities that form the cornerstone of the program. Our approach to developing *GetActive+* is informed by the socioecological model [49], Aarons' stage model [50], and Proctor's framework for implementation [51]. Development will be iterative and will entail (1) using qualitative methods (focus groups and individual interviews) to assess provider and patient perceptions about the program and treatment needs and (2) conducting an open pilot with qualitative exit interviews to examine feasibility, acceptability, fidelity, and preliminary effectiveness in improving physical and emotional function and putative mechanisms. We will use qualitative information from the exit interviews to triangulate acceptability and obtain patient feedback about the treatment components and study procedures. We hypothesize that *GetActive+* will be feasible (≥75% agree to participate), be acceptable (≥75% of those enrolled complete 8 out of 10 sessions), be delivered with fidelity (≥75% sessions are delivered as intended), and show evidence for effectiveness in improving quantitative outcomes. We will use the information gained from the open pilot to refine the intervention and finalize the manual, assessments, and study protocol to support the successful completion of a future, hybrid, type-1, effectiveness-implementation trial. As a large portion of older adults in community clinics speak Spanish, we are also developing a Spanish version of *GetActive+*. Our ultimate goal is to create a program that can be delivered by providers of any specialty in a group format, to enhance the feasibility of dissemination to any community clinic. Given that different clinics have different resources, provider availability, and patient payment systems, this flexibility will maximize patient access while minimizing copayments.

In this paper, we have described the protocol and status of the qualitative phase and open pilot of *GetActive+*. We have discussed the challenges and flexibility required to refine and adapt a manualized chronic pain treatment for this setting. Ultimately, we aim to provide a framework for increasing access to evidence-based psychosocial pain management for older adults with chronic pain in underserved communities.

Methods

Phase 1: Qualitative Interviews

Study Design

We elicited feedback from stakeholders (providers and patients) through qualitative focus groups and individual interviews, with the goal of identifying and addressing barriers to and facilitators of implementation. Interviews were delivered in person at the clinic or via secure, live videoconferencing. Staff participants included primary care physicians, nurses, physical therapists, medical interpreters, and administrative staff. Ongoing interviews with Spanish-speaking patients are conducted by trained native speakers.

Setting and Participants

This study was conducted at the Massachusetts General Hospital (MGH)–Revere HealthCare Center (RHC), a community health care clinic that serves an economically and ethnically diverse population, approximately half of whom identify as immigrants, Asian, Black, Latino, or multiracial.

The inclusion criterion for providers for the qualitative interviews was as follows: any staff member of RHC. The inclusion criteria for patients for the qualitative interviews were as follows: (1) a patient at RHC; (2) aged ≥55 years; (3) self-reported chronic musculoskeletal pain (ie, pain duration >3 mo); (4) pain score ≥4 on the Numerical Rating Scale [52]; (5) no self-reported cognitive challenges that would interfere with participation (eg, cognitive impairment or dementia); (6) no self-reported, currently active, untreated psychotic or substance use disorder; (7) self-reported ability to walk for at least 6 minutes, including with assistive devices; and (8) English or Spanish fluency. Exclusion criteria were as follows: (1) current serious medical illness that is expected to worsen in the next 6 months (eg, advanced cancer) and (2) currently active and untreated serious mental health condition (eg, bipolar disorder, schizophrenia, or substance use disorder) that could interfere with focus group participation. Focus groups were conducted separately with patients and providers.

Recruitment, Screening, and Enrollment

The RHC medical director or study champions—primary care physicians in the clinic who assisted in recruitment—identified potential participants for the qualitative phase with RHC staff. All RHC staff were notified that their participation in the focus groups or interviews was voluntary, that results would not be reported to leadership, and that they will be able to withdraw at any time. Participants reviewed the institutional review board–approved study fact sheet independently using REDCap (Research Electronic Data Capture; Vanderbilt University) tools hosted at MGH; a HIPAA (Health Insurance Portability and Accountability Act)-approved electronic data capture system) [53]. Those who indicated their verbal agreement to participate were enrolled.

Potential participants for the focus groups and interviews with RHC patients were recruited via referrals from study champions and other RHC medical providers. Study champions encouraged referrals from fellow staff. Patient participants were also

XSL•FO
RenderX

recruited through flyers posted in the clinic and an advertisement on the MGH web research recruitment platform. Following eligibility screening by a research assistant, participants reviewed a study fact sheet and provided verbal consent to participate. Participants were notified that their participation in the focus groups or interviews was voluntary and that they will be able to withdraw at any time. Patients who were ineligible or uninterested were given a chronic pain resource sheet.

Qualitative Interviews

We used a similar semistructured, qualitative interview guide for both provider and patient interviews. Qualitative interview guides centered on three major domains: (1) needs and characteristics of older adults with chronic pain at RHC, including how environmental, sociocultural, behavioral, and medical factors influence and are influenced by pain and perceptions about pain treatments; (2) program preferences, including feedback about the general program content, structure, format, and skills (including audio examples of program skills); and (3) potential barriers to and facilitators of program participation and implementation, including questions related to transportation and homework completion. Interviews were conducted by trained facilitators, primarily, clinical psychologists and a trained research assistant. A trained bilingual research assistant conducted the Spanish focus groups and interviews.

Multiple reminder calls were conducted, and emails were sent before the focus groups. Nevertheless, on multiple occasions, attendance was not sufficient to conduct the group. Potential participants expressed that they had other competing responsibilities (eg, caregiving roles and medical appointments) that interfered with focus group participation. Therefore, we adopted a more flexible procedure, allowing for the completion of individual interviews via Zoom (Zoom Video Communications) or phone to ensure that we could get the information needed to inform program refinement while working with the needs of the clinic population.

Data Coding and Analysis

We conducted rapid data analysis (RDA) following each interview to determine real-time data saturation and develop *GetActive+* and the study protocol before conducting more extensive qualitative analyses [54]. RDA is a valid and reliable qualitative data analysis method that is recommended in studies where there is a need for real-time data to inform intervention adaptation and implementation [54-56]. RDA bypasses the process of transcription and in-depth coding; instead, data are organized immediately following qualitative interviews based on a template created from the interview script [57]. In this study, RDA was conducted within 24 hours of the interview, typically immediately after its completion. Our RDA template was organized into the following domains: (1) living with chronic pain: challenges, needs, and treatment (eg, description of the clinic population); (2) program implementation and preferences (eg, feedback about the core program skills); and (3) barriers to and facilitators of program implementation (eg, barriers to and facilitators of patient participation and homework completion). On the basis of the RDA literature, the completed template was reviewed by another member of the study team and entered into a matrix of responses [55,58], which informed the manual and procedure adaptations before the open pilot. The matrix was organized in a hybrid, inductive-deductive manner based on a combination of the domains from the RDA template and the information that emerged from qualitative interviews that was most useful in guiding the program adaptations. Each row consisted of one of the following domains: clinic population, usual pain care at the clinic, initial reactions to the program, format and delivery modality, core skills, program barriers and facilitators, and focus group recommendations. Each column represented a single group or individual interview.

Formal, planned, qualitative analyses are ongoing and will be used to provide an in-depth synthesis of the qualitative data, including comparisons between provider and patient feedback. These analyses involve the transcription of audio recordings and data analysis using the program, Dedoose [59]. We generated a qualitative codebook using a hybrid, deductive-inductive approach [60], wherein codes are created based on a priori categorizations using theoretical frameworks (eg, the socioecological model) and then revised based on novel content identified from the data. We allowed for new codes to be created directly from the data analysis process. Overall, 2 trained research assistants coded the first 20% of the transcripts under the guidance of a psychologist to resolve discrepancies between coders until sufficient concordance was achieved, following which the codebook was solidified, and the remaining transcripts were coded by a single coder.

Intervention Refinement

We used RDA to inform intervention refinement. We made the following modifications: (1) added psychoeducation about the nature of chronic pain to increase the understanding of core program principles and improve treatment buy-in; (2) simplified the program language and presentation to ensure that the manual was concise and at a sixth-grade reading level; and (3) consolidated the skills and ensured more time for experiential learning, check-ins, and group discussions to facilitate both skill mastery and social connection. In addition, because of high rates of stress, trauma, and grief in this clinic population, we focused the program skills on the impact of these factors on the pain experience and discussed how program skills can target both pain and these psychosocial factors. For example, the importance of using mindfulness to facilitate awareness about the impacts of stressors on pain was noted throughout the refined intervention. Finally, consistent with the goals of our subsequent effectiveness trial, the program emphasizes flexibility within fidelity, whereby we aim to deliver the active ingredients of the program while allowing flexibility with regard to the delivery format (eg, in-person or virtual), skill delivery contextualization, and support for the interventionist to adapt and differentiate support based on need [61]. Additional modifications and cultural tailoring of the intervention are expected as we develop the Spanish version of *GetActive+*.

XSL•FO
RenderX

Phase 2: Open Pilot of *GetActive+* With Exit Interviews

Study Design

GetActive+ is a 10-week group program designed to be led by any provider available in a community clinic. The open pilot English version of *GetActive+* is delivered by a mental health professional and a nurse practitioner in groups of 3 to 10 members. The nurse practitioner conducts 5-minute, individual, medical check-ins before or after the group session to assess current pain levels and discuss medical concerns that could interfere with activity engagement (eg, acute injuries and fall risk). The medical check-ins are optional. The nurse practitioner can refer to additional medical care, including contacting primary care providers, as needed.

The open pilot study is registered on ClinicalTrials.gov (trial registration: NCT05782231).

Setting and Participants

Inclusion criteria for the open pilot are identical to those for the qualitative phase, with the following exceptions: patients must be cleared for participation by medical staff and cognitive functioning is assessed using the Short Portable Mental Health Questionnaire [62] with a requirement of <4 errors to participate. An additional exclusion criterion was added that excluded those unable or unwilling to wear an ActiGraph, a device required for baseline and postintervention assessment of objective physical function.

Initial recruitment, screening, and enrollment procedures are identical to those of phase 1. Once a patient referral is received, a research assistant conducts a phone screening call with the patient. The research assistant provides a detailed introduction of the program, explaining the aim, format, modality, and participant requirements. All patient information, contacts, screening outcomes, and participant status are recorded in a secured, study-specific tracking log. If a patient is eligible and interested in participating, the research assistant collects their availability and preferred method of contact. If a patient is deemed ineligible, they are emailed a chronic pain resource sheet with information about pain management. Eligible participants are scheduled for an in-person clinic visit, where they provide written informed consent and complete the baseline assessments. Baseline sessions are scheduled based on the availability of the group leader, participants, and room to work within the clinic's existing programming. The research assistant conducts a scheduling call to all participants, encouraging each individual to record the date and time of the baseline session in their phone, in their calendar, or on their refrigerator. Owing to our issues with focus group attendance, as documented previously, we instituted a system of reminder calls to ensure attendance. Participants receive one call in the week before the baseline session and another on the day of the baseline session. Once the program begins, participants receive 1 reminder call in the morning of the session. They additionally receive calls if there are missing assessments or if follow-up information is needed regarding a concern that arose in the group (eg, safety considerations after a fall). We use a flexible approach in adapting to the needs of the group members, including providing GrandPad tablets for older adults with low income, giving them secure access to the study website (including skill recordings), assessments, and Zoom (for those who attend virtually).

Intervention

GetActive+ session contents are described in Table 1. The program begins with pain education, including information about how pain originates in the brain rather than because of tissue damage, that any stressors that dysregulate the nervous system can increase pain, and that chronic pain often involves a false alarm that fires in the absence of actual ongoing harm to the muscles and tissues. This information is presented to reinforce that participation in activities of daily living including light activity (eg, walking) is safe, regardless of the presence of pain. Participants are informed that the purpose of the program is to increase the time they spend in being active, such as engaging in walking, active hobbies, or chores. They are asked to reflect about their typical day and to contemplate what their day would look like if the program was successful and how they would like to increase their activity in ways that are meaningful to them. *GetActive+* then focuses on a series of skills in 4 categories, with primary focus on activity engagement skills including participating in active chores and hobbies that are meaningful and quota-based pacing to safely break the connection between pain and activity. Quota-based pacing is the cornerstone of the intervention and consists of setting weekly, realistic activity goals to increase participants' engagement in active hobbies, chores, and walking over time (eg, increasing activity by 5-10 min/d each week). The purpose of quota-based pacing is to build a sustainable habit that can be continued after the program ends. Emphasis is placed on the individuality of the participant's experience such that they are encouraged to choose activities that are meaningful to them. Similarly, they are provided with a range of complementary skills throughout the program to assist them in increasing activity and reducing pain interference; they are encouraged to choose those that are most applicable to their individual goals and experience. These skills are mind-body skills (eg, deep breathing, body scan, mindful walking, self-compassion, social support, and acceptance) to change one's relationship with pain (eg, reduce reactivity, fear, and ruminative self-talk through relaxation response and mindfulness exercises) and to facilitate activity engagement, pain behavior awareness skills to understand the "downward spiral" (eg, how lack of activity perpetuates chronic pain and emotional and physical disfunction), and cognitive skills to learn to identify and challenge negative automatic thoughts. All participants receive a treatment manual with descriptions of the skills and worksheets to record their individual cognitions, emotions, and behaviors surrounding pain and their weekly pacing plans to increase activity engagement.

XSL•FO
RenderX

Table 1. *GetActive+* intervention content in each session.

Session	Topic	Skills
1	Chronic pain education	Identifying the true vs false pain alarms and understanding the downward spiral of pain disability
2	Catching unhelpful thoughts and increasing activity	Identifying negative automatic thoughts that lead to pain interference and introducing quota-based pacing
3	Becoming aware	Mindfulness and body scan
4	Staying engaged with life	Mindful walking and engagement in meaningful activities
5	Working with unhelpful thoughts	Education about cognitive distortions and challenging negative automatic thoughts
6	Taking a pause to check in	Review of all skills, progress in activity engagement, and motivation to continue
7	Caring for yourself when you are in pain	Mindfulness of pain and self-compassion
8	Feeling connected with others	Discussion about the impact of pain on social connection and how to increase connection, including through walking with others
9	Promoting acceptance	Acceptance, including finger trap demonstration
10	Staying on track and maintaining your progress	Review of skills and plan for continuing engagement in activity following treatment

The beginning of each session consists of an overview and check-in regarding activity goals and skill use. Depth rather than breadth is emphasized in the check-in, in that clinicians are instructed to troubleshoot a particular skill, activity goal, or barrier to increasing activity, rather than reviewing the week in its entirety. Clinicians form a case conceptualization to individualize the intervention and target participant-specific barriers to activity engagement. For example, a participant with increased anxiety might be encouraged to use mindfulness skills to notice how fears about pain are preventing them from engaging in activity, whereas a participant who tends toward stoically increasing activity regardless of consequences would be encouraged to use mindfulness skills to notice when they are entering a boom-and-bust cycle. Participants are encouraged to try all the skills and are informed that skills are often most helpful with practice; however, it is also noted that the program represents a toolkit of skills and that, ultimately, they can choose those they feel are most applicable to them. We anticipate that the *GetActive+* Spanish version will retain the core components of the program, with additional tailoring based on information from qualitative interviews and focus groups.

Clinicians note the feedback about the intervention components following each session, including whether skills are understood, require additional clarification, and are perceived as useful. This information will be used to further refine *GetActive+* at the end of the open pilot phase.

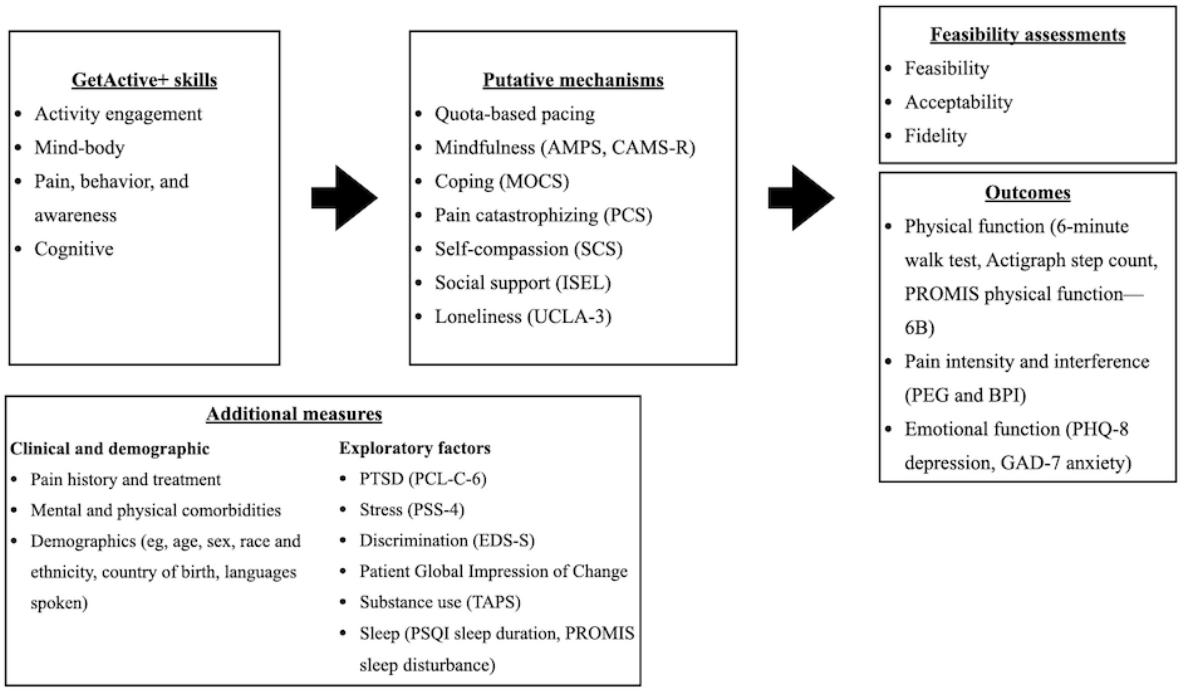
Treatment Fidelity

Consistent with our ultimate goal of creating a skills-based activity program that can be flexible and delivered by any provider, we are using interdisciplinary clinician teams. English-speaking groups are currently led by a Doctor of Philosophy–level clinical psychologist in conjunction with a nurse practitioner. The psychologist has experience with both chronic pain management and skill training intervention groups. The nurse practitioner is experienced in geriatrics, including pain management and medical considerations of older adult populations. In the open pilot, we used a sequential approach to training in which the nurse practitioner completed training on the program, consisting of a description of the development and initial testing of GetActive, theoretical rationale and core principles of the program, core skills, and role plays. She observed 1 group led by the clinical psychologist, codelivered the second group, and is currently leading the delivery of the third group, which will be recorded and rated for competency. She will be rated on (1) *GetActive+* general intervention principles and theoretical background; (2) *GetActive+* skill delivery; and (3) nonspecific competencies such as establishing rapport with participants, problem solving, and time management. The lead clinician, in conjunction with the study team, created a clinician version of the manual, informed by the experience of conducting the intervention in the open pilot. The clinician manual consists of guidance about timing, suggested language, and advice about how to maximize the key targets of the intervention. We opted to have the open pilot sessions cofacilitated by a mental health professional (psychologist and social worker) and nurse practitioner together as a way to allow the nurse practitioner to contribute to the clinician manual with real-time feedback. This manual will allow for wide dissemination, so that any provider, regardless of background, will be able to deliver the intervention.

Intervention Fidelity

We use session content adherence checklists to ensure that all components of the intervention are delivered in compliance with the study protocol. Clinicians complete an adherence checklist and a session note summarizing the session content and any issues that arise regarding individual concerns and progress and any information that is important for case conceptualization. Sessions are recorded, and 20% (6/30) will be reviewed for fidelity. Feedback is provided during weekly supervision, led by one of the study's principal investigators (A-MV). Participants who miss a session are offered one-on-one makeup sessions. Home practice is logged manually by

XSL•FO
RenderX



participants, tracked through the completion of web-based surveys sent either through email or SMS text message, and discussed in each session by the clinicians. Issues with compliance are discussed in supervision. Procedures follow the National Institutes of Health (NIH) Science of Behavior Change recommendations [63] and have been used by the multiple principal investigators and in previous clinical trials.

Assessments

Overview

Study assessments are depicted in Figure 1. Self-report measures and behavioral assessments of physical function (6MWT and ActiGraph-measured step count) are administered at baseline (1 week before session 1) and after the intervention (1 wk following session 10). Measures are collected either electronically (using the secure, HIPAA-approved REDCap platform on a study device) or using pen and paper, depending on device availability and participant preference. Measures are administered before and after the intervention, with the exception of the demographic questions (baseline only) and Patient Global Impression of Change (after the intervention only).

Figure 1. Diagram of *GetActive+* skills and assessments. AMPS: Applied Mindfulness Process Scale; BPI: Brief Pain Inventory; CAMS-R: Cognitive and Affective Mindfulness Scale–Revised; EDS-S: Everyday Discrimination Scale–Short; GAD-7: 7-item Generalized Anxiety Disorder Scale; ISEL: Interpersonal Support Evaluation List; MOCS: Measure of Current Status; PCL-C-6: 6-item Post-Traumatic Checklist–Civilian Version; PCS: Pain Catastrophizing Scale; PEG: Pain, Enjoyment of Life, and General Activity scale; PHQ-8: 8-item Patient Health Questionnaire; PROMIS: Patient-Reported Outcomes Measurement Information System; PSQI: Pittsburgh Sleep Quality Index; PSS-4: 4-item Perceived Stress Scale; PTSD: posttraumatic stress disorder; SCS: Self-Compassion Scale; TAPS: Tobacco, Alcohol, Prescription Medications, and Other Substance; UCLA-3: University of California Los Angeles–3 Loneliness Scale.

Primary Outcomes

Primary outcomes for the open pilot feasibility trial are described in Table 2 and include a priori benchmarks for feasibility, acceptability, and fidelity, informed by Aarons' stage model [50] and Proctor's framework for implementation [51].

Table 2. Feasibility benchmarks.

Implementation outcome	Definition	Recommended implementation step in the model by Aaron et al [50]	Benchmark
Feasibility	Suitability and practicality	Early (steps 1-3)	≥75% of those who are approached agree to participate in intervention; qualitative feedback
Acceptability	Satisfaction with or tolerability of the proposed approach	Early (steps 1-3)	≥75% of those who are enrolled complete at least 8 out of 10 sessions; qualitative feedback
Fidelity	Delivery of *GetActive+* as intended	Early to middle (steps 2-3)	≥75% of the session components are delivered by clinicians as intended; 20% of the sessions are rated

XSL•FO
RenderX

Secondary Outcomes

We will include the following: (1) performance-based, objective, and self-reported physical function; (2) pain intensity and interference; (3) depression symptoms; and (4) anxiety symptoms.

Performance-based physical function is measured using 6MWT [64,65]. 6MWT is designed to measure the total distance covered by an individual in 6 minutes, with greater distances covered indicating better physical function. Objective physical function is assessed using ActiGraph GT3X-BTLE [66], which measures average step count over the course of a 5-day to 7-day period. Self-reported physical function is assessed using the Patient-Reported Outcomes Measurement Information System Physical Functioning Short Form 6b [67], a measure of the ability to engage in physical activities, including active household tasks. Scores range from 8 to 40, with higher scores indicating greater physical function. Self-reported physical function will be the primary outcome in the subsequent fully powered trial.

We assess pain intensity and interference using the Brief Pain Inventory–Short Form [68]. The pain severity subscale measures pain at its worst, least, average, and current state. The pain interference subscale assesses interference of pain in general activity, mood, walking ability, work, relationships, sleep, and enjoyment of life. Scores for both subscales range from 0 to 10, with higher scores indicating more severe pain severity or interference. Depressive symptoms are assessed using the 8-item Patient Health Questionnaire [69]. Scores for the 8-item Patient Health Questionnaire range from 0 to 24, with higher scores indicating more severe depressive symptoms. The 7-item Generalized Anxiety Disorder scale [70] is used to assess symptoms of generalized anxiety, with scores ranging from 0 to 21 and higher scores indicating greater anxiety.

Other Assessments

Other assessments include the following: (1) putative mechanisms, (2) exploratory measures including NIH Helping to End Addiction Long-Term Initiative Core Data Elements measures, and (3) other auxiliary measures. These measures are included in the open pilot to test for feasibility of these assessments before the effectiveness-implementation trial.

Putative Mechanisms

Quota-based pacing is measured using a 4-item scale consisting of a subsection of items from the Activity Pacing Questionnaire [71]. Scores range from 5 to 20, with higher scores indicating increased pacing. The 13-item Pain Catastrophizing Scale [72] is used to assess pain rumination, magnification of the intensity of pain, and helplessness regarding the ability to cope with pain. Scores range from 0 to 52, with higher scores indicating increased pain catastrophizing. The Applied Mindfulness Process Scale [73] is used to assess the use of mindfulness in response to challenges of daily living. It consists of 15 items, and total scores range from 0 to 60, with higher scores indicating greater use of mindfulness. Similarly, participants' broad conceptualization of mindfulness is assessed using the 12-item Cognitive and Affective Mindfulness Scale–Revised [74]. Its scores range from 12 to 48, with higher scores representing increased levels of mindfulness. We assess self-reported social support using the Interpersonal Support Evaluation List [75]. This measure consists of 12 items, and scores range from 12 to 48, with higher scores indicating strong social support. In contrast, the University of California Los Angeles–3 Loneliness Scale [76] is used to assess social isolation and perceived lack of social support. Total scores on this scale range from 3 to 9, with higher scores indicating greater social isolation. The participants' ability to practice healthy coping skills is assessed using the Measure of Current Status [77]. Total scores on the Measure of Current Status range from 0 to 52, with higher scores reflecting stronger ability to recognize and cope with stress. The Self-Compassion Scale–Short Form [78] is used to assess a participant's level of self-compassion. Scores are calculated by averaging the responses to the 12-item measure and range from 1 to 5. Higher scores are associated with higher levels of self-compassion. Finally, fear of physical activity is assessed by the Tampa Scale for Kinesiophobia–11. Scores range from 11 to 44, with higher scores reflecting more severe kinesiophobia [79].

This study is funded by the NIH Helping to End Addiction Long-Term Initiative, which requires core data elements to ensure that data can be compiled and analyzed across studies. In accordance with the data collection standards, pain interference is measured using the Pain, Enjoyment of Life, and General Activity scale [80], which assesses pain intensity and related interference in the enjoyment of life and activities of daily living. Scores range from 0 to 10, with higher scores indicating more severe pain and related interference. The Patient Global Impression of Change [81] is used to assess changes in pain in response to treatment. Scores range from 0 to 6, with higher scores indicating worse outcomes. The Tobacco, Alcohol, Prescription Medications, and Other Substance [82] screening questionnaire is used to assess substance use. Each substance is scored individually on a single-item scale of use ranging from 0 to 4, with lower scores indicating more frequent use. Sleep duration per night is measured using a single item from the Pittsburgh Sleep Quality Index [83]. Sleep quality is assessed using the Patient-Reported Outcomes Measurement Information System–Sleep Disturbance scale. Scores range from 6 to 30, with greater scores indicating more sleep disturbance.

Other Auxiliary Measures

We included measures to assess the elevated rates of trauma, stress, and discrimination in this population. We are using the 6-item Post-Traumatic Checklist–Civilian Version [84] to assess current symptoms of posttraumatic stress disorder. Scores range from 6 to 30, with higher scores indicating high posttraumatic stress disorder symptoms. The 4-item Perceived Stress Scale [85] is used to measure participants' self-perception about stress levels. Total scores for this scale range from 0 to 16, with higher scores representative of more severe stress. To assess another significant stressor for many in this patient population, experiences of discrimination are measured using the Everyday Discrimination Scale–Short [86]. Total scores for this scale range from 0 to 25, with higher scores indicating greater frequency of discriminatory experiences.

XSL•FO
RenderX

Clinical and Demographic Variables

We assess general, pain-related information using the author-constructed Pain, Medication, and Medical History questionnaire, which measures self-reported (1) type of pain, (2) pain location and intensity, (3) pain treatments, (4) pain medications, (5) cannabis use for pain, (6) medical comorbidities, and (7) mental health conditions and medication. We additionally obtain the following demographic variables: age and birth date, gender, biological sex, race, ethnicity, education level, employment status, marital status, household income, disability status, language fluency, people in the household, Rural-Urban Commuting Area code (ie, zip code), country of birth, country lived in before the age of 12 years, years lived in the United States, parents' countries of origin, ethnic identity, and languages spoken at home. There is no summary score; each item is scored individually.

Finally, exit interviews assess participants' perceptions about the treatment and study procedures. Topics include what was the most and least helpful about the intervention, any topics that were not addressed that could be included, perceptions about each of the mind-body skills, comfort with participating in a skills-based treatment as opposed to a support group, and barriers to and facilitators of engagement with the material. Perceptions about the providers, assessments, homework, and group format will also be evaluated. RDA is used to analyze the exit interview data to inform the remaining open pilot groups and the subsequent trial.

For our Spanish open pilot, we used validated Spanish versions of the abovementioned questionnaires when they were available. A native speaker translated the remaining study measures.

Data Analysis

Feasibility-related open pilot study measures will be assessed using a priori determined benchmarks for feasibility, acceptability, and fidelity based on our previous studies and recommendations in the field (Table 2) [87,88]. Given the concerns regarding the use of open pilot studies to calculate effect sizes [89,90], sample size estimates and proposed analyses were determined with the primary goal of establishing feasibility, as opposed to powering for specific effects for the quantitative outcomes. Preliminary effectiveness of the secondary outcomes will be examined using simple 2-tailed *t* tests. Evidence of effectiveness will be determined if the minimal clinically important difference for the specific quantitative outcome is included within the 95% CI for the change score.

Ethical Considerations

The MGH institutional review board approved all the study procedures and determined that phase 1 of the study was exempt from written informed consent (institutional review board number for phase 1: 2022P001691). All phase 2 procedures were approved by the institutional review board before data collection (institutional review board number for phase 2: 2023P000362).

Results

We began enrolling participants for the qualitative phase in November 2022 and the open pilot phase in May 2023. We conducted 25 provider interviews and 3 focus groups and 8 interviews with 18 English-speaking patients. The average age of the providers was 48.56 (SD 11.66) years. Most providers were women (21/25, 84%), non-Latino (22/25, 88%), and White (15/25, 60%). On average, they had 18.84 (SD 11.15) years of experience in working with patients, and approximately half (11/25, 44%) reported that they received mental health training as part of their degree. For demographic information about the patient qualitative and open pilot samples, refer to Table 3. RDA was completed before the initiation of the open pilot to inform the manual and program adaptations. The open pilot phase is ongoing. Older adults who participated in the qualitative phase were also invited to participate in the open pilot, with 44% (8/18) enrolling in the open pilot. We completed 2 English-speaking focus groups (group 1: 8/20, 40% and group 2: 6/20, 30%), and one is ongoing (6/20, 30%). In the first group, 100% (8/8) of the participants attended all the sessions, with only 1 dropout across the 2 groups so far. We have also conducted 3 individual interviews with Spanish-speaking older adults and will continue to obtain qualitative assessments with Spanish-speaking participants. We plan to conduct 2 open pilot groups in Spanish.

Discussion

Principal Findings

This paper describes the study protocol for the adaptation and pilot effectiveness testing of a mind-body activity intervention, *GetActive+*, delivered as part of shared medical visits to older adults with chronic pain in an underserved community clinic. Older adults with chronic pain in community settings often lack access to evidence-based psychosocial treatment options. Given that their pain experience may be affected by socioeconomic factors that may influence the generalizability of interventions, we used a sequential approach to refine *GetActive+* for this setting. First, we conducted focus groups and qualitative interviews with patients and providers to evaluate patient experiences with pain and socioeconomic impacts on the pain experience; we also solicited feedback about the intervention components and logistical barriers to and facilitators of success. Next, we are conducting an open pilot with exit interviews to assess the intervention's feasibility and acceptability and evaluate the signals of improvement in key outcomes, including physical function. We are conducting ongoing English-speaking groups. We are also simultaneously conducting focus groups and qualitative interviews with Spanish-speaking older adults to inform the open pilot in Spanish, which will be conducted by a Spanish-speaking provider.

Chronic pain interventions need to be adaptable to be easily disseminated to the millions of older adults with chronic pain, most of whom receive their treatment in community settings as opposed to academic medical centers where treatment trials are typically conducted. Shared medical visits represent an important avenue for increasing the access to evidence-based pain management interventions [38,91]; however, existing interventions have shown limited effects on key pain outcomes, including pain interference [34,39], possibly owing to overemphasis on broad education rather than skill training [35,37]. *GetActive+* is unique in its emphasis on activity engagement and the use of mind-body skills to facilitate increases in activity. Furthermore, our program emphasizes the development of skill mastery and group cohesion by reserving one-third to half of each session for checking in and troubleshooting skill use.

This protocol demonstrates the importance of flexibility in adapting an intervention to a community setting. We used an observational approach to training that allowed a nurse practitioner to work side by side with a psychologist to learn to deliver the intervention. In turn, the nurse practitioner contributed to the development of the clinician manual and training protocol. We will use a similar approach to train a social worker for the open pilot focus groups in Spanish. We reduced the number of skills in the intervention to increase the opportunity for group discussion and interpersonal connection. We increased the psychoeducation about the impact of stressors on pain, including incorporation of discussions about how stress, trauma, and grief influence the experience of pain throughout the treatment. We changed the language in the manual to be less wordy and increased the number of experiential exercises.

Results of this trial will inform a subsequent hybrid, implementation-effectiveness trial (N=200) to evaluate the effects of *GetActive+* on physical function (self-report, performance based, and step count), depression, and anxiety. In preparation for the trial, we will continue to refine the intervention based on both the quantitative and qualitative findings from the open pilot and feedback from the clinicians delivering the intervention. In the long term, if *GetActive+* proves to be successfully implemented and effective in this community clinic, we will aim to disseminate it broadly. The goal is to have an intervention that can be taught by any health professional, including those who have the most regular access to and strongest relationships with patients in these settings, such as medical interpreters or community health workers. Provider resources are limited, and consequently, there needs to be flexibility in who can administer psychosocial treatment. Thus, we aim to have an intervention for which any health practitioner can be trained to successfully deliver the group. To

XSL•FO
RenderX

facilitate wide dissemination, our final training protocol and clinician manual for *GetActive+* will include specific guidelines and strategies oriented to address the training needs based on the type of provider, previous training, and expertise. If successful, this program will offer the potential for wide dissemination of mind-body skills with a focus on increasing physical activity, a key predictor of physical, cognitive, and emotional functioning in older adults.

Limitations

Although we are currently only conducting focus groups or interviews and open pilot groups in English and Spanish, we aim to include groups for Cambodian-speaking and Arabic-speaking patients in the future. We hope to improve on this limitation in the subsequent trial. Furthermore, this clinic, although ethnically diverse, lacks a substantial proportion of African American patients; thus, they are underrepresented in our groups compared with the general US population.

Conclusions

We have iteratively adapted and are currently testing the *GetActive+* mind-body activity intervention for older adult patients with chronic pain in a community clinic setting using shared medical visits. By the end of this trial, we will have a finalized intervention and study procedures that will enable us to test implementation and effectiveness in this setting. This trial has the potential to address the chronic pain epidemic by informing the adaptation of psychosocial pain management programs for wide dissemination in community clinics broadly. Such studies are essential for reducing health disparities and ensuring that historically underserved older adults with chronic pain have access to evidence-based pain management programs.

Acknowledgments

This study was funded by the National Center for Complementary and Integrative Health (NCCIH; 1R61AG08103401) to A-MV and CR. A-MV is supported by an NCCIH K24 mentoring award (K24AT011760). JG is supported by an NCCIH K23 Mentored Patient-Oriented Research Career Development Award (K23AT01065301A1). KM is supported by a National Institute on Aging career enhancement supplement (3R61AG081034-01S1). This study was funded by the HEAL Initiative (https://heal.nih.gov/): Advancing Health Equity in Pain Management [92].

Data Availability

Once the trial is complete, data will be made available upon request.

Abstract

Background: Alzheimer disease and related dementias are debilitating and incurable diseases. Persons with dementia and their informal caregivers (ie, dyads) experience high rates of emotional distress and negative health outcomes. Several barriers prevent dyads from engaging in psychosocial care including cost, transportation, and a lack of treatments that target later stages of dementia and target the dyad together. Technologically informed treatment and serious gaming have been shown to be feasible and effective among persons living with dementia and their care partners. To increase access, there is a need for technologically informed psychosocial interventions which target the dyad, together in the home.

Objective: This study aims to develop the toolkit for experiential well-being in dementia, a dyadic, "bio-experiential" intervention for persons with dementia and their caregivers. Per our conceptual model, the toolkit for experiential well-being in dementia platform aims to target sustained attention, positive emotions, and active engagement among dyads. In this paper, we outline the protocol and conceptual model for intervention development and partnership with design and development experts.

Methods: We followed the National Institutes of Health (NIH) stage model (stage 1A) and supplemented the model with principles of user-centered design. The first step includes understanding user needs, goals, and strengths. We met this step by engaging in methodology and definition synthesis and conducting focus groups with dementia care providers (N=10) and persons with dementia and caregivers (N=11). Step 2 includes developing and refining the prototype. We will meet this step by engaging dyads in up to 20 iterations of platform β testing workshops. Step 3 includes observing user interactions with the prototype. We will meet this step by releasing the platform for feasibility testing.

Results: Key takeaways from the focus groups include balancing individualization and the dyadic relationship and avoiding confusing stimuli. As of September 2023, we have completed focus groups with providers, persons with dementia, and their caregivers. Additionally, we have conducted 4 iterations of β testing workshops with dyads. Feedback from focus groups informed the β testing workshops; data have not yet been formally analyzed and will be reported in future publications.

Conclusions: Technological interventions, particularly "bio-experiential" technology, can be used in dementia care to support emotional health among persons with a diagnosis and caregivers. Here, we outline a collaborative intervention development process of bio-experiential technology through a research, design, and development partnership. Next, we are planning to test the platform's feasibility as well as its impact on clinical outcomes and mechanisms of action.

Introduction

Overview

Approximately 6.7 million Americans have a diagnosis of Alzheimer disease or related dementias (dementia) and rates are continuing to rise with the increasing aging population [1]. Even with the advent of disease-modifying agents [2], dementia remains a debilitating and incurable disease that impacts cognitive, emotional, social, and behavioral functioning [3,4]. In particular, psychological health concerns, such as stress, anxiety, depression, and social isolation, are common across the illness process and impact outcomes among both persons with the diagnosis and their care network.

More than 11 million Americans are the informal caregivers for a person with dementia [5]. Informal caregivers (ie, someone who provides care for a person with dementia not paid through an agency, often a family member or friend) serve a critical role in providing care for persons living with dementia. Caregivers take on a multifaceted role, including providing direct care assistance (ie, activities of daily living), instrumental activities of daily living (eg, finances and shopping), and emotional support. A large body of literature demonstrates that dementia caregivers report high levels of stress, and often, report a greater impact on mental and physical health than informal caregivers of nondementia illnesses and chronic diseases [6,7]. Depression occurs in at least a third of all dementia caregivers [8]. Increased caregiver stress relates to poor caregiver mental and physical health [9,10] and mortality among their care recipients [11].

Psychosocial factors are interdependent between persons with dementia and their caregivers, such that distress from 1 member of the dyad impacts the other. Evidence suggests that psychologically based dyadic interventions may reduce caregiver burden [12-14] and improve quality of life among persons living with dementia [13]. Dyadic interventions that target the person with dementia, the caregiver, and their interpersonal relationship can have synergistic effects on individual interventions and maximally benefit both members of the dyad [15,16].

Several barriers exist to engaging caregivers and persons with dementia in psychosocial interventions. First, many psychosocial interventions require a trained provider and protected time, often around 60-90 minutes a week for 8-12 weeks. Care is costly, and not always covered by insurance, and dyads often face the price of lost wages and transportation [10]. Furthermore, psychosocial care is overly focused on the early stages of dementia, when the focus is often on education and planning [17]. Additionally, there are few interventions that target the dyad together and even fewer in the late stages [18,19].

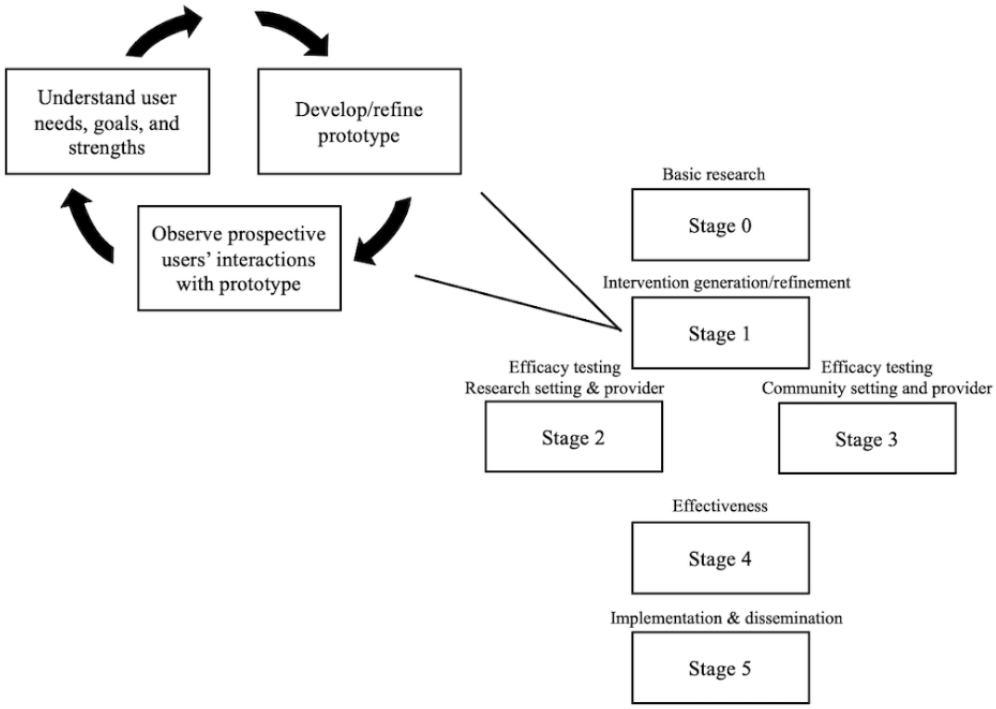
Technology can help bypass the barriers as interventions can be delivered at home at the convenience of the dyad and without a trained clinician. A growing body of literature supports the use of technology to provide feasible and effective psychosocial interventions among older adults, specifically those living with dementia and their care partners [20]. Technological interventions are available in several modalities for this population, including mobile apps to improve independent living and cognition among persons with dementia [21] or web-based life-review therapy to decrease depression and increase well-being [22].

A complementary area of research suggests that serious gaming, games intended for purposes other than entertainment (ie, learning) [23,24], may be enjoyable and improve mental health outcomes among older adults with dementia [25,26]. Though the field of serious gaming research is dominated by younger adults, evidence suggests that older adults enjoy serious gaming and are motivated by factors including social wellness and mutual participation to engage in serious gaming [27]. Serious gaming engages users in multiple activities and experiences. Similarly, an emerging field that combines elements of serious gaming with multisensory stimulation [28] (ie, “bio-experiential” design) represents an unexplored opportunity to support persons with dementia (including those with advanced symptoms) and their care partners with important benefits for their well-being. Such interventions can provide accessible opportunities for both persons with dementia and their caregivers to reduce stress and depression and improve well-being [29-31].

Objectives

In this paper, we aim to describe the protocol for the iterative development of the toolkit for experiential well-being in dementia (TEND), a dyadic technology-based intervention for persons with dementia and their caregivers. We partnered with Studio Elsewhere, a design and technology studio to develop the intervention. TEND combines serious gaming with bio-experiential design to provide dyads with the opportunity to engage in choice-based experiences together with the goal of regulating emotions, supporting interpersonal relationships, and increasing well-being. Furthermore, here we describe a model for the codevelopment of interventions through the partnership of design and development experts and interdisciplinary scientists from an idea to a full product.

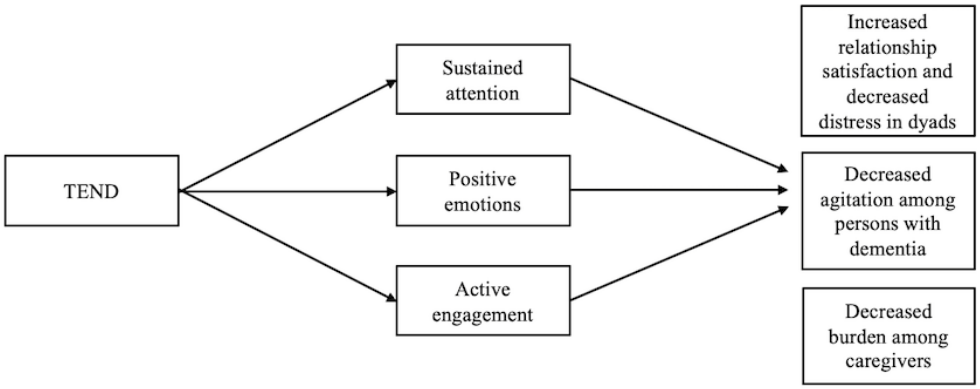
Methods



Overview

Our process follows stage 1A of the National Institutes of Health (NIH) stage model for Behavioral Intervention Development [32,33], which includes the generation of our new intervention TEND. NIH stage 1 involves stakeholder feedback, development of the intervention prototype including the conceptual model, testing through an open pilot with an exit interview, followed by refinement of the intervention and conceptual model. Consistent with guidelines for the development of

XSL•FO
RenderX



technology-enhanced interventions, we supplement the NIH model with principles of user-centered design as outlined in the process model for user-centered design [34], see Figure 1. This model was appropriate for this study as it allows for intervention development that is highly iterative and places user feedback at the forefront of design choice, which are necessities for promoting the usability of new technology among persons living with dementia [35]. Though steps may be repeated, our process consists of three key steps (and phases): (1) understanding user needs, goals, and strengths, (2) developing and refining the prototype, and (3) observing user interactions with the prototype [36]. These steps align with stage IA of the NIH stage model and position us to progress to feasibility testing (NIH stage IB), after gaining user feedback in this study.

Figure 1. National Institutes of Health stage model 1A: user-centered design.

Our initial conceptual model for TEND (Figure 2) is rooted in the theories of flow [37], positive resonance theory [38], and behavioral or unmet needs theory of dementia [39,40]. As the dyad participates together, we expect TEND to engage putative mechanisms of sustained attention, positive emotions, and active engagement, leading to improvement in outcomes of relationship satisfaction, and distress in dyads, agitation among persons living with dementia, and caregiver burden among caregivers [41].

Figure 2. TEND conceptual model. TEND: toolkit for experiential well-being in dementia.

Ethical Considerations

The Mass General Brigham Institutional Review Board approved all study procedures (2022P001401). Participants reviewed the approved fact sheet and provided verbal consent to all study procedures. In the consent process, participants were informed that all data would be deidentified and that their responses and decision to participate or not participate would not affect the care they received at Mass General Brigham. Providers received US $30 and persons with dementia and their caregivers received US $50 in gift cards respectively for their participation.

XSL•FO
RenderX

Phase 1: Understand User Needs, Goals, and Strengths

Overview

The initial phase represented the discovery process, aimed at establishing the initial parameters and definition of the product. In this phase, we engaged in the following activities: (1) methodology and definition synthesis and (2) key stakeholder focus groups.

Methodology and Definition Synthesis

We facilitated communication within our interdisciplinary team by first establishing a common language and definitions. The team members specialize in various disciplines, including clinical psychology, geriatric and palliative medicine, and design technology. As we bridged research expertise with technological and creative design expertise, it was imperative to establish standardized terms. To address possible inconsistencies in terminology, we established a consistently evolving web-based team "dictionary" of agreed-upon definitions. The research, design, and development teams conduct in-person meetings to facilitate definition agreement. Due to the travel burden, weekly web-based meetings are conducted via Zoom (Zoom Video Communications) with the team members, each providing perspectives essential to product development. Team members participate in these weekly meetings to develop a platform by integrating perspectives from engineering, design, research, and clinical medicine together.

Key Stakeholder Focus Groups

Design

Focus groups were conducted to identify the emotional needs and technology preferences of key stakeholders, including clinicians, persons with dementia, and caregivers. The feedback from persons living with dementia, caregivers, and interdisciplinary dementia care providers was used to guide design choices.

Recruitment

We recruited 10 dementia care clinicians from dementia clinics associated with the Departments of Neurology, Psychiatry, and Internal Medicine. We recruited 11 caregivers and persons with dementia from various sources, including the dementia care collaborative program, and through direct contact with Alzheimer disease and other related dementia caregivers within an academic health system. We received institutional review board approval on August 8, 2022. Recruitment flyers were disseminated to referral sources digitally. Interested potential participants were instructed to contact the assigned research assistant. The research assistant confirmed the interest and availability of the potential participants. Inclusion criteria included the age of 18 years or older and self-identified as a dementia care provider, a caregiver for a person living with dementia, or a person living with dementia. After reading the informed consent, the research assistant assessed the persons with dementia's ability to provide verbal consent through the University of California, San Diego brief assessment of capacity to consent questionnaire [42]. If the person with dementia scored a 1 or 0 on University of California, San Diego brief assessment of capacity to consent questionnaire, suggesting they did not comprehend the purpose of the group interview nor what they would be doing, the research assistant asked them to provide assent and asked their caregiver to provide their verbal consent. Providers and caregivers provided verbal consent to participate.

Procedures

Focus groups were conducted over Zoom for approximately 60 minutes. We conducted 5 focus groups separated into groups of dementia care providers, caregivers, and dyads. Users viewed the proposed components of the platform and early content to provide feedback and identify potential uses and gaps. We selected questions for stakeholders based on themes that required high priority early on in the design process. Themes included safety considerations, barriers to use, and utility across subtypes and stages of dementia. As part of the discovery phase, focus groups allowed for generative feedback to steer the direction of the platform toward the confirmed needs and preferences of the users.

Analysis

We identified rapid data analysis (RDA) as our analysis plan to facilitate rapid intervention development while maintaining scientific rigor [43-45]. We conducted rapid qualitative analysis because our goal was not to elicit new perspectives or an in-depth understanding of dyadic relationships in dementia but to understand key intervention elements, safety issues, and facilitators and barriers to implementation of the technologically mediated biopsychosocial intervention being developed.

Phase 2: Developing and Refining the Prototype

Overview

Throughout phase II the prototype is refined through a user feedback process to increase program fidelity and user-centeredness [34,36]. Similar to the key stakeholder interviews, we are engaging in a feedback loop to effectively disseminate information from users to the research, design, and development teams. While phase I focused on understanding user needs, goals, and strengths, phase II is characterized by developing and refining the prototype.

β *Workshops*

Design

We are implementing up to 20 iterations of platform β testing workshops, a period in which a product (the platform) is released to users to test in a real-world environment to determine any issues prior to initial release [46]. The team presents platform developments to users for iterative collaborative input and feedback on feasibility, satisfaction, and usability.

Recruitment

We are recruiting dyads for platform β testing. Similar to focus group recruitment, dyads are recruited from sources including the dementia care collaborative program, and through direct contact with Alzheimer disease and other related dementia caregivers within the internal health system. Inclusion criteria are similar to that of phase I (see above) and include only persons living with dementia and their caregivers. Dyads are invited to participate in multiple workshops, if interested.

XSL•FO
RenderX

Procedures

β testing workshops are conducted through Zoom for approximately 90 minutes and are facilitated by research staff and the design and development team. Conditions are intended to replicate a typical user scenario in which persons living with dementia and caregivers use the web-based platform together. Users are presented with a developed platform and toolkit to navigate. Research, design, and development staff are able to directly observe the usability of the platform. Furthermore, design and development staff inquire about platform use and acceptability to amend features and guide the next iteration of β testing.

Data Collection

Research staff elicit qualitative data from participants through exit interview questions gathering feedback on the platform. Additionally, staff interview participants with a series of quantitative questionnaires, including an adapted feasibility scale [47] and an adapted system usability scale [48]. Research staff records the interview to engage in behavioral observation using the Video Coding–Incorporating Observed Emotion scale [49,50] to gauge emotion, verbal engagement, visual engagement, collective engagement, and agitation among persons with dementia.

Data Analysis

We will conduct RDA. The analysis plan is similar to that of phase I (see above). We will review the recorded interviews to examine changes in emotion, engagement, and agitation among persons with dementia and the correlating platform features.

Results

As of August 2023, we have completed phase I. Focus group qualitative data has not yet been formally analyzed outside of RDA and will be reported in future publications. Key takeaways from the focus groups included prioritizing individualization, avoiding potentially confusing stimuli, and focusing on the dyadic relationship. Findings from the focus groups informed the β testing workshops. As of September 2023, we have completed 4 iterations of platform β testing workshops.

Discussion

Principal Findings

Guided by the process model for user-centered design [34] and the NIH stage model [32], above, we have delineated the initial process of user-centered design for a partnership between design and development experts and interdisciplinary scientists. We have engaged in codevelopment through methodology and definition synthesis, focus groups, and β workshops (currently ongoing). Combining serious gaming with bio-experiential design to develop the initial TEND platform, we aim to regulate emotions, support interpersonal relationships, and increase well-being. As bio-experiential technology emerges as a promising field within health care, we have the opportunity to mitigate traditional barriers to effective and equitable dementia care.

Within the development of this bio-experiential design, we outline an effective strategy for academic and design and development team partnership. Multidisciplinary team partnerships are especially beneficial in developing technologies for dementia, as scientific findings and procedures may support adaptations and user experiences [51]. For example, by partnering with researchers, developers are able to address cognitive and functional deficits through adaptations to technology including customization, errorless learning [52], and simple narratives [53]. We adapted to the challenges of codevelopment between distinct teams by establishing a common language and definitions and weekly meetings. The web-based, immersive platform and toolkit developed by Studio Elsewhere is guided by a concept generation and feedback loop incorporating key stakeholders throughout phases I and II.

Through aims 1 and 2 of our partnership, we expect to develop the experimental platform and refine and test the platform. We anticipate these efforts will result in a free interactive, immersive bio-experiential web platform and accompanying toolkit, after subsequent testing for efficacy in a large group of dyads. We anticipate that the resulting technologies will be easily implemented in the home to engage persons with dementia and caregivers in meaningful and relationship-enhancing activities. Consistent with existing literature on technology adaptations for older adults and persons living with disabilities, this study demonstrates various user design considerations, including cognitive, communication, sensory, and physical deficits common with dementia and advancing age [54,55]. In particular, our team is tasked with designing technology that is engaging for both persons with dementia and caregivers, who likely present with varying cognitive abilities and technological literacy. Further, the technology must be appealing and usable across dyads. Our approach outlined here will result in a bio-experiential technology that will be ready for more rigorous testing in the next phase of the work. Following these phases, we aim to conclude with the final stages of user-centered design, observing prospective users' interactions with the prototype [34]. In future studies, we will optimize the platform through engaging in pilot testing and efficacy testing with the goal of wide implementation.

As the field of technological interventions and serious gaming expands and the need for cost-effective and dyadic interventions increases, there is an urgency for technology-enhanced dyadic and psychosocial intervention in dementia informed by behavioral science. Not only do persons with dementia and caregivers find psychological benefit from technological interventions, but they are often highly enjoyable. Here, we outline a highly collaborative intervention development model to address traditional barriers and promote psychosocial wellness among this population through a bio-experiential intervention.

Limitations

We anticipate several limitations with this research. Participants must have access to technology equipped with audio and video capture devices to participate in focus groups and workshops, which may exclude low socioeconomic status participants. Additionally, while we engage in β testing workshops over Zoom to replicate real-life environments, the presence of

XSL•FO
RenderX

research personnel and design and development team members may unintentionally influence participant reporting on feasibility and usability scales. Furthermore, in research with persons with advanced dementia, the reliability of data is a concern for participants and proxies.

Conclusions

In this protocol, we outline the development of bio-experiential technology for persons with dementia and their caregivers, as well as the partnership between design and development experts and interdisciplinary scientists. This program of research has the potential to address clinical challenges (eg, depression and agitation) among persons with moderate-severe dementia, a population with few evidence-based treatments, and improve outcomes among dyads. Further, the ability to deliver a technology-based intervention in the home has implications for increasing access and translatability. The novelty of a cognitively mismatched dyadic intervention developed based on user-centered design principles will provide a methodological and conceptual framework for future investigators in this field.

Abstract

Background: Mobile health apps have the potential to motivate people to adopt healthier behavior, but many fail to maintain this behavior over time. However, it has been suggested that long-term adherence can be improved by personalizing the proposed interventions. Based on the literature, we created a conceptual framework for selecting appropriate functionalities according to the user's profile.

Objective: This cross-sectional study aims to investigate if the relationships linking functionalities and profiles proposed in our conceptual framework are confirmed by user preferences.

Methods: A web-based questionnaire comprising several sections was developed to determine the mobile app functionalities most likely to promote healthier behavior. First, participants completed questionnaires to define the user profile (Big Five Inventory-10, Hexad Scale, and perception of the social norm using dimensions of the Theory of Planned Behavior). Second, participants were asked to select the 5 functionalities they considered to be the most relevant to motivate healthier behavior and to evaluate them on a score ranging from 0 to 100. We will perform logistic regressions with the selected functionalities as dependent variables and with the 3 profile scales as predictors to allow us to understand the effect of the participants' scores on each of the 3 profile scales on the 5 selected functionalities. In addition, we will perform logistic ordinal regressions with the motivation score of the functionalities chosen as dependent variables and with scores of the 3 profile scales as predictors to determine whether the scores on the different profile scales predict the functionality score.

Results: Data collection was conducted between July and December 2021. Analysis of responses began in January 2022, with the publication of results expected by the end of 2022.

Conclusions: This study will allow us to validate our conceptual model by defining the preferred functionalities according to user profiles.

Introduction

Background

Healthy lifestyle behaviors have increased the life expectancy of those who adopt them and help individuals to live not only longer but better [1]. More specifically, adopting a healthy diet, maintaining a healthy weight, quitting smoking, drinking alcohol in moderation, and regular exercise are 5 behaviors associated with lower mortality. An increasing number of health apps aiming to help people adopt better health behaviors are reaching the market annually, with over 35,000 health apps available in 2018 [2]. Smartphone apps offer new opportunities to adopt health-related behaviors by providing immediate access to information about one's health, reminders to take medication, or help track one's progress [3].

Several scales exist to measure the quality of these health-related mobile apps, such as the Mobile App Rating Scale [4] and the App Behavior Change Scale [5]. A common feature of these scales is to consider a mobile app's personalization as a quality factor. Indeed, personalization is an important aspect to consider when creating an app that enables behavior change. For example, it has been shown that messages tailored to the user tend to be read more, recalled more, attract more attention, be better remembered, be a topic of discussion with others, and be perceived as personally relevant compared to untailored messages [6].

Development of a Mobile App Model for Behavior Change

Based on a previous literature review, we identified the personality traits more likely to adopt certain app functionalities [7]. These findings led to the development of a model indicating the type of features preferred according to a user profile. When designing a mobile app aiming at behavior change for health, designers can refer to our model as a guideline to know what functionalities they should privilege for their apps, given the profile of the intended users. For example, if a person is extroverted according to the Big Five, it will be relevant to privilege functionalities allowing comparison and cooperation between users [8].

Our model contains 17 functionalities presented in detail in Multimedia Appendix 1. For the user profile, we relied on the most common classification dimensions found in the literature, as follows: personality profiles [8-16], game preference [11,17,18], and perception of social norm [19] (Table 1). Gender and age are also important, and a recent review showed a difference in the type of functionality preferred according to gender, although no study in the review included individuals older than 31 years [17].

One of the most popular scales to measure personality is the Big Five, which defines the user's personality according to the following 5 dimensions: openness, agreeableness, conscientiousness, neuroticism, and extraversion. Game preference was measured with the Hexad Scale model [18], which defines the user's gamer profile according to the following 6 dimensions: disruptor, achievers, free spirit, player, socializer, and philanthropist. For example, participants with the profile "player" are motivated by extrinsic rewards and will do anything to earn a reward within a system. This type of profile is interesting to consider for apps that use gamification, which is also a concept widely used nowadays to incite behavior change. We can define gamification as "the use of game design elements in non-game contexts" [21]. Indeed, gamification positively affects motivation, engagement, and enjoyment [22]. Finally, the perception of social norm is the "individual's perception that other individuals important to the respondent believe that the respondent should perform the behavior of interest" [23]. This perception can help or hinder the performance of the behavior, depending on how the user's entourage perceives it. Therefore, it is important to consider this factor, and, depending on this perception, different functionalities can be included.

Table 1. Profiles considered in our conceptual framework.

Profiles	Scale
Personality	Big Five
Game's preferences	Hexad Scale [18]
Perception of social norms	Theory of Planned Behavior [20] Action

Objectives

This study aims to validate our conceptual framework by investigating if the proposed relationships between the functionalities and profiles are reflected in the preferences of our target population in an experimental setting.

Methods

Ethics Approval

The University Ethics Commission has approved this study for ethical research at the University of Geneva (CUREG_2021-04-38).

Study Design

We performed a cross-sectional study to address our aims. Participants responded to a web-based questionnaire to define their profile. Then, they were presented with a series of prototyped functionalities to be ranked according to their preferences to analyze if they corresponded to those defined in our conceptual framework. We chose to contextualize the functionalities of adopting healthy diet and fitness apps as these issues allow to target a generic public. Indeed, the desire to stay fit is a behavior that most adults want to adopt. To ensure data are completely anonymous, participants' IP addresses were not collected. We tested the questionnaire for usability and technical issues with 5 participants. This web-based survey is in

XSL•FO
RenderX

accordance with the Checklist for Reporting Results of Internet E-Surveys [24].

Outcomes

The primary outcome is the preferred functionalities given the user profile.

Secondary outcomes are the feature preferences related to past or current use of mobile health (mHealth) apps, and the preference of functionalities according to the participant's state of motivation to change behavior.

Study Population and Sample Size

The target population for this study included all individuals older than 18 years who understood French. We chose to conduct the questionnaire in French as this population was not necessarily fluent in English and comprised mainly native French speakers. An English language questionnaire would have introduced an element of bias as it might not have been correctly understood. Recruitment was conducted by posting messages on social networks (Facebook and Twitter) targeted at students at the University of Geneva, a young student population. The message indicated that we were seeking to recruit participants for a web-based study lasting 12 minutes as part of a research study conducted by the University of Geneva, with a focus on identifying user preferences based on their profile for a mobile app aimed at helping people get in shape. We also stated that the collected data remain completely anonymous.

For the calculation of the sample size, based on the hypothesis that altruistic people according to the Big Five prefer social networks [11,17], we used the multiple regression power calculation on R (R foundation for Statistical Computing), with the following measures: u=3; f^2=0.07; P=.05; power=0.9; and variance=202.403. To estimate variance, we relied on a previous study [25] investigating the preference of users classified according to the Big Five on posters. More specifically, we looked at the variance of altruistic participants (n=46) according to the Big Five on the average ratings of a poster representing a social network promoting blood donation (score from 0 to 100). Thus, we obtained a sample size of 206.

Procedure

Participants were asked to complete the web-based questionnaire developed using Qualtrics software (Qualtrics; Multimedia Appendix 2). First, they completed the consent form describing the purpose of the study and the procedure and informing them of their right to withdraw from the study. They were asked to confirm that they have read and understood the consent form and agree to have their responses used in our research and scientific publications. They can then access the rest of the questionnaire if they accepted these clauses. If not, they were informed that without their consent, we cannot collect their data and must terminate the survey. Next, participants were asked to answer demographic questions. In the case of a participant younger than 18 years, we explain that only those aged >18 years can participate and therefore we cannot continue with the questionnaire. Eligible participants continued to answer the questionnaire online where they had to (1) respond to scales to measure their profile, and then (2) look at the 17 features, select 5, and indicate on a score from 0 to 100 how much these features would motivate them to get back in shape.

Measures and Measurement

Demographic Questions

Participants were asked to indicate their gender, age, occupation, and level of education.

Questions About Their Use of mHealth Apps

Participants were asked if they use mobile apps aiming at behavior change (such as to help them eat healthier or exercise) to find out if they were already familiar with mHealth apps and whether they already like certain functionalities. If so, we asked them to select which functionalities they used most often and which they never used. These questions allowed us to observe whether participants already familiar with mHealth prefer certain features, as well as whether they prefer the same features among the 17 proposed.

Profile Assessment

Big Five

To assess participants' personalities, we relied on the Big Five Inventory-10 scale in French, translated and validated by Courtois [26]. With Cronbach alpha coefficients ranging from .37 to .83, the internal scale reliability of the Big Five Inventory-10 is low. This is because Cronbach alpha is not designed to evaluate scales with a low number of items [26]. This scale is composed of 10 items, 2 items per Big Five dimension. Participants are asked to indicate on a 5-point Likert scale whether they strongly approve or strongly disapprove of statements about themselves. For example, “I see myself as someone who is reserved” or “I see myself as someone who is easily anxious”. The score for each dimension is calculated by adding the scores for the two statements concerning the dimension after reversing the items.

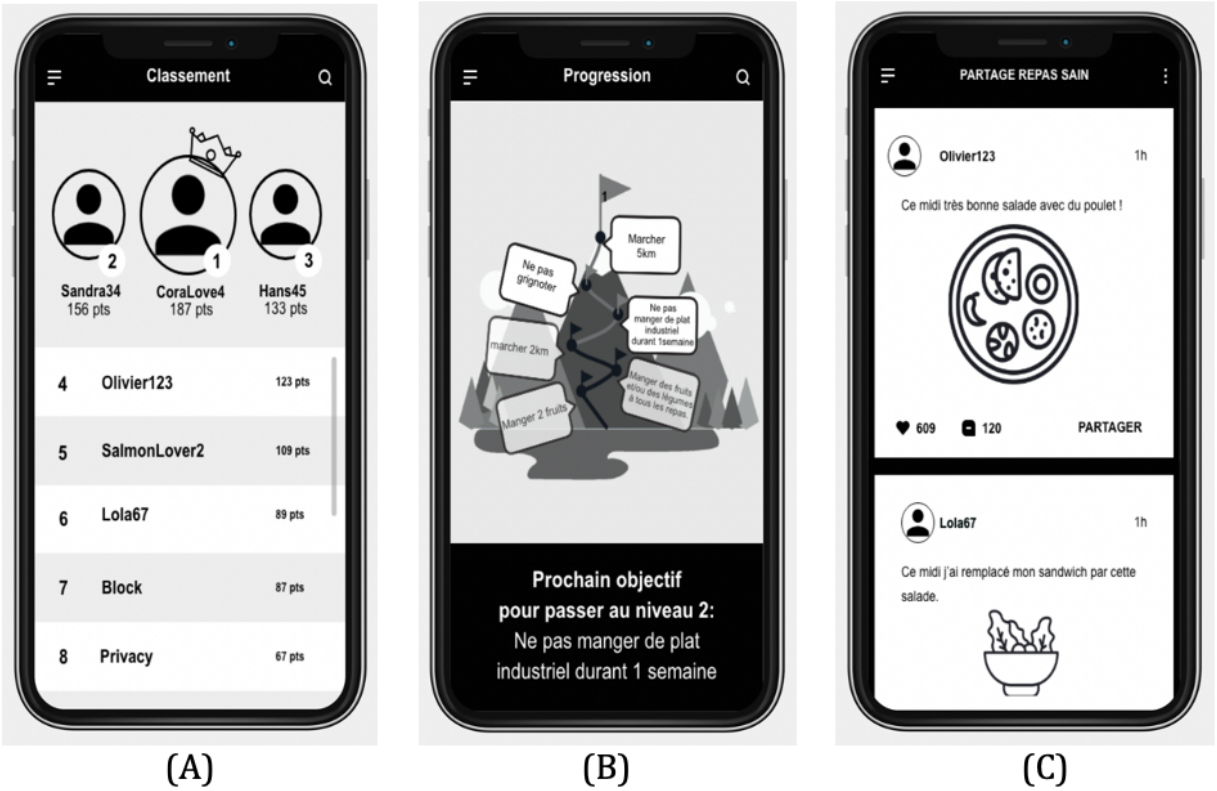
This scale was chosen because it has a factorial structure identical to that of the full version of the Big Five Inventory scale in French [26]. Therefore, it has the advantage of effectively measuring personality with a small number of items. As our protocol contains several scales, we preferred to choose the shortest valid versions to avoid participant fatigue with an excessively long questionnaire.

Gamer Profile

To identify participants' gamer profiles, we chose the Hexad Scale, created and validated by Tondello [18]. The internal scale reliability is good with Cronbach alpha coefficient for each dimension ranging from .70 to .89 [18]. This scale consists of 24 items, 4 per dimension. Users must rate how well each article describes them on a 7-point Likert scale. For example, there are items such as “I like competitions, where a prize can be won” or “Interacting with others is important to me.” Items are presented in a randomized manner, and the score is calculated by adding the scores for each dimension.

XSL•FO
RenderX

Perception of Social Norm



For the perception of social norm, we chose two items concerning this dimension of the Theory of Planned Behavior questionnaire of Ajzen [20]. We adapted the items to the context of our mobile app, which is to eat healthier and do more physical activity. Thus, the two items are as follows: "Most people who are important to me approve of the fact that I eat healthier and do more physical activity" and "Most people like me eat healthily and do physical activity." Participants were asked to respond to these statements on a 7-point scale ranging from "agree" to "disagree." The calculation was done by adding up the scores, with a high score indicating a heightened social norm perception.

Choice of Functionalities

Presentation of the Functionalities

From the literature, we identified 17 functionalities commonly proposed in behavior change apps. We then created a prototype for each of these functionalities. All functionalities and their definition are presented in Multimedia Appendix 1. We chose a visual design as neutral as possible for the prototypes (ie, in black and white with no images, only icons). This aims to minimize the bias due to design preference (ie, Figure 1). The 17 prototype screenshots were presented randomly to the participants to avoid a primacy or recency effect. During the study, participants discovered every functionality, one by one, by its representation in an image and accompanied by a short description. Then, they chose the 5 functionalities they considered to be the most motivating to stay fit.

Figure 1. Example of screenshots of the prototype app, including the (A) functionality competition, (B) functionality level and progression, and (C) functionality social network.

Explanation of Choice

For each functionality selected, participants were asked to indicate how much that functionality would motivate them to adopt healthier behavior on a scale of 0 to 100. Then, they were asked why they chose these functionalities. Excluded functionalities will default to a score of 0.

Analysis

Overview

We will exclude incomplete questionnaires and analyze only questionnaires that have been completed entirely.

Demographic characteristics of all participants will be presented using descriptive statistics (mean, standard deviations, or frequencies and range) in a table. A table will also provide responses about their use of mobile apps for health.

Quantitative Data

Primary Outcome

We will perform logistic regression with the functionalities as dependent variables and with scores of the 3 profile scales as predictors. This analysis will allow us to understand the effect of the participants' scores on each of the 3 scales (Big Five Inventory-10 scale in French, Hexad Scale, and perception of the social norm) on the 5 selected functionalities. By performing

XSL•FO
RenderX

a logistic regression for each feature, it will be possible to determine whether the scores on the different scales predict the selection of the functionality.

In addition, we will perform a logistic ordinal regression with the motivation score of the functionalities chosen as dependent variables and with scores of the 3 profile scales as predictors. By performing this regression for each functionality motivation score, it will be possible to determine whether the scores on the different scales predict the functionality score.

Secondary Outcome

To test whether there is a difference in functionality selection by age or gender, we will run logistic regressions with the choice of the functionality as the dependent variable and age or gender as the independent variables. In addition, we will perform an ordinal regression with the motivation score of the functionalities as the dependent variable and age or gender as the independent variable. There will be one regression per feature.

To test whether participants indicated that they preferred functionalities that are the same as the ones already used in their current mHealth app, we will run simple regressions with the feature they already use as the independent variable and whether this feature was chosen as the dependent variable. There will be one regression per feature.

We will use the Bonferroni correction for all our regressions to avoid a type 1 error.

Qualitative Data

Qualitative analysis of the free text for the question regarding the explanation of the participants' choice was performed, and common themes extracted. Response categories will be defined when reading the responses.

Results

Recruitment and testing were conducted during July 2021. The deadline for the completion of the web-based questionnaire by participants was end of December 2021. We began analyzing the responses in January 2022, and the publication of results is expected at the end of 2022.

Discussion

Principal Findings

This study will define the preferences of functionalities of users with a specific profile (eg, what kind of functionalities are preferred by a user according to their personality). This protocol is important as its sample will enable to validate a model built on several previous studies and reviews. In turn, this will allow developers to build mobile apps that will be more efficient as adapted to each user. Thus, with this research, we will be able to better refine our conceptual framework, which will allow the mobile app designer to select features tailored to their users according to their profile and thus increase their involvement in the mHealth app.

The main interest of this research is that it gathers all the user profiles identified in the literature and all the functionalities generally implemented in mHealth. Indeed, we find studies allowing us to link personality and gamification elements [8,9,14], personality, gamer profile, and gamification elements [11], personality and sensitivity to persuasion strategies [10,27], or personality and need for cognition [28]. Moreover, these studies are not necessarily specific to the field of mobile apps for behavior change. Some studies are more focused on preferences related to video games [9,14,29] and others on the type of messages and feedback [19,30]. Therefore, our research allows to combine what has been done previously in different studies and to corroborate their findings for mHealth apps regarding user preferences according to their specific profile.

Limitations

Our study has some limitations. We designed it to be as neutral as possible to limit preferences linked to the design of one of the prototyped functionalities. However, it is still possible that participants may prefer a certain functionality because they found it more visually attractive. Our results are also possibly not generalizable to the whole population. Indeed, since recruitment was conducted at the university and on social networks, it is expected that most participants were students aged 18-25 years. Finally, as the questionnaire was in French language and only individuals living in the canton of Geneva and the surrounding area were included, it can only be generalized to this population (ie, French-speaking people of Switzerland and France).

Conclusion

It is important to help people adopt better health behaviors. Mobile apps are an interesting channel to support this effort because they integrate functionalities such as goal setting or self-monitoring that have been proven to foster behavior change. However, app efficiency can be improved by responding to user preferences according to their specific profiles. Our study will provide an additional evidence base to propose an accurate personalization conceptual framework for the development of future mHealth apps.

Acknowledgments

We thank all participants for their valuable contribution.

Abstract

Background: Anxiety is one of the most common psychiatric comorbidities in people with epilepsy and often involves fears specifically related to the condition, such as anxiety related to the fear of having another seizure. These epilepsy- or seizure-related fears have been reported as being more disabling than the seizures themselves and significantly impact quality of life. Although research has suggested that exposure therapy (ET) is helpful in decreasing anxiety in people with epilepsy, no research to our knowledge has been conducted on ET in people with epilepsy using virtual reality (VR). The use of novel technologies such as an immersive VR head-mounted display for ET in this population offers several benefits. Indeed, using VR can increase accessibility for people with epilepsy with transportation barriers (eg, those who live outside urban centers or who have a suspended driver's license owing to their condition), among other advantages. In the present research protocol, we describe the design of an innovative VR-ET program administered in the home that focuses on decreasing anxiety in people with epilepsy, specifically anxiety related to their epilepsy or seizures.

Objective: Our primary objective is to examine the feasibility of the study protocol and proposed treatment as well as identify suggestions for improvement when designing subsequent larger clinical trials. Our secondary objective is to evaluate whether VR-ET is effective in decreasing anxiety in a pilot study. We hypothesize that levels of anxiety in people with epilepsy will decrease from using VR-ET.

Methods: This mixed methods study comprises 3 phases. Phase 1 involves engaging with those with lived experience through a web-based questionnaire to validate assumptions about anxiety in people with epilepsy. Phase 2 involves filming videos using a 360° camera for the VR-ET intervention (likely consisting of 3 sets of scenes, each with 3 intensity levels) based on the epilepsy- and seizure-related fears most commonly reported in the phase 1 questionnaire. Finally, phase 3 involves evaluating the at-home VR-ET intervention and study methods using a series of validated scales, as well as semistructured interviews.

Results: This pilot study was funded in November 2021. Data collection for phase 1 was completed as of August 7, 2022, and had a final sample of 18 participants.

Conclusions: Our findings will add to the limited body of knowledge on anxiety in people with epilepsy and the use of VR in this population. We anticipate that the insights gained from this study will lay the foundation for a novel and accessible VR intervention for this underrecognized and undertreated comorbidity in people with epilepsy.

Introduction

Background

Anxiety is the most common psychiatric comorbidity in people with epilepsy, with approximately 28% of the population suffering from at least one anxiety disorder, although different studies have reported varying prevalence [1]. In addition to decreasing quality of life and self-efficacy, anxiety may limit independence in people with epilepsy, who are already facing restrictions or limitations owing to other consequences of their neurological condition, such as suspension of their driver's licenses [2]. People with epilepsy with comorbid anxiety also report more negative side effects from their antiseizure medications as well as poorer memory compared with those that do not have anxiety [2]. Moreover, anxiety may have a negative impact on seizure management; for example, individuals with idiopathic generalized epilepsy in particular have reported that sleep deprivation and stress are seizure triggers [3]. Yet, anxiety in people with epilepsy has received little research attention and is commonly not recognized nor treated [1,2].

Hingray et al [1] proposed 4 main types of anxiety disorders that are associated with epilepsy in adults: epileptic social phobia, seizure phobia, epileptic panic disorder, and anticipatory anxiety of epileptic seizures. The anxiety faced in people with epilepsy tends to stem from the uncertainty that is associated with the nature of the disorder. Moreover, people with epilepsy may fear places where they have previously experienced a seizure, as well as situations that could be physically dangerous should they have a seizure [1]. This anxiety can result in avoidance of situations that are crucial for independent daily living (such as taking public transit or a shower) [1]. In some cases, this anxiety may lead to obsessive behaviors and agoraphobia [1].

The underlying theoretical model of clinical anxiety implicates a series of cognitive and behavioral processes such as dysfunctional beliefs, classical conditioning, and operant conditioning [4]. In general, people with anxiety are characterized by two types of dysfunctional cognitions: (1) exaggerated estimates of the likelihood of negative consequences related to the feared condition and (2) exaggerated estimates of the severity of harm [5]. Over time, the fear becomes reinforced and may lead to conditioned behaviors in response to such stimuli [5]. To manage these manifestations of anxiety, individuals frequently adopt safety behaviors that reduce their feelings of fear in the short-term, such as avoiding the situation that leads to their anxiety [5]. Because of the short-term relief that they feel from these safety behaviors, individuals with anxiety often continue displaying these behaviors, which ultimately works to maintain or increase the anxiety associated with their feared situations [5]. These safety behaviors may impede everyday functioning and lead to a decreased quality of life as well as fewer opportunities for positive experiences, further impacting mood regulation [5-7]. For example, a safety behavior may include only leaving the house with trusted individuals [1,8]. However, it should be noted that in some cases, these behaviors may be warranted if they are required for seizure safety as indicated by a neurologist (ie, not considered safety behaviors fueled by anxiety) [1].

Exposure therapy (ET) is an evidence-based technique [9,10] that is helpful in facilitating the management of dysfunctional anxiety associated with a specific or generalized stimulus and associated safety behaviors [5]. Graded ET involves repeatedly exposing people to realistic situations that trigger their anxiety, often in a hierarchical manner [5]. ET targets feared stimuli that can be clustered in different categories. The categories may include situations that involve animals or specific human populations (such as spiders, people with HIV, and clowns), objects or specific spaces (eg, toilets, knives, and certain numbers), specific situations (such as driving, darkness, and feeling uncertain), thoughts and beliefs (eg, unwanted sexual thoughts, memories of traumatic events, and premonitions of untimely accidents), or interoceptive and physiological stimuli (eg, racing heart, feeling out of breath, and a skin blemish) [5].

Ultimately, ET aims to help individuals understand that they are capable of being in the situations that provoke their anxiety without needing to implement their safety-seeking behaviors that perpetuate avoidance behaviors [5]. By training individuals to overcome the thought patterns that cause their debilitating anxiety, ET may also help to interrupt the cycle of anxiety by disconfirming the individual's misperceptions of their threats [5].

Virtual reality (VR) is a computer-simulated environment that allows users to feel as though they are in a different physical place, and it has been used as a tool to deliver ET for a variety of anxiety disorders. For example, VR-ET has previously been used to treat posttraumatic stress disorder, social anxiety disorder, and panic disorder [11]. VR has also been increasingly used as a nonpharmacological therapy for a variety of conditions, such as for people with dementia [12], including veterans with dementia [13]. Recent feasibility studies have also suggested that VR may be used to decrease anxiety in patients in the intensive care unit [14]. However, people with epilepsy have commonly been excluded from VR studies owing to the concern that using it may trigger seizures in people with photosensitive epilepsy. Although limited research is available on the use of VR in people with epilepsy, hesitations regarding the use of VR in this population have not been substantiated, and clinicians and researchers are increasingly considering VR for use in this population [15-17].

XSL•FO
RenderX

Some studies have highlighted that VR can complement imaginal and in vivo exposures [18,19], which are often otherwise difficult to implement. For instance, limitations of imaginal exposures include that individuals may try to avoid thinking about the scene that makes them anxious or they may struggle to imagine the scene accurately [5]. As VR elicits realistic sensory-motor experiences, using VR to deliver ET may be more successful than imaginal exposures for individuals who have difficulty mentally conjuring up distressing scenes or for individuals who try to avoid thinking about them [20,21]. A further limitation of in vivo exposure is treatment adherence; users commonly drop out before completing the recommended number of sessions. As VR-ET does not place individuals in the actual physical environment, participants have the opportunity to learn how to cope with the feared situation in a less threatening environment [22]. Thus, VR-ET has the potential to increase individuals' willingness to do in vivo exposures and decrease avoidance in the real physical environment because their preparedness makes the natural stimuli appear less overwhelming [23].

Research has suggested that including ET as a part of treatment for anxiety may also be helpful for people with epilepsy [24,25]. To our knowledge, no research has been conducted to date on ET in people with epilepsy using VR. In this population specifically, using an immersive VR head-mounted display (HMD) for ET has several advantages over traditional therapies. For example, research not specific to epilepsy has illustrated that VR-ET is especially useful when it is impractical to do exposures in person, such as during the COVID-19 pandemic [26]. Even outside of the pandemic, using VR to deliver this customizable therapy limits the need for travel, thereby removing a barrier for people with epilepsy because driver's licenses are typically suspended for 6 months to 1 year after a confirmed seizure. Moreover, using VR for ET offers the potential for significant time and cost savings compared with traditional ETs, in addition to increasing equitable access to mental health resources for those outside of urban centers [27].

Study Overview and Objectives

We are designing and evaluating a VR-ET program specifically for people with epilepsy and anxiety in a pilot clinical trial (Trial Registration: ClinicalTrials.gov NCT05296057) that will be divided into 3 phases. Phase 1 will involve engaging with those with lived experiences through a web-based questionnaire. The aim of phase 1 will be to validate assumptions about anxiety specifically related to epilepsy or seizures. Videos of scenes that are most commonly reported as generating anxiety in people with epilepsy will then be filmed using a 360° camera in phase 2. In phase 3, these VR exposure scenarios will be piloted by people with epilepsy in a clinical trial.

Table 1 represents a visual overview of the study methodology. This table was designed using the template provided by the Standard Protocol Items: Recommendations for Interventional Trials. It outlines the assessments at various time points: T0 (baseline), T1.1 (first day of the VR-ET intervention), T1.12 (the twelfth and last day of the VR-ET intervention, depending on each participants' progress that may be extended to T1.13 or T1.14), and T2 phases (1 week after the last exposure session).

The primary objective of this pilot clinical trial is to examine the feasibility of the study protocol, determine effect sizes, and identify suggestions for improvement when designing a subsequent larger clinical trial. The secondary objective is to evaluate whether VR-ET reduces epilepsy-related anxiety in people with epilepsy.

Methods

Ethics Approval

The study was approved by ClinicalTrials.gov (ID: NCT05296057) on March 25, 2022, and was fully approved by the York University Human Participants Review Committee on May 31, 2022 (certificate number: 2022-105). Amendments to Phases 2 and 3 were approved by the York University Human Participants Review Committee on September 15, 2022.

Data Collection and Storage

Any digital data, such as responses to web-based questionnaires, will be uploaded and saved to a secure server. Any hard copy documents will be stored in a locked cabinet. Both digital data and hard copy documents will be retained for 10 years after the end of the study and then securely destroyed.

Phase 1

Phase 1 Overview

Very little research currently exists on the specific epilepsy-related fears that people with epilepsy experience. As such, the first phase of this study will aim to validate assumptions about the most common epilepsy-related fears in this population so that the videos recorded in phase 2 are reflective of fears that are relevant for exposure in phase 3. To gather these data, phase 1 consists of a web-based survey delivered over the Qualtrics platform to 2 groups of participants: (1) people with epilepsy and (2) people that are affected by epilepsy but do not have epilepsy themselves (eg, through a family member, as a personal caregiver, as a health professional, or if they work with people who have epilepsy).

Phase 1 Recruitment

The investigators are using a diverse recruitment strategy. First, we are leveraging our connection with relevant community associations, namely Epilepsy Toronto. Epilepsy Toronto is an association that works to support people with epilepsy and their loved ones. Epilepsy Toronto has agreed to send an advertisement on their email listserv as well as post the study advertisement on their social media accounts. Second, a snowballing strategy will be used wherein participants will be prompted at the end of the questionnaire to share the link with others in their network. Phase 1 had a target sample size of 15 participants, including individuals with epilepsy and individuals affected by epilepsy.

XSL•FO
RenderX

Phase 1 Eligibility

Individuals aged 18 years and older who have epilepsy or are affected by epilepsy (such as through a family member that has epilepsy) may participate in this study. Phase 1 does not have any exclusion criteria.

Phase 1 Consent

The phase 1 informed consent form appears as the first page of the Qualtrics questionnaire and requires a digital signature. The Qualtrics questionnaire is configured such that participants cannot progress to the questionnaire without first providing explicit consent.

Phase 1 Protocol

Both groups of participants are asked to list up to 5 scenes (ie, locations, situations, or environments) that generate epilepsy-related anxiety in people with epilepsy, based on their personal experience. Participants are then asked to describe the scene that causes the greatest amount of anxiety in more detail. If the participant chooses, they may describe other scenes that they listed in more detail as well.

The questions included in the phase 1 questionnaire were selected and phrased so that they guide the filming of the 360° videos in phase 2 to resemble the anxiety provoking scenes as realistically as possible (Textbox 1). Analysis of phase 1 responses may identify ways in which the phrasing of questions may be improved in a later study to increase the realism of the exposures and thus the efficacy of the intervention.

XSL•FO
RenderX

Textbox 1. Overview of the questions asked in the phase 1 questionnaire (version completed by individuals with epilepsy). Individuals affected by people with epilepsy completed a version with alternate wording appropriate to their perspective.

1. Demographics:
   - A. Year of birth
   - B. Sex at birth
   - C. Describe the type of epilepsy or seizures you have and the symptoms that you experience during a seizure. *The intention of asking this question is to determine if the symptoms that the person with epilepsy experiences during a seizure (such as losing consciousness, muscle control, etc) influences their anxiety.*
2. Scenes:
   - A. List up to 5 scenes (such as situations, locations, or environments) where you feel anxiety related to your epilepsy or seizures. Next to the open-ended spaces to list each scene, participants are asked to rank their avoidance behavior from the following options:
     - Avoid completely
     - Often avoid
     - Sometimes avoid
     - Do not avoid (but still feel anxious)
   - B. To ensure that the 360° videos, which will be recorded in phase 2, are realistic and resemble the scenes from the person with epilepsy's point of view as closely as possible, participants are asked to provide detail about the scene that causes the greatest amount of anxiety, as if they were designing a scene for a movie from their perspective. Participants are prompted to do so by asking:
     - What do you see, hear, and feel?
     - What are you and others doing in this scene?
     - What in particular about this scene makes you anxious?
     - What changes to this scene would (1) increase and (2) decrease your anxiety? *Since ET often involves exposing people to their fears in a hierarchical manner, the VR-ET program will involve exposing participants to levels of the scenes reported in phase 1. Although subject to change based on phase 1 results, exposures will have 3 levels. This question about how changes to the scene may increase or decrease anxiety will help determine the different films that should be recorded to represent the fear.*
   - C. Participants are given the option of describing additional scenes.
   - D. Closed-ended questions: Participants are provided with a series of scenes developed based on the researchers' knowledge of epilepsy or seizure-related anxiety, as well as evidence from the literature [1,25] and asked to rate how likely these scenes would generate epilepsy- or seizure-related anxiety. The rating options are as follows: strongly agree, somewhat agree, somewhat disagree, strongly disagree, and prefer not to say. The specific scenes are listed below. Ratings on these scenes will also help to inform phase 2 recordings.
     - On a subway platform
     - On a subway train
     - On a bus
     - On stairs or elevated platforms
     - In a washroom or other place with hard surfaces
     - At a shopping center
     - Completely alone
     - With a few people that I know (but not well)
     - With a few people that I have a close relationship with
     - At a large social gathering or party where I only know a few people
     - At a large social gathering or party where I know some or all people
     - Surrounded by complete strangers in a public setting
     - Going for a walk outside
     - Exercising with gym equipment
   - E. Is there anything else you'd like to share about your epilepsy- or seizure-related anxiety?

XSL•FO
RenderX

Phase 1 Data Analysis

Sections 2A-2C and 2E of the phase 1 questionnaire (Textbox 1) will be coded by 2 researchers and then analyzed using the constant comparison method. The purpose of this analysis will be to determine which scenes were most commonly reported in the open-ended questions and the attributes that the virtual environment will reflect when they are recorded in phase 2. Section 2D of the phase 1 questionnaire (Textbox 1) will be analyzed using descriptive statistics, including calculating the frequencies of each discrete variable.

Phase 2

Phase 2 Protocol

Phase 2 will involve the development of the minimal viable product VR intervention. Although the design of the exposure hierarchies may be subject to change based on results from phase 1, we aim to record 3 sets of scenes in phase 2. Each set will have 3 scenes of different intensity levels that are designed to generate increasing amounts of anxiety (Figure 1). The scenes will be recorded using a 360° camera. Using 360° video is a cost-effective way to design photorealistic virtual environments with potential to create an increased sense of presence during exposure sessions when compared with computer-generated graphics [28,29]. An example of a scene that was recorded with a 360° camera can be seen [30] (click and drag on the video to scroll in 360°).

Participants will then be exposed to the 3 scenes of the set that most closely resemble their own epilepsy-related fears in phase 3 using the VR HMD. In summary, it is expected that phase 2 will involve filming nine 360° videos (3 sets × 3 scenes each). When filming these videos, we will ensure to the best of our abilities that any possible sensory triggers for people with epilepsy, such as common visual or auditory triggers, will not be included in the videos.

Phase 2 will not involve any data analysis.

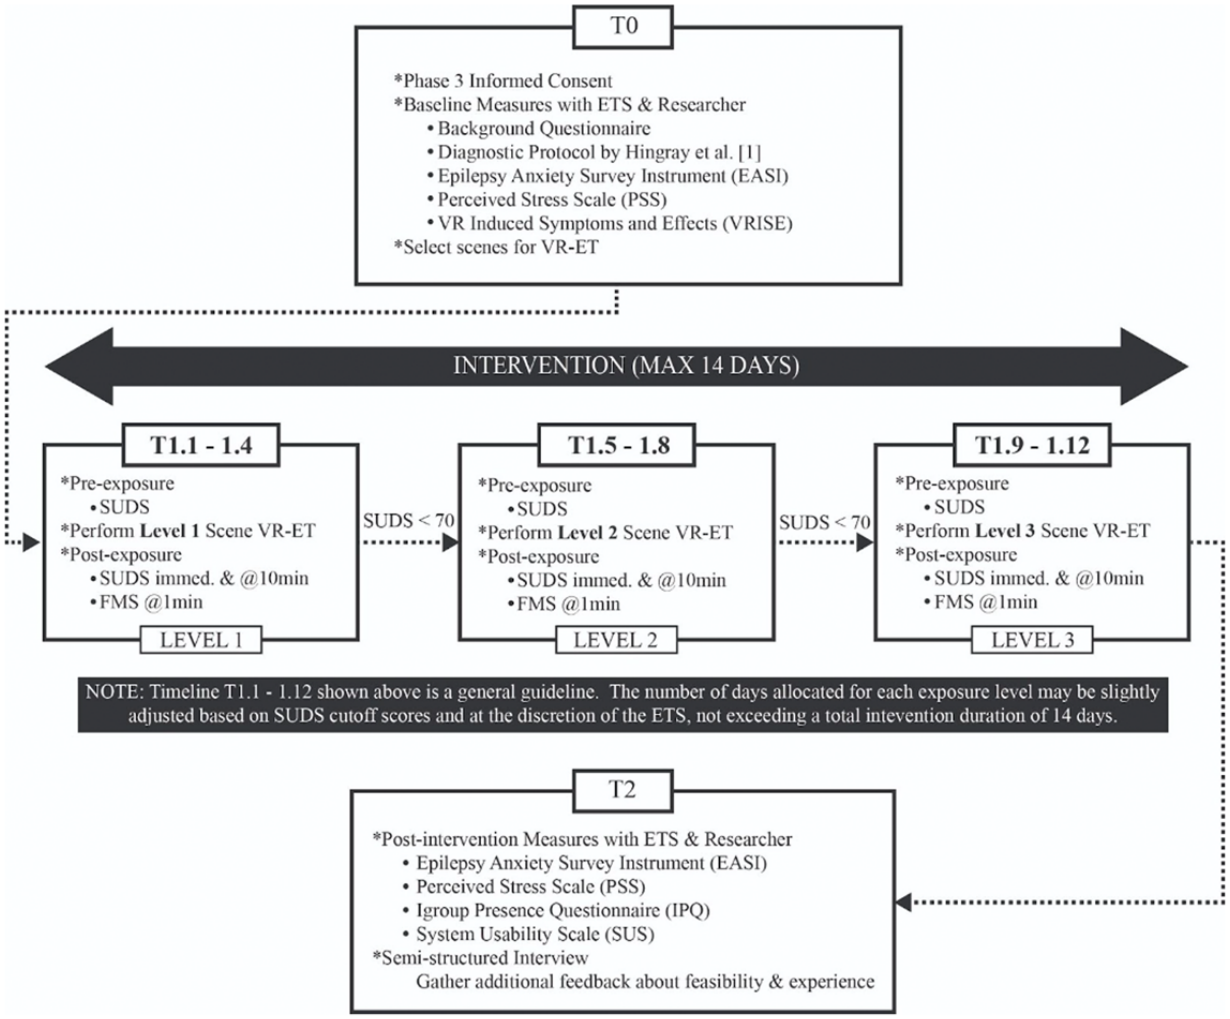
Figure 1. Examples of virtual reality (VR) scenes that may be shown during the VR exposure therapy. Top: Toronto subway station with a few people; equirectangular frame from a 360° VR film. Bottom: A subway that has arrived at a Toronto station with no people around; 360° VR snapshot.

Phase 2 Recruitment

Phase 2 does not include any participants and only involves members of the research team. Specifically, the research team will record the 360° videos, and those who sign release forms will be actors in the videos.

The researchers will ensure that while recording the videos, any bystanders who happen to be present at the scene are at least 2 m away from the lens of the VR 360° camera. At a distance of 2 m, the resolution of a 360° video is typically too low for faces to be identifiable, and so the privacy of bystanders will be maintained. Only members of the research team involved in the recordings who have signed release forms will be within 2 m of the 360° camera, as appropriate for the scene. Researchers who will be interacting with participants face to face in phase 3 (over a video call or in person) will not be included as actors in the videos.

Phase 3



Phase 3 Overview

Participants in phase 3 will undergo the VR-ET intervention program, which will take place over approximately 2 weeks (Figure 2). Before beginning the program, participants will have an interview with an ET specialist (ETS) where they will discuss which set of scenes recorded in phase 2 fits best with their greatest anxieties. Participants will also respond to several questionnaires and assessments. Each participant will begin with the lowest exposure level (in other words, the scene that generates the least amount of anxiety) and gradually work their way up to the highest exposure level (which is the scene that generates the greatest amount of anxiety). Ideally, each exposure

XSL•FO
RenderX

level will be performed every day for approximately 4 days, after which the participant will move onto the next level. Each day that they complete an exposure, participants will provide a score on the Subjective Units of Distress Scale (SUDS) at 3 specific time points. To help determine the efficacy of VR-ET, participants will have a second interview and repeat certain assessments 7 days after completing the ET program. It is hypothesized that VR-ET will help participants to habituate to their fears and ultimately lead to decreased anxiety.

Figure 2. Overview of the schedule for phase 3. ETS: exposure therapy specialist; FMS: Fast Motion Sickness Scale; SUDS: Subjective Units of Distress Scale; VR-ET: virtual reality exposure therapy.

Phase 3 Recruitment

Phase 3 will use the same recruitment methods as phase 1, including advertising through Epilepsy Toronto and using a snowball sampling strategy. In addition, phase 1 participants will be given the opportunity at the end of the questionnaire to enter their email address if they wish to receive more information about participating in phase 3.

Our target sample size for phase 3 is 5 people with epilepsy (people that do not have epilepsy themselves will not be included in phase 3). A sample size of n=5 was determined to be appropriate as this pilot study is evaluating feasibility of VR-ET for this population without aiming to determine clinical efficacy. In addition, sample size calculations are not necessary for feasibility studies according to the Consolidated Standards of Reporting Trials guidelines [31].

Phase 3 Consent and Eligibility

Overview

Participants will answer an eligibility screening after providing digital explicit consent through the phase 3 informed consent form (delivered over the Qualtrics platform). The eligibility screening will be completed over a telephone or video call with a member of the research team to help create rapport.

Even if the participant does not meet any of the exclusion criteria, they may be excluded from the study at any point. For example, if the research team is concerned that the treatment may have more negative consequences than positive for any reason, the principal investigator will consult with the ETS or make an executive decision to withdraw the participant from the study. However, information collected up until withdrawal may be (anonymously and in aggregate) included in the study

XSL•FO
RenderX

analysis and findings. Participants are made aware of this in the phase 3 informed consent form.

Phase 3 Inclusions

Individuals with diagnosed epilepsy aged 18-65 years with self-reported mild or moderate epilepsy-related anxiety may participate in this study.

Phase 3 Exclusions

ET works by increasing anxiety in the short-term for the purpose of decreasing anxiety in the long-term. Because it is expected that participants' anxiety will rise during the ET sessions, anyone who was told by a neurologist or personally believes that stress has provoked their seizures in the past will be excluded from phase 3. Anyone with a self-reported diagnosis of panic disorder or self-reported severe epilepsy-related anxiety will also be excluded from this pilot study. However, should VR-ET for people with epilepsy become a standard treatment, people whose seizures are triggered by stress should decide with their medical team if the benefits of this treatment outweigh the risks. Therefore, people with epilepsy should consider whether a long-term decrease in stress from VR-ET (and a consequent decrease in seizures triggered by stress) may be worth the short-term increase in stress and the accompanying risk of seizures.

Those who have been told by a neurologist that they have photosensitivity or that they have had photoparoxysmal responses during an electroencephalogram will also be excluded from phase 3 [15]. Excluding people with photosensitivity from the study is not expected to significantly impact the sample size because only approximately 3% to 5% of people with epilepsy have photosensitive seizures [32]. However, even individuals who were never told by a neurologist that they have had photosensitive seizures but believe that photosensitivity may contribute to their seizures will also be excluded from phase 3 [15]. Similarly, individuals who previously experienced seizures after being in a VR environment will also be excluded from this study.

As depression and anxiety are common in people with epilepsy [2], many people that are interested in participating in the study may be taking psychotropic medications, such as antidepressants. Because antidepressants may take up to 12 weeks to show their full effects, it would be unclear whether improvements in anxiety from baseline are due to a response to medication or VR-ET [33]. Similarly, drugs such as benzodiazepines, which are used to treat seizures, may act to suppress the anxiety felt by people with epilepsy during VR-ET [34]. Therefore, to better evaluate the impact of VR-ET alone, people who began taking antidepressants, benzodiazepines, or medical marijuana within 12 weeks of phase 3 will be excluded.

Although individuals will not be excluded from the study if they have been taking benzodiazepines for longer than 12 weeks before starting phase 3, they will be asked to avoid taking them before the exposure session (only if possible and if it does not interrupt their antiseizure medication schedule). This is because benzodiazepines have immediate effects and may therefore artificially lower participants' SUDS scores [35]. A complicating factor in this regard is that some people with epilepsy are prescribed drugs such as benzodiazepines as a rescue medication and may therefore use them to stop or prevent seizures [34,36]. In clinical practice, it is possible that the patient may take a benzodiazepine before, during, or after performing an exposure solely out of fear that they will have a seizure (and not necessarily because they are actually about to have a seizure). In this case, the patient would be actively avoiding the anxiety that is associated with the exposure. By using avoidance, the exposure's usefulness is nullified because the patient is shielded from feelings of fear. They also momentarily lose the opportunity to learn that they are capable of handling these feelings of anxiety.

Other phase 3 exclusion criteria include individuals who have tonic-clonic seizures more than once a month, individuals who have functional seizures, individuals who cannot speak or understand English, individuals with open wounds on their face, and individuals with cervical conditions or injuries that would make it unsafe for them to use an HMD.

We will not be excluding individuals with memory deficits, as memory issues are common in people with epilepsy [37]. It is not a concern that memory difficulties will prevent participants from using the VR device properly as they will always be on a video call with a member of the research team who can guide the participant in using the VR headset as necessary.

Phase 3 Protocol

Baseline (T0)

Baseline Interview

Before beginning the VR-ET intervention, participants will have a one-on-one interview with an ETS over a telephone or video call. In this interview, the ETS will explain the 3 sets of scenes that were recorded in phase 2. Then, through discussion, the ETS and participant will determine which exposure set fits best with their individual epilepsy-related fears.

After choosing the appropriate exposure set, the ETS and participant will discuss the most appropriate order in which the 3 scenes associated with the set should be delivered during the intervention. As ET is typically delivered in a hierarchical manner, participants will be exposed to the scenes in the order of least anxiety provoking to most anxiety provoking. The order of exposure scene delivery will be individualized for each participant based on their unique experiences and fears. For example, the exposure set that fits best with 2 participants (hereinafter referred to as participants A and B) may be a shopping mall with its associated social aspects. In this case, the 3 levels may be scenes of a shopping mall with crowds of different sizes (eg, scenes with 2, 10, and 30 people). Participant A may have a fear of not being around many people in a public setting, such as a shopping mall, because it could mean that less help would be available in case they were to get a seizure. Therefore, participant A would first be exposed to the mall scene with 30 people, then 10 people, and then finally 2 people. In contrast, participant B may have a fear of being around many people in a public setting because they worry that having a seizure is embarrassing and would prefer to be surrounded by fewer people if they were to have a seizure [1]. Thus, the ETS would decide with participant B that they should first be exposed

XSL•FO
RenderX

to the mall scene with 2 people, then 10 people, and finally 30 people. In summary, opportunities for tailoring the therapy will be built into the intervention through the (1) selection of scenario (location or theme), (2) selection of scenes (based on specific fears within a location such as the number of people in the scene), and (3) ordering of the scenes.

The aim of ET is to expose individuals to their fears until they habituate to the anxiety and learn to predict the outcome of their feared event as less anxiety provoking than they anticipated. Therefore, it is expected that participants may experience anxiety in anticipation of the exposure, during the exposure, and for a short period after completing the exposure. Although ET typically involves letting anxiety subside without instituting coping mechanisms, special considerations must be taken when working with the epilepsy population. Specifically, stress is a commonly self-reported seizure trigger for some people with epilepsy [38]. Although people with epilepsy for whom stress is a known or suspected seizure trigger will be excluded from phase 3, there is still a risk that stress may provoke a seizure in participants. To help prevent this, a number of protocols will be set in place (Textbox 2).

Textbox 2. Protocols put in place in case participants become too anxious before, during, or soon after the exposure sessions.

Coping mechanisms

- Before the baseline interview, participants will be sent a document that provides anxiety coping mechanisms, namely a mindfulness strategy, a self-compassion strategy, and a meditative technique. Participants will be encouraged to practice these coping mechanisms before the interview as they will then review them with the exposure therapy specialist.
- Before each exposure, the researcher will remind participants that, if they feel too overwhelmed during the exposure, they should remove the virtual reality head-mounted display even if they have not completed the full exposure and use the coping mechanisms that they prepared with the exposure therapy specialist. (If the participant stops the exposure early and uses a coping mechanism, the researcher will make a note of this. Postsession Subjective Units of Distress Scale (SUDS) scores will be recorded regardless.)
- If the participant scores >70 on any of the SUDS tests after completing the exposure, whether they ended the exposure early or not, they will be instructed by the research member on the video call to use the coping mechanisms. (The remaining SUDS scores will still be recorded.)

Additional strategies

- If the participant's anticipatory anxiety SUDS score (ie, the SUDS score that the participant records before performing the exposure) is >70 on the first day of beginning a new exposure level (eg, level 2), participants will still be encouraged to attempt the new level if their 10-minute postexposure SUDS score the previous day for the lower level (level 1) was <70.
- Even though we are excluding individuals who experience panic attacks, there is a risk that participants may panic before, during, or after the exposure. Therefore, members of the research team will be trained by a clinical neuropsychologist on how to identify when someone is having a panic attack and reach out to an on-call health professional.

Assessments

At baseline, the participant will also complete several assessments (Table 1 and Textbox 3), specifically the background questionnaire (Textbox 4); proposed diagnostic protocol for epilepsy-specific anxiety disorders [1]; Epilepsy Anxiety Survey Instrument (EASI); Perceived Stress Scale (PSS); and Virtual Reality Induced Symptoms and Effects (VRISE) assessment.

XSL•FO
RenderX

Textbox 3. Assessments at T0.

Background questionnaire

- This questionnaire was created by the authors of this paper to be conducted at the baseline interview (Textbox 4). Its main purpose is to collect phase 3 participants' demographic information and information about their history with anxiety and epilepsy.

Epilepsy Anxiety Survey Instrument (EASI) [39]

- The EASI is validated for assessing epilepsy-related anxiety features and severity. Note that by using the EASI, we are simultaneously using the brief Epilepsy Anxiety Survey Instrument (brEASI) [39]. The brEASI is a validated screening tool for anxiety disorders in people with epilepsy and is made up of 8 items that are already asked in the EASI. The brEASI is based on the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders [40].

Perceived Stress Scale

- The Perceived Stress Scale assesses how an individual perceives their own levels of stress.

Proposed diagnostic protocol for epilepsy-specific anxiety disorders [1]

- Hingray et al [1] suggested a diagnostic enquiry for 4 proposed anxiety disorders specific to epilepsy: anticipatory seizure anxiety, seizure phobia, epileptic social phobia, and epileptic panic disorder. They also suggested an assessment for symptom severity of each of these disorders and an evaluation of avoidance behaviors.
    - Note: On the basis of responses to the assessment by Hingray et al [1], individuals who appear to have epileptic panic disorder according to a clinical neuropsychologist will be excluded from the study.

Virtual Reality Induced Symptoms and Effects (VRISE) assessment [41]

- The VRISE assessment is one of the 4 domains included in the Virtual Reality Neuroscience Questionnaire and evaluates the intensity of motion sickness. The 3 other domains included in the Virtual Reality Neuroscience Questionnaire (user experience, game mechanics, and in-game assistance) are not relevant to our study. A lower score on the VRISE assessment suggests greater motion sickness.
    - Note: Participants who score less than 25 on the VRISE assessment after virtual reality training during T0 will be withdrawn from the study.

XSL•FO
RenderX

Textbox 4. Overview of the questions to be asked in the Background Questionnaire (T0).

1. Demographics
   - A. Contact information of the participant and their emergency contact
   - B. Year of birth
   - C. Sex assigned at birth and gender
   - D. Address that the participant will be doing the video calls from
2. Technology use
   - A. Previous experience with virtual reality (if any)
   - B. Comfort level on a scale of 1-10 with computers, smart phones, video call technology (specifically Zoom), virtual reality headsets
   - C. Low vision
   - D. Recent eye surgery
3. Epilepsy
   - A. Type(s) of seizures
   - B. Date of epilepsy diagnosis
   - C. Sensory triggers
   - D. Epilepsy safety protocol that should be set in place in case the participant were to have a seizure during the video call
4. Anxiety
   - A. Presence of anxiety as a side effect from any antiseizure medications currently taken
   - B. Anxiety disorder diagnoses. Participants will be asked to list any anxiety disorders that they were diagnosed with and the dates of diagnoses
   - C. History of experiencing preictal or postictal anxiety
   - D. Previous or current cognitive behavioral therapy (CBT). *If yes*:
     - i. Date the CBT program began
     - ii. Date the CBT program was completed (or the expected completion date)
     - iii. The helpfulness of the CBT program
     - iv. If the CBT program is focused on anxiety. *If yes*, if it involved targeting epilepsy-related anxiety
     - v. If the CBT included exposure therapy
   - E. If the participant has previously undergone or if they are currently undergoing any exposure therapy. *If yes*, they will be asked similar questions as 4D (i-iv)
5. Medical marijuana and medication use: (As this question and others in the study may be sensitive and yet important for evaluating the impact of the intervention, all outcome measures will be prefaced with an explanation of the importance of answering honestly and to the best of participants' abilities, as well as a reminder that participation is voluntary and that questions may be skipped without repercussion.)
   - Current antiseizure medication(s)
   - Current medical marijuana use
   - Current antidepressants or medications to treat anxiety

Equipment Setup

The only in-person aspect of T0 will be when a member of the research team visits the participant's residence to set up the VR equipment (Oculus Quest 2) and teaches them how to use and store the device. In teaching participants how to use the VR HMD, participants will practice using the device set to a neutral scene that is not expected to provoke anxiety in people with epilepsy according to phase 1 or existing literature. After using the VR HMD, participants will complete the VRISE questionnaire (Textbox 3) to record their baseline motion sickness tendencies. Note that anyone who scores below 25 on VRISE after using VR with a neutral scene will not be allowed to continue with the study.

At this time, the researcher will review the overall layout of the experiment and arrange a schedule with the participant for the exposure sessions, which will take place daily over one-on-one video calls. Ideally, the video calls (and therefore, exposure sessions) will take place at approximately the same time each day. Indeed, exposures should be performed at similar times

XSL•FO
RenderX

each day to limit inconsistent and extraneous reasons for increased baseline anxiety levels.

Exposure Session Protocol (T1)

Overview

The VR-ET intervention will consist of an exposure session every day for up to 14 days over a one-on-one video call with a researcher. During each exposure session, the participant will be seated in a chair at their home. Exposures will be performed for approximately 5 minutes, which is lower than the recommended 10-minute threshold for mitigating motion sickness [42]. Each day that the participant performs an exposure, they will complete assessments: SUDS 3 times; the Fast Motion Sickness Scale; and, although not a formal assessment, participants will be asked about the frequency in which they used coping mechanisms during the exposure session and in the 10-minute period afterward (Textbox 5).

Textbox 5. Assessments at T1.

Subjective Units of Distress Scale (SUDS)

- The purpose of collecting SUDS scores will be to quantitatively assess:
  1. How participants' anxiety in anticipation of performing the exposure compares to their anxiety immediately after completing the exposure
  2. If their anxiety decreases over time after completing an exposure session (ie, immediately after the exposure vs 10 minutes after the exposure)
  3. If their overall anxiety progressively decreases over the course of each exposure level
- Each day that they perform an exposure, the participant will record a SUDS score at 3 time points:
  A. Before putting on the head-mounted display and beginning the exposure. This measures the anxiety that the participant feels in anticipation of performing the exposure.
  B. Immediately after completing the exposure
  C. 10 minutes after completing the exposure

Fast Motion Sickness Scale [43]

- The purpose of collecting Fast Motion Sickness Scale scores will be to quantitatively measure motion sickness, specifically the general discomfort and nausea components, that participants may have experienced during the virtual reality exposure session. Participants will complete this assessment shortly after completing the first postexposure SUDS.

Frequency of coping mechanism use

- After completing the first postexposure SUDS test, participants will be asked how often, if at all, they used the coping mechanisms provided during the exposure (Textbox 2). After completing the second postexposure SUDS test, participants will be asked again about how often, if at all, they used the coping mechanisms since performing the exposure. The purpose of collecting this information is to understand whether differences in the use of coping mechanisms is related to the efficacy of the virtual reality exposure therapy intervention.

The purpose of having a researcher on a video call with the participant during exposure sessions is 3-fold. First, it provides a safety plan in case participants were to have a seizure during the exposure. This was put in place not because it is expected that participants might be triggered by the VR-ET but rather because people with epilepsy are prone to seizures, and therefore, it is important to have a seizure protocol in place. In the background questionnaire, the participant will provide details such as their emergency contact's information, if they would like the researcher to call their emergency contact or an ambulance if they have a seizure (some people with epilepsy prefer an ambulance not to be called), and if they would prefer for the researcher to keep their video on for safety or to turn it off for privacy. Second, if the participant experiences panic, the researcher will contact an on-call health professional. Third, through discussion with a clinical neuropsychologist, being in someone's presence (even virtually) while performing an exposure acts as a behavioral commitment from the individual who is receiving the treatment. Therefore, the participant will be less likely to display avoidance behaviors in relation to performing the exposure.

Exposure Session Timeline

Each participant will begin with the exposure scene that generates the least amount of anxiety and gradually work their way up to the scene that provokes the most anxiety. Each exposure scene will be performed daily for approximately 4 days, after which the participant will move onto the next level. However, if SUDS scores are >70 and at the discretion of the ETS, the current scene may be repeated until the participant is ready to progress. If a participant's SUDS score is too high to begin the first level, they will be exposed to a different set and its associated scenes, even if it does not fit with their own anxiety as closely.

As such, the overall schedule may vary for each participant based on their individual progress. The participant is expected to complete the intervention in 12 days but will be allowed up to 14 days if additional days are required to complete a scene. If a participant has a seizure at any point during the 12 to 14 days that they are receiving the intervention, the VR-ET will be discontinued as a precautionary measure. However, data provided up until that point may still be used in analyses and they will participate in T2.

XSL•FO
RenderX

Postintervention (T2)

One week after completing the VR-ET intervention, the participant will answer several assessments (Table 1 and Textbox 6), specifically EASI; PSS; Igroup Presence Questionnaire (IPQ) [44]; and the System Usability Scale (SUS) [45]. The proposed diagnostic protocol for epilepsy-specific anxiety disorders [1] will not be repeated at T2 and will instead inform some of the open-ended questions that will be asked in the semistructured exit interview that will take place over telephone or video conferencing (Textbox 6). The interview will be conducted either by an ETS or a member of the research team and will aim to gather additional feedback about the participants' experience. For example, participants will be asked to provide feedback on their experiences with the various devices, the subjective impact of the therapy, and what may be improved about the program and ET scenarios. Similar to T0, the only in-person aspect of T2 will take place when a member of the research team goes to the participant's residence to collect the VR equipment.

Textbox 6. Outcome measures at T2.

Repeat: Epilepsy Anxiety Survey Instrument and Perceived Stress Scale

Igroup Presence Questionnaire [44]

- The Igroup Presence Questionnaire assesses the subjective experience of being in a virtual environment when one is physically situated in another

System Usability Scale [45]

- The System Usability Scale assesses usability of the hardware and software

Semistructured Exit Interview

- To collect feedback (preferences and suggestions for improvement) on the:
  - Virtual reality system usability and training
  - Virtual reality exposure scenes
    - (ie, how realistically the videos simulated real-world scenarios that provoke anxiety for the participant)
  - Intervention impact on anxiety
  - Treatment delivery and format
  - General experience

Phase 3 Data Analysis

As both quantitative and qualitative data will be collected in phase 3, a mixed methods approach will be used. Quantitative statistical analyses will be performed using the MiniTAB statistical package [46] and SPSS software (version 27.0; IBM Corp) [47]. To investigate the normal data distributions of the dependent variables, ranges of skewness and kurtosis will be determined. The Kolmogorov-Smirnov and the Shapiro-Wilk tests will also be performed to evaluate statistical significance (mean, 95% CI) and normality of the distributions. In addition, Cronbach α will be performed for each self-report questionnaire's subscales. To explore sociodemographic features, frequencies, means, and standard deviations will be calculated.

To explore the effects of VR-ET, data collected at T0 and T2 will be compared. Clinically significant effects of the intervention will be investigated using the Jacobson-Truax method, based on the measures' clinical cut-offs (Table 2). Moreover, SUDS scores (before the exposure, immediately after the exposure, and 10 minutes after the exposure) collected every day of T1 will be compared with each other. Participants' SUDS scores that are recorded immediately after the exposure may be lower than their anticipatory anxiety levels, and if so, this may encourage the participant to do the next exposure. We will also consider our study to be successful if participants' SUDS scores remain high in the first postexposure SUDS test but decrease at the 10-minute postexposure SUDS test. However, the study may still be deemed successful with unchanging SUDS scores if participants have reduced anxiety and engage in fewer safety-seeking behaviors after completing VR-ET, as based on T2 findings.

Using thematic analysis, qualitative responses to assessments and interviews will be assessed by the research team and then reported as frequencies using the procedure outlined by Braun and Clarke [48]. The constant comparison method will be used to analyze the responses to the open-ended questions asked at T0 and T2 [49].

XSL•FO
RenderX

Table 2. Clinically significant scoring for the phase 3 assessments.

	Items	Range	Scores	Citation
Assessments				
Epilepsy Anxiety Survey Instrument	18	0-54	Higher scores suggest more severe anxiety	Scott et al [39]
Brief Epilepsy Anxiety Survey Instrument	8	0-24	≥7 suggests a likely anxiety disorder	Scott et al [39]
Perceived Stress Scale	14	0-56	Higher scores indicate greater perceived stress levels	Cohen et al [50]

Results

This study was funded by a joint Junior Faculty Funds and Minor Research Grant from the York University Faculty of Health in November 2021. Recruitment for phase 1 was completed as of August 7, 2022, and had a final sample of 18 participants. Results for phase 1 will be published once data collection and analysis have been completed; data collected as of August 7, 2022, may be requested by contacting the corresponding author.

We are leveraging discussions with experts in the field to design the first VR-ET program specific to people with epilepsy which have led to some minor amendments (Textbox 7) to our original protocol.

Textbox 7. Summary of study amendments to improve the study's methodology.

A. Phase 1 questionnaire
   i. *Updated* the wording and layout so that it would be faster, simpler, and more intuitive for participants to fill out.
   ii. *Added* relevant questions, such as the specific prompts for each scene.

B. Phase 1 informed consent form
   i. *Updated* the wording to remove any language that may have overstated the risks of filling out the questionnaire.
   ii. *Adapted* it to be deliverable over a web-based platform.

C. Phase 2 recordings
   i. *Updated* the guidelines so that common sensory triggers for seizures will be avoided. This was added after discussion with an epileptologist about the use of virtual reality in people with epilepsy.

D. Phase 3 assessments
   i. *Added*: Epilepsy Anxiety Survey Instrument, Igroup Presence Questionnaire; System Usability Scale.
   ii. *Removed*: Beck Anxiety Inventory; Generalized Anxiety Disorder-7 scale.

E. Honorarium
   i. *Added* for phases 1 and 3.

Discussion

Principal Findings

Although the primary anxiety treatments for people with epilepsy are cognitive behavioral therapy and pharmacological treatments, minimal research has investigated anxiety treatments specifically for this population [51,52]. Moreover, few studies have investigated the use of ET for treating anxiety in people with epilepsy [24,25]. No studies to our knowledge have delivered ET to people with epilepsy using VR, despite VR-ET's efficacy in other populations and the benefits that it could offer to people with epilepsy [11].

The main amendments made to the protocol included changes to the phase 3 anxiety assessments, after consultation with a clinical neuropsychologist who specializes in treating people with epilepsy. Indeed, when assessing anxiety in people with epilepsy, it is important to use validated assessments that do not inquire about physical manifestations of anxiety that may be confused with consequences of the neurological disorder. For example, the Beck Anxiety Inventory has been shown to be potentially less accurate in measuring anxiety in people with epilepsy because it contains items that reflect antiseizure medication side effects and symptoms of epilepsy, as opposed to symptoms of anxiety [39]. The Generalized Anxiety Disorder-7 scale was removed because it focuses on generalized anxiety disorder rather than anxiety in general or epilepsy-specific fears. Instead, the EASI was added.

The IPQ and SUS were also added to assess the feasibility of the intervention as well as provide validated feedback on participants' experiences with the technology in preparation for the subsequent larger clinical trials. For example, the IPQ will help assess participants' sense of presence in the virtual scene, which is important in VR-ET so that it resembles the real-life scenes that participants fear as closely as possible [18]. The IPQ will also be useful for determining if phase 2 was successful in

XSL•FO
RenderX

realistically capturing the scenes. The interview at T2 will expand on responses to the IPQ as participants will be asked to provide verbal feedback on how future studies could improve the realism of the VR-ET scenarios, as well as the sense of presence that they generate. Furthermore, the SUS will provide useful information for optimizing procedures for training participants on how to use the VR equipment. The SUS may also help to identify if there were greater difficulties for people with cognitive deficits and inform how we could design a system that is accessible for all potential individuals with epilepsy. To assess motion sickness tendencies and symptoms after the VR-ET sessions, the VRISE and Fast Motion Sickness Scale were also included.

Limitations

Pilot studies play a key role in the development or refinement of new interventions, assessments, and other study procedures, with the primary role of a pilot study being to examine the feasibility of a research endeavor [53]. Although the nature of a pilot study allows for a small sample size, we acknowledge that this is a limitation of both phases 1 and 3 and that, as a result, caution should be applied to the generalization of the findings. The sample sizes were determined based on resource constraints (funding and time) and are appropriate for a feasibility study that does not aim to assess clinical efficacy. To help account for the small sample size of phase 1, the baseline interview of phase 3 will act as an extension of phase 1 where we will gain more insight into the specific epilepsy- and seizure-related fears that people with epilepsy experience.

Another limitation to the generalizability of our findings is that phase 3 does not include a control group. Participants will be recruited to a known, albeit experimental, study and assessments will be conducted in an unblinded fashion. The choice to run an open-label pilot with no control group was intentional. Our primary goal is to report on the feasibility of recruitment, intervention design and implementation, as well as participant retention. Given the novelty of this initiative and our resources (funding and time), the research team agreed that this was the most appropriate way to systematically gather and incorporate user feedback before evaluating VR-ET on a larger scale. Future studies with larger sample sizes, a control group, and randomization will be necessary to evaluate clinical efficacy.

We acknowledge that it may not be feasible in clinical practice for therapists to have daily communication with their clients or patients. However, we are designing the intervention this way purposefully for the pilot study to maximize safety in case of a seizure or concerning psychological distress, such as a panic attack. In addition, as discussed with a clinical neuropsychologist, it will maximize the chances of therapeutic success if participants are in communication with someone, such as a therapist or researcher, while doing the exposures to help them form a behavioral commitment. Because this is a pilot study, it aligns more with the purpose of the research to maximize the chances of therapeutic success rather than to assess the feasibility of the proposed intervention within a professional setting. However, the ability to implement self-guided sessions in a controlled and safe virtual environment is an advantage of VR therapy. Therefore, future studies should investigate participants' adherence to VR-ET and its efficacy when they perform the exposures daily without a researcher or therapist present.

Another limitation is that while we ask participants to avoid taking a benzodiazepine before performing the exposure and after their exposure until their anxiety settles, we cannot enforce this request because benzodiazepines may be used to treat seizures [34]. As previously discussed, taking a benzodiazepine can limit the effectiveness of the ET. It may be worthwhile to conduct future clinical trials in a safe and well-monitored environment, such as a hospital epilepsy monitoring unit, where participants are restricted from taking a benzodiazepine as much as possible. In this scenario, the participants would be in a safe environment in case they were to have a seizure and potential confounding effects would be reduced.

In conclusion, we are proposing a novel VR-ET as a treatment specific to people with epilepsy and their unique fears relating to their condition. VR is an especially promising tool for ET broadly as it allows for tailored exposure and control over the visual and auditory stimuli. When considering people with epilepsy, VR-ET offers additional advantages for this population. For example, given that the therapy can be administered in the comfort of one's home, it increases accessibility for individuals with restricted independence and ability to travel. Overall, this study will contribute significantly to the fields of VR, ET, anxiety, and epilepsy and lay the groundwork for a more equitable therapy program for this population.

Acknowledgments

This study is being funded by a joint Junior Faculty Funds and Minor Research Grant by the Faculty of Health at York University.

Data Availability

Data sharing is not applicable to this study as no data sets were generated or analyzed. The data collection tools (eg, surveys) created for this study are available from the corresponding author on reasonable request.

Authors' Contributions

LA and HGG contributed to the conception of the study. All authors (HGG, LA, SL-F, DT, SP, and LRH) contributed to the design of the protocol. HGG wrote the first draft of the manuscript, and all authors edited and revised the final manuscript. The

Abstract

Background: Spinal metastases of lung cancer (SMLC) usually have a high degree of malignancy and require multimodality treatment. Patients with SMLC who experience clinical symptoms (eg, local pain, emerging or potential spinal instability, and progressive neurological dysfunction) require surgical treatment. However, there are discrepancies in the comparison of outcomes between surgical treatment and nonsurgical treatment.

Objective: This paper presents the protocol for a study that aims to compare the clinical outcomes of surgical treatment and nonsurgical treatment for SMLC, explore the prognostic factors of SMLC, and establish a survival prediction model based on these prognostic factors.

Methods: This is a prospective cohort study, with an anticipated sample size of 240 patients (120 patients in the surgical group and 120 patients in the nonsurgical group). We will collect baseline data, including demographic, clinical, and radiological information, as well as data from patient-reported questionnaires. Patients will be followed up at 3, 6, 12, and 24 months after treatment, and survival status will be assessed every 3 months. The primary outcome is the overall survival period. Prognostic factors associated with overall survival will be analyzed by univariate and multivariate Cox proportional hazards regression. Odds ratios with 95% CIs will be presented. Statistical significance is set at $P<.05$.

Results: This study has been approved by our institute's Medical Science Research Ethics Committee (IRB00006761-M2021085) after a careful audit of the design and content. Patient enrollment began in June 2022 at our hospital. Data collection is expected to be completed by early 2026, and the study results will be published by mid-2027.

Conclusions: In this study, we propose to set up a prospective cohort of patients with SMLC to investigate the outcomes between surgical treatment and nonsurgical treatment. We will explore the role of surgical treatment in SMLC and provide guidance to peer surgeons.

KEYWORDS

spinal metastasis of lung cancer; spinal metastases of lung cancer; lung cancer; surgery; overall survival; prediction model; protocol

Introduction

Background

The effective integration of therapeutic modalities into the treatment of metastatic lung cancer on the spine is a source of debate. Lung cancer is a moderate to high malignancy, and metastasis to the spine usually represents the end stage of the disease [1,2]. According to the scoring systems for spinal metastasis by Tomita et al [3] and Tokuhashi et al [4], patients with spinal metastases of lung cancer (SMLC) are expected to live less than 1 year. Thus, more conservative treatments have been given in the past. In recent years, advances in radiation therapy and systemic antitumor drugs, such as stereotactic body radiotherapy (SBRT), target therapies, and immunological therapies have demonstrated encouraging therapeutic outcomes and have largely expanded the survival time of patients with SMLC [5-11]. At the same time, surgical treatment has been widely accepted for some SMLC cases [12]. A comprehensive treatment, composed of antitumor drugs, radiotherapy, and surgery, has been the current state-of-the-art therapeutic modality for SMLC.

Generally, patients with SMLC experiencing the following symptoms are referred for surgery: severe and refractory local pain, emerging or potential spinal instability, and progressive neurological dysfunction [8,13-17]. After the surgery, adjuvant therapies, including radiotherapy and systemic drugs, are undertaken. Most researchers have stated that adjuvant radiotherapy should be completed around 6 weeks after the operation to spare time for physical recovery and avoid problems related to wound healing [18]; yet, this is difficult to do in a real-world setting [19]. Additionally, previous studies have described discrepancies in the efficacy of surgical treatment for patients with SMLC [20]. According to these works, the median survival time after surgery was reported to range from 2 to 14 months [21]. Because of limitations that included a retrospective study design, no control group, etc, the conclusions of related studies lack high-quality evidence.

Objective

In our study, a prospective, specific disease cohort of SMLC will be used to compare the effectiveness of surgical treatment and nonsurgical treatment. This study will provide useful information to explore the role of surgical treatment in comprehensive SMLC treatment and develop suitable treatment guidelines.

The primary aim of this study is to investigate and compare treatment outcomes in patients with SMLC. In addition, we also plan to analyze various prognostic factors of SMLC, such as treatment modalities, tumor subtypes, pre- and postoperative neurological function, and more.

Methods

Study Design

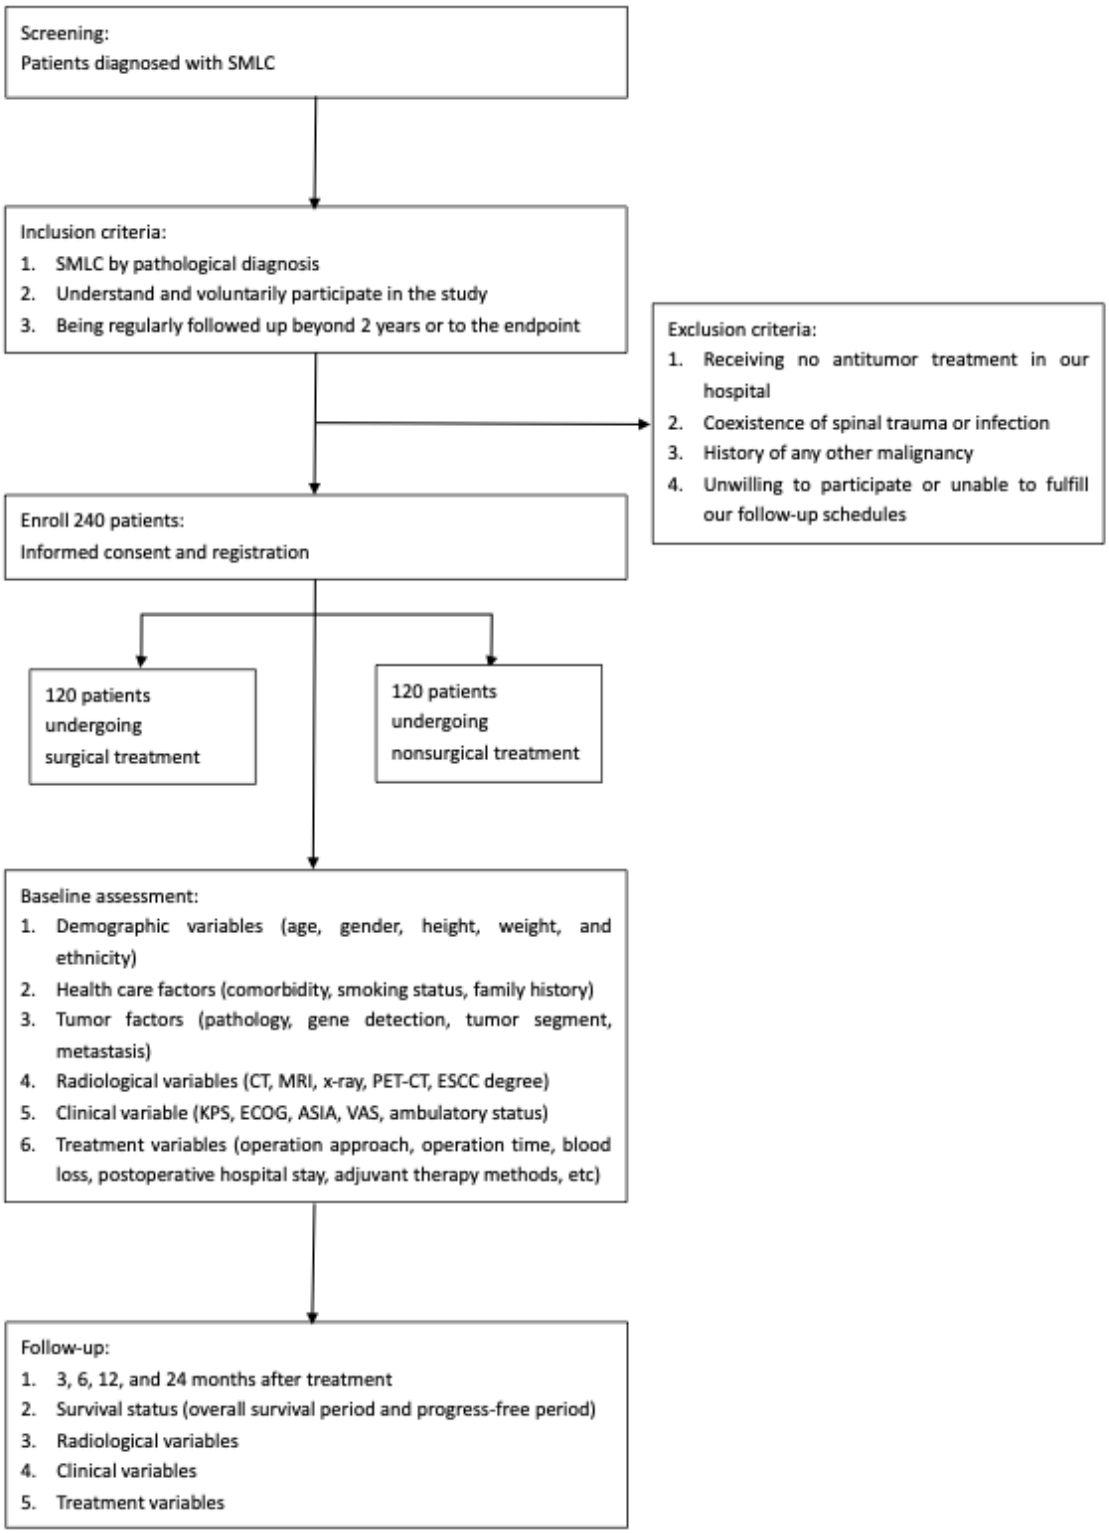
This study is a prospective cohort study. We will compare the treatment outcomes of surgical and nonsurgical methods for SMLC in a real-world clinical scenario. The study will enroll 240 patients (120 patients in the surgical group and 120 patients in the nonsurgical group) from June 1, 2022, to June 30, 2027. The patients will be visited postoperatively at 3, 6, 12, and 24 months. The study is due to be completed on June 30, 2029.

Sample Size and Study Timeline

In this study, we plan to compare the overall survival (OS) time between the two groups and explore its prognostic factors. The sample size calculation was based on the survival time and estimation of influencing factors. According to an unpublished retrospective study performed at our center and previous literature [20,21], the average OS time was 11 (SD 4) months in the surgical group and 9 (SD 3) months in the nonsurgical group. Assuming an overall Type 1 error (α) of .05 and Type II error (β) of .1, we need 66 patients in each group. Additionally, there are 12 predictive factors we plan to analyze in the prediction model. According to the sample size estimation method for multivariable regression models, 100 cases in each group are needed (the ratio of surgical to nonsurgical group is 1:1). Considering a final follow-up rate of 80%, a minimum of 120 patients will be required for each group. There were approximately 25 patients undergoing surgery per year at our center; therefore, we plan to enroll the patients over the next 5 years. Since more patients are treated nonsurgically than surgically, all nonsurgical patients treated during the first 5 years will be enrolled.

The study duration is estimated to be 7 years to ensure that all recruited patients are followed up for 2 years. Each visit's timeline and tasks are presented in Multimedia Appendix 1.

Patient Enrollment and Group Allocation



All patients with SMLC being treated at our center are potential candidates, and those who meet the inclusion and exclusion criteria will be eligible for enrollment in our study. Patients who receive surgical treatment along with postoperative systemic comprehensive treatment will be enrolled in the surgical group. Patients who receive only conservative treatment (eg, radiotherapy, chemotherapy, targeted molecular therapy, immunological therapy, etc) without surgical treatment will be enrolled in the nonsurgical group. All study procedures, as well as the participants' rights, responsibilities, benefits, and risks, will be communicated, and participants will sign an informed consent form. Figure 1 displays the study flowchart.

In order to participate, patients will need to meet certain eligibility criteria. The inclusion criteria are (1) a pathological diagnosis of SMLC, (2) understanding and voluntarily participating in the study, and (3) being regularly followed up beyond 2 years or to the endpoint. Exclusion criteria include:

XSL•FO
RenderX

(1) not receiving antitumor treatment at our hospital, (2) coexistence of spinal trauma or infection, (3) history of other malignancies, and (4) unwillingness to participate or inability to adhere to our follow-up schedule.

Figure 1. Study flowchart. ASIA: American Spinal Injury Association; CT: computed tomography; ECOG: Eastern Cooperative Oncology Group; ESCC: esophageal squamous cell carcinoma; KPS: Karnofsky Performance Scale; MRI: magnetic resonance imaging; PET-CT: positron emission tomography–computerized tomography; SMLC: spinal metastases of lung cancer; VAS: visual analogue scale.

Treatment

A surgical decision is made following the advice of our institutional multidisciplinary treatment team for spinal metastasis. There are 3 indications for surgery at our center: severe yet drug-resistant local pain, progressive neurological dysfunction, and emerging or latent spinal instability. Otherwise, patients are referred for nonsurgical treatment.

XSL•FO
RenderX

In the surgical group, patients are given surgical treatment, neurological rehabilitation, and adjuvant therapies (ie, SBRT and antitumor drugs). In this setting, we have established a synchronized workflow for surgery-based multimodality therapy instead of the conventional step-by-step schedule. A synchronized workflow means that neurological rehabilitation is incorporated and commenced right before the surgery and that SBRT and antitumor drugs are started early and simultaneously during the process of rehabilitation.

In the nonsurgical treatment group, patients are treated with adjuvant therapies exclusively, including radiotherapy, chemotherapy, targeted therapy, immunological therapy, etc. Considering the existence of various adjuvant modalities, this study will only enroll patients who receive both locoregional radiotherapy and antitumor drugs.

Outcomes

Primary Outcome

The primary outcome metric of the study is the OS period. OS is defined as the time after the start of any antitumor therapy for SMLC to death of any cause.

Secondary Outcomes

Secondary outcomes include the following:

1. The progress-free survival period, defined as the time after the start of antitumor therapies until disease progression.
2. Recovery of SMLC-related symptoms, defined as the relief of locoregional pain, which is measured by visual analogue scale (VAS) values, and the recovery of neurological status, which is assessed using the American Spinal Injury Association (ASIA) score. Immediate improvement in VAS and ASIA scores is assessed before discharge.
3. Recovery of self-care performance, assessed using the Karnofsky Performance Scale (KPS) score and the Eastern Cooperative Oncology Group (ECOG) performance score.
4. Quality of daily life, assessed by the Short Form 36 Health Survey Questionnaire.

Other outcomes for evaluation include complications in antitumor treatment. Surgical complications are rated according to the system proposed by Clavien et al [22], whereas toxicity of radiotherapy and antitumor drugs is graded using the National Cancer Institute's Common Toxicity Criteria for Adverse Events (version 5.0). The endpoint of the study is the death of the recruited patient. The primary outcome is assessed by the endpoint of the study, whereas secondary and other outcome metrics are assessed at each visit.

Exposure Measures

The exposure measures of interest include demographic variables, clinical data, and treatment-related factors. Demographic variables include age, gender, height, weight, and ethnicity. Clinical data are composed of health care factors (comorbidity, smoking status, family history of tumors); tumor factors (pathology, gene detection, tumor segments, and metastatic status); radiological variables (computerized tomography, magnetic resonance imaging, x-ray, positron emission tomography–computerized tomography, and degree of epidural spinal cord compression); and clinical variables, which include onset time, general status (KPS, ECOG score), neurological function (ASIA score), pain (VAS value), and ambulatory status. Treatment-related factors include operation approach, operation time, blood loss, postoperative hospital stay, adjuvant therapies, etc.

Data Management and Supervision

We will assign a specific investigation team to assess outcomes and process the data, and train the team in this regard. In addition, we will formulate some basic rules for the process of patient follow-up; outcomes assessment; and data entry, coding, and storage, namely double assessment, dual entry, and checks by independent investigators. Outcome assessors will be blinded to the patients' intervention allocation. Our institute's scientific research supervising team, which excludes all investigators in this study, will monitor the study process, data safety and authenticity, and occurrence of adverse events.

Statistical Analysis

Statistical analysis will be performed using SPSS for Windows (version 20; IBM Corp). The Lilliefors test will be used to examine whether the data are normally distributed. Data will be presented as percentages, mean (SD), or median (range) accordingly. The 1-tailed unpaired Student *t* test and Pearson χ^2 test (or the Fisher exact test) will be used to make comparisons between different groups. The OS and progress-free survival curves will be plotted using the Kaplan-Meier method, and a comparison of the two groups will be performed via the log-rank test. The influencing factors will be analyzed by univariate and multivariate Cox proportional hazards regression. Statistical significance is set at $P<.05$. The survival prediction model will be established by multivariate Cox regression models and the Kaplan-Meier survival curves. The predictive ability of the final model will be evaluated using the Harrell concordance index (C-index) and calibration curves.

Ethics Approval

This study, which will be conducted according to the Declaration of Helsinki, has been approved by the Medical Science Research Ethics Committee of the Peking University Third Hospital (IRB00006761-M2021085) after a careful audit of the design and content.

Informed Consent and Funding

We will fully inform the patients of the purpose and procedures of this study, as well as their obligations and potential costs and risks. An informed consent form has been drafted and will be signed voluntarily by each participant.

This study is a self-organized project and receives no financial support or funding from any commercial entity. Therefore, conduct of the study, data processing, and interpretation of the results will not be influenced by any commercial entity.

Results

Study design, ethical review, and research registration have been completed. Enrollment commenced in June 2022, and enrolled patients are being visited regularly. Patient enrollment

XSL•FO
RenderX

is expected to be completed by June 2027, and the study results will be submitted for publication in early 2029.

Discussion

Expected Findings

We anticipate that the findings of our cohort study will support the use of a surgical treatment strategy for patients with SMLC. Although we understand that a combination of different antitumor therapies, namely comprehensive treatment, is recommended for patients with SMLC, there is no consensus or established guideline on how to practice it. Our study aims to explore surgery-based comprehensive treatment for patients with SMLC. Through this study, we aim to validate our proposed synchronized schedule for a multimodality therapy and eventually hope to establish a survival prediction model.

Previous Studies

Fundamentally, the primary goals of surgery are to restore spinal stability, relieve pain, and decompress tumor mass squeezing of the spinal cord, if any. Yao et al [20] reviewed studies on spinal metastasis and found that surgery could significantly improve neurological function and quality of life, even for patients with advanced lung cancer. However, we have not yet gained firm evidence on the impact of surgery on patients' survival, though many papers have reported favorable postoperation outcomes. Truong et al [17] recruited patients with SMLC undergoing surgery and found that 14 (16%) out of 87 patients survived beyond 12 months. Chen et al [23] reported the median survival of their cohort to be 12 months; patients undergoing excisional surgery had a longer survival time than those with palliative surgery. Contrarily, in a systematic review by Armstrong et al [21], the authors reported unfavorable outcomes for surgical intervention, of which a shorter median OS was found in the surgical group compared to the nonsurgical group (7.5 months vs 8.5 months). This result was echoed in Amelot et al's [24] study. These authors concluded that survival of SMLC depends merely on genotype and neurological and personal status, and scarcely on surgical resection. In the past decade, the combination of separation surgery and high-dose hypofractionated SBRT has emerged as an effective option for spinal metastasis, including SMLC [18]. The core principle of this procedure is to circumferentially remove the tumor mass encasing the spinal cord and create a safe zone between the cord and the tumor (≥3mm) for the subsequent delivery of radiation treatment [9,25,26].

As our understanding of the molecular biology of lung cancer increases, many mutated targets are being identified, including the epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase, ROS1, BRAF V600E mutation, etc [6,7,27,28]. Targeted drugs can act directly on these specific mutations and diminish tumor cells. Dohzono et al [29] compared the median OS of patients with SMLC receiving or not receiving EGFR tyrosine kinase inhibitors and found the former group enjoyed a longer OS period (21.4 months vs 6.1 months). In recent years, the application of some immunotherapeutic drugs has proven to be effective [7]. The concept of immunotherapy is to introduce specific blockers to inhibit some immunological signaling paths that are related to the development and metastasis of tumors. Currently, anti-PD-1 and anti-PD-L1 antibodies have been recognized as the choice of care for some advanced lung cancers after the failure of first-line cytotoxic therapy [30]. Borghaei et al [28] found that the median OS period of PD-L1(+) patients who received specific targeted blockers was longer than that of PD-L1(–) patients (17.7 months vs 10.5 months). Furthermore, systematic use of bone-targeted agents (eg, bisphosphonates and denosumab) has significantly reduced devastating spinal-related events, such as paralysis and loss of self-care ability [31].

Strengths and Limitations

The main strength of our study is that it is the first research project to examine the feasibility and outcomes of synchronized adjuvant therapies after surgical intervention for SMLC in a prospective cohort and using a more scientific methodology. This methodological merit will strongly empower the justification for using positive yet invasive treatment modalities instead of conventional palliative care in patients with SMLC. Second, for the purpose of rapid recovery, we are starting rehabilitative intervention at an early stage after surgery. In addition, we recognize the importance of starting adjuvant therapies early after surgery, and this practice will be implemented and examined in our clinical trial.

There are some potential biases in this study that might compromise the reliability and accuracy of the results, but we have designed some solutions to reduce bias. First, though it is difficult to blind the intervention providers and patients, outcome assessors and data processors will be blinded. Second, during the follow-ups, we will encourage face-to-face interviews, but online interviews will also be accepted, considering the possible emergence of scenarios like a COVID-19 surge, in order to reduce the rate of dropout.

Conclusions

We present the protocol for a prospective cohort study of patients with SMLC. Through this study, we will explore the outcomes of surgery-based comprehensive treatment. In addition, we will also investigate prognostic factors of SMLC and provide references for peer surgeons.

Abstract

Background: The COVID-19 pandemic has disrupted the health care system, limiting health care resources such as the availability of health care professionals, patient monitoring, contact tracing, and continuous surveillance. As a result of this significant burden, digital tools have become an important asset in increasing the efficiency of patient care delivery. Digital tools can help support health care institutions by tracking transmission of the virus, aiding in the screening process, and providing telemedicine support. However, digital health tools face challenges associated with barriers to accessibility, efficiency, and privacy-related ethical issues.

Objective: This paper describes the study design of an open-label, noninterventional, crossover, randomized controlled trial aimed at assessing whether interactive voice response systems can screen for SARS-CoV-2 in patients as accurately as standard screening done by people. The study aims to assess the concordance and interrater reliability of symptom screening done by Amazon Alexa compared to manual screening done by research coordinators. The perceived level of comfort of patients when interacting with voice response systems and their personal experience will also be evaluated.

Methods: A total of 52 patients visiting the heart failure clinic at the Royal Victoria Hospital of the McGill University Health Center, in Montreal, Quebec, will be recruited. Patients will be randomly assigned to first be screened for symptoms of SARS-CoV-2 either digitally, by Amazon Alexa, or manually, by the research coordinator. Participants will subsequently be crossed over and screened either digitally or manually. The clinical setup includes an Amazon Echo Show, a tablet, and an uninterrupted power supply mounted on a mobile cart. The primary end point will be the interrater reliability on the accuracy of randomized screening data performed by Amazon Alexa versus research coordinators. The secondary end point will be the perceived level of comfort and app engagement of patients as assessed using 5-point Likert scales and binary mode responses.

XSL•FO
RenderX

Results: Data collection started in May 2021 and is expected to be completed in fall 2022. Data analysis is expected to be completed in early 2023.

Conclusions: The use of voice-based assistants could improve the provision of health services and reduce the burden on health care personnel. Demonstrating a high interrater reliability between Amazon Alexa and health care coordinators may serve future digital tools to streamline the screening and delivery of care in the context of other conditions and clinical settings. The COVID-19 pandemic occurs during the first digital era using digital tools such as Amazon Alexa for disease screening, and it represents an opportunity to implement such technology in health care institutions in the long term.

KEYWORDS

voice-based technologies; Amazon; Alexa; SARS-CoV-2; COVID-19; digital screening

Introduction

The COVID-19 pandemic has led to over 551,000,000 cases and 6,300,000 deaths across the world [1]. This high rate of mortality can be partly attributed to an aging population and the fact that comorbidities such as cardiovascular disease significantly increase the risk of death. As a consequence of COVID-19's infectiousness and high rate of mortality, the pandemic has exerted a significant pressure on health care resources such as the availability of health care professionals and their services [2]. As a result of this pressure, telemedicine and artificial intelligence (AI) technologies have proliferated to increase the efficiency of health care and address the unmet needs of a strained health care system [3]. Indeed, the rapid adoption of digital technology in health care delivery has increased as a result of the ongoing global digitalization [4]. For example, programs such as chatbots have gained popularity in promoting COVID-19 vaccination, and telemedicine-based health care delivery has become a patient-accepted and sustained addition to ambulatory care [5-7].

AI is a technology that enable machines to comprehend, act, and learn by simulating human-like intelligence. Machines and computer applications using AI can distinguish, classify, and retrieve information via algorithmic training [8]. These technologies are beneficial as they can be used in health care systems for intelligent screening, thus limiting contact between health care workers and patients. Additionally, intelligent screening systems such as interactive voice response systems have the potential to help control the spread of COVID-19 by streamlining patient monitoring, contact tracing, and continuous surveillance. However, a potential limitation of telemedicine and AI technologies is the potential for inaccurate data capture due to the absence of face-to-face communication. Telemedicine and AI technologies that use interactive voice response systems, such as Amazon Alexa, have been shown to be able to facilitate patient screening within a hospital environment [9]. In fact, previous research has demonstrated good agreement and high interrater reliability (IRR) between Amazon Alexa and health care providers [10]. However, such research has been primarily observational, resulting in a high potential for risk of bias from the priming effect, which can occur when an exposure to certain screening strategy influences responses to a subsequent one. In addition, it is unclear how such technologies perform when interacting with patients who are older and have multiple comorbidities such as those with heart failure (HF) [11]. Additional knowledge gaps include questions related to ethical and privacy concerns of patients exposed to digital tools [12].

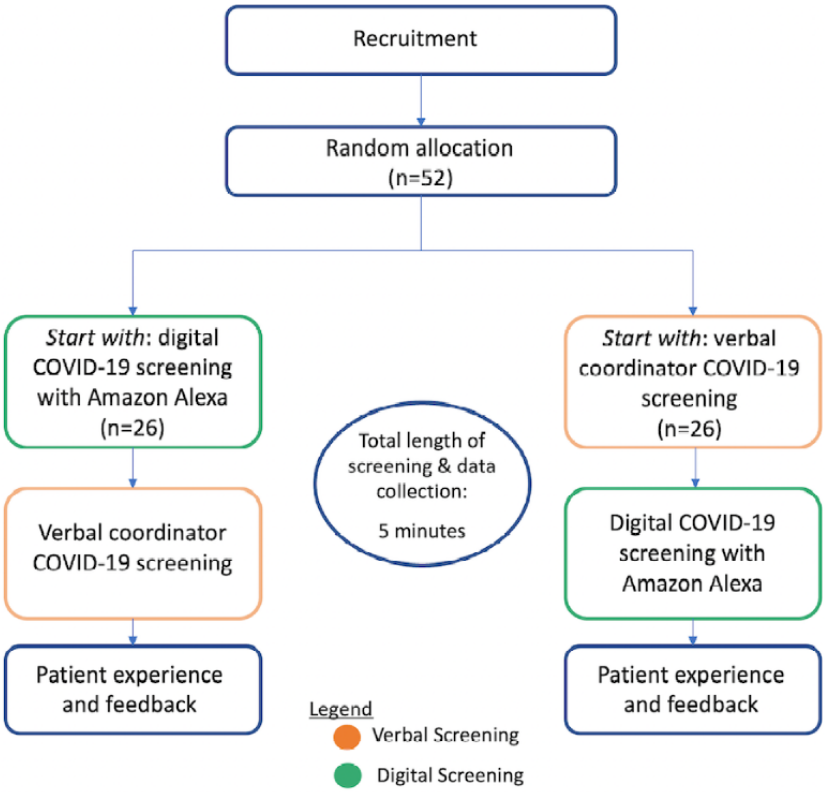
To address this knowledge gap, we aim to conduct a two arm, crossover, randomized controlled trial to evaluate the accuracy of data capture by Amazon Alexa versus health care providers in the context of COVID-19 screening. In addition, patient-centric decision-making and concerns surrounding the use of such interactive voice response systems will be evaluated via Likert scales in a postscreening survey.

Methods

Overview

The study presents no more than minimal risk of harm to participants and involves no procedures for which written consent is required. All collected data will be anonymous, and all participants will be deidentified and given an identification number. No compensation will be offered to the participants.

Study Design and Setting



The VOICE-COVID-19-II study is designed as an open-label, noninterventional, crossover, randomized controlled trial comparing the accuracy of data capture by Amazon Alexa versus health care providers in the context of SARS-CoV-2 screening. Patients visiting an HF clinic at the Royal Victoria Hospital (RVH) of the McGill University Health Center (MUHC), in Montreal, Quebec, will be eligible for inclusion. In total, 52 participants will be recruited at the RVH HF clinic. Patients will be randomized to first be screened for symptoms of SARS-CoV-2 by either Amazon Alexa or the research coordinator; participants will then subsequently cross over and be screened by either Amazon Alexa or the research coordinator. Each patient's responses to both the Amazon Alexa– and research coordinator–administered survey will be compared.

The order of screening will be determined randomly by 1:1 block randomization. A flowchart of the study is shown in Figure 1. The Amazon device will not record any personal health information nor health data. After the completion of the SARS-CoV-2 screening, a survey will be presented by the coordinator to patients to assess their perceived user preference

XSL•FO
RenderX

and Alexa software application engagement. The postscreening survey will evaluate the sense of privacy and data safety concerns regarding the use of digital screening, as well as the interest of patients in receiving voice response systems at home, experience with voice response systems, and interest for digital health care aid based on cohort demographics.

Figure 1. Consolidated Standards of Reporting Trials (CONSORT) diagram of the study.

Eligibility Criteria

Patients and employees aged older than 18 years at the RVH HF clinic will be eligible for inclusion. Individuals of all sexes, races, and ethnicities will be eligible to participate in the study. Exclusion criteria include inability to speak English or French and inability to interact with the device as defined by severe speaking impediments, hearing loss, and neurological problems.

Ethics Approval

This study was approved by and received a waiver of documentation of consent from the institutional Research Ethics Board (REB; approval 2020-6583) at the MUHC. Any modification to the protocol will be reported to the REB (Multimedia Appendix 1).

Device Used

The screening device that will be used is the Amazon Echo Show 8. With Amazon Web Services, an Alexa Skill will be developed using the Amazon Alexa Developer Kit. An Alexa Skill is an interactive voice interface that allows users to interact with a device, hands-free. Skills are based on vocal interaction models that help Alexa determine a user's request. The voice algorithm is first based on automatic speech recognition (ASR), followed by natural language understanding (NLU). ASR is speech recognition software that converts spoken words in text. ASR helps detect audio waveform patterns, matching each waveform with sounds from a given language (English or French for this trial). However, because vocal intonations and inflections vary widely, NLU is used for the rearrangement of spoken data into a computer-readable format. NLU processes the request by decrypting the ASR-converted message. NLU interprets the input, extracts the data, and restructures it so that machines may understand and analyze it. Together, this allows for human-computer interaction, allowing devices to understand commands without the syntax of computer languages.

In this study, the Amazon Echo 8 will be used to screen patients for SARS-CoV-2 through a series of questions. The Alexa Skill built for this study is a predetermined sequence of screening questions triggered by a vocal request. Requests include answering a question by "yes" or "no," stating numbers (subject's age and ID number), etc. To activate the SARS-CoV-2 screening process, a prespecified activating utterance is programmed: "Alexa, Clinic Visit." Each response to a question act as a trigger for the next question. The questions are based on Health Canada recommendations and clinical consultations and will be regularly updated with new guidelines and approved vaccines. The skill will be available in both French and English. Therefore, patients will be able to choose their language of preference and interact with the device in the most effective way. The screening questions used for this study are available in Table 1. No personal health data will be recorded by the Amazon Echo 8.

Alexa will be used to collect and transfer data to secure servers owned by the principal investigator. The virtual servers are located in Canada and are protected behind a secure firewall. These servers undergo daily backups of the data in case of

XSL•FO
RenderX

corruption. No personal health care information will be stored on these servers. Furthermore, a log will be kept of the IP addresses logging on the server.

Table 1. COVID-19 screening questions.

Screening questionnaire (English)	Response type
1. Welcome to check-in assist, *bienvenue dans* check-in assist. To continue in English, say English. *Pour continuer en français, dites français.*	Binary mode (English/French)
2. We can help you see if you have symptoms of the COVID-19 virus. What is your participant number?	Numbers
3. Do you work in the hospital?	Binary mode (Yes/No)
4. What is the reason for your visit? You can say appointment, visitor, delivery, pick-up or other.	Predetermined options
5. Have you traveled outside of Canada in the last 14 days?	Binary mode (Yes/No)
6. Have you been in close contact with a confirmed case of COVID-19 without protective equipment?	Binary mode (Yes/No)
7. Do you currently have any of the following symptoms: fever, runny nose, sore throat, or diarrhea?	Binary mode (Yes/No)

Recruitment

Participant recruitment will be conducted in teams of 2 bilingual coordinators. A relative degree of quietude will be exercised to avoid issues of device communication during the digital screening portion of this study. Consequently, recruitment will be done in physicians' offices when patients with HF are either waiting for their appointment or have completed their clinic visit. Patients will undergo the screening process in a designated office to ensure privacy.

During recruitment, the number of patients who accepted or refused to participate will also be recorded. At the beginning of every HF clinic, medical staff and physicians will be alerted of the presence of research coordinators on site. The team will obtain consent from the physicians on duty to collaborate with the patients in their offices. The Amazon Echo will then be plugged into the fully charged uninterrupted power supply (UPS) and connected to the Wi-Fi. Both the tablet and the Echo device will be configured, and the activation code will be spoken to verify if the Alexa Skill is still responding and functional.

Participants meeting the eligibility criteria will undergo SARS-CoV-2 screening by both Amazon Alexa and a research coordinator in random order. No personal health information or health data will be collected through the Alexa device. Verbal informed consent forms are approved by the REB. If the participant is eligible and informed consent has been obtained, past medical history data will be collected to analyze the study's demographics. Participants will be informed that enrollment in the study is on a voluntary basis and that withdrawal from the study is possible at any stage. Withdrawal of consent will not affect subsequent medical treatment of patients nor their relationship with the treating physician.

To be able to move efficiently across the clinic, the clinical setup consisting of a tablet, the Amazon Echo, and a UPS on a mobile cart. A tablet will be used for Research Electronic Data Capture (REDCap) access, where randomization, coordinator screening, and patient feedback will be recorded. REDCap is a secure web application for building and managing online surveys and databases. Additionally, a UPS will be used to keep the Amazon Echo continuously powered. This will be done to avoid the reconfiguration period that occurs each time after the Amazon Echo device is powered off. The UPS used in this study will be a Schneider Electric 600 Volt-Amp.

Participants will remain 6 feet (1.83 m) away from the Amazon Echo. The 3 devices (Echo, tablet, and UPS) will be cleaned with bleach-based wipes in between every participant. The duration of the screening process is estimated to be 5 minutes.

Data Collection

Patient recruitment and data collection will be conducted at the site of recruitment. Data related to the trial will be anonymized and recorded in a coded, password-protected digital file behind the coordinating center's institution firewall. Only the principal investigator will have access to the code. All the information collected will remain confidential to the extent required and provided by law. The collected data will be kept for 25 years after the end of the study before being destroyed. There will be no data monitoring committee in this study as no therapeutic intervention is involved. Open access to the manuscript will not be provided.

Randomization and Blinding

The order of screening is randomized as this study is a crossover trial with a higher potential for risk of bias from the priming effect. Participants will be randomly assigned to either start with the digital SARS-CoV-2 screening or with the coordinator screening. Randomization will be done in a 1:1 ratio using a randomization procedure generated by REDCap. Both participants and coordinators involved will not be blinded to the allocation process.

Outcome Measures

The primary outcome of the study will be the concordance of screening for symptoms of SARS-CoV-2 carried out by the Amazon Alexa device compared with the manual screening carried out by a trained research coordinator. The secondary outcome will be a 5-point Likert scale and binary mode responses evaluating patients' perceived comfort interacting with Alexa. The above outcomes will be measured as part of the postscreening survey carried out by the research coordinator at the end of the SARS-CoV-2 symptom-screening process and inputted into a secure web application form. The ease of the Amazon Alexa screening process, privacy and data safety concerns, interest in digital health care at home, and willingness

XSL•FO
RenderX

to be vaccinated will be asked with a standard 5-point Likert scale. The relationship between the participant's vaccine status and the answers regarding the participant's comfort with digital health use, as well as the relationship between interest in voice response systems use at home and cohort demographics (eg, gender, age, and relevant medical history) will be determined by a linear regression model. Finally, any technical issues will be noted manually, on the REDCap platform, as well as any comments, remarks, and questions made by the research participants. These notes will be taken into consideration in the evaluation of the efficiency and accessibility of the digital Amazon screening. However, it is important to note that given that the survey questions are clear and objective, there is little risk of bias that in-person observations will affect the internal validity of the study's results.

Statistical Analysis

The coprimary end points for this study relate to the IRR on the accuracy of the randomized screening data from Amazon Alexa compared to coordinator data as the comparator. IRR will be evaluated using simple and weighted Cohen κ statistics (where possible) and percentage concordance between responses obtained from Amazon Alexa and research coordinators. The calculated κ scores will be compared between the 2 study arms for each screening question. In addition, linear mixed-effects model will be used to investigate differences in the 2 study arms, adjusting for the fixed effect of the screening order and the random effect of correlated observations in the demographic data. Furthermore, postscreening survey questions will be examined and presented on a Likert scale. This study will aim to recruit at least 52 participants, with minimally 26 participants in each study arm. The estimation of the sample size is based on the *kappaSize* package in R (version 4.1.2; R Foundation for Statistical Computing), with a 1-tailed test null κ score of 0.6 assuming a proportion of positive ratings of 0.9 and a preliminary κ score of 0.9 [13,14]. The sample size will also be adjusted with the power analysis of one-way ANOVA and the chi-square test to obtain a power of 0.8, accounting for a large effect size of above 0.4 and a significance level of .05. The demographic data will be presented in the baseline characteristics table, with categorical variables as counts (percentages) and continuous variables as medians and interquartile ranges.

Intervention and Comparator

Participants allocated to the intervention group will initially undergo screening by the Amazon Alexa device for symptoms of SARS-CoV-2 (screening questions in Table 1). All questions, excluding the first question to determine the preferred language, allow for the collection of responses that serve as epidemiological or clinical risk factors that predict the risk of having an infection with SARS-CoV-2. These participants will then undergo the same screening process, but by a trained research coordinator. Meanwhile, patients allocated initially to the comparator group will first undergo screening by a trained research coordinator, followed by digital screening by the Amazon Alexa device.

At the end of this process, all participants will undergo a postscreening survey (Table 2) conducted by a trained research coordinator. The goal of this postscreening survey is to evaluate user preference, concerns about privacy and data storage, and the Alexa software application engagement. The survey will ask 11 questions about their screening experience and their perception of voice-based technology. Questions 1, 2, and 6 allow specific evaluation for participants comfort with utilizing technology. More specifically, answers to these questions could serve as markers for the device's perceived functionality and reliability as well as possibility for remote screening. Questions 3, 4, and 5 allow the collection of responses to assess the patient's perception relative to data security. Questions 7 and 8 measure the participant's subjective perception of the device's effectiveness. Questions 9, 10, and 11 assess the overall ease of use of the device.

Other variables will be collected in the postscreening phase of the study such as SARS-CoV-2 vaccine status, assigned sex at birth, and duration of digital screening. These variables will be utilized for stratification-based statistical analysis on the answers obtained in the postscreening survey.

Prespecified subgroups of interest include those by language (French and English), sex, and age.

Table 2. Postscreening survey questionnaire.

Postscreening survey questions	Response type
1. Did you feel comfortable speaking into the Amazon Alexa device?	5-point Likert scale
2. Have you used this type of device before or do you own this type of device?	Binary mode
3. Would you feel comfortable being screened for symptoms using the Amazon Alexa device?	Binary mode
4. Do you have any concerns about privacy or data safety?	5-point Likert scale
5. Do you feel your data would be kept secure by such a device?	5-point Likert scale
6. Can you see yourself using such a device at home to assist with any healthcare needs?	5-point Likert scale
7. Did you feel the check-in asked the screening questions appropriately?	5-point Likert scale
8. Did you feel the check-in minimized your chance of contracting COVID-19?	5-point Likert scale
9. Was the language easy to understand?	5-point Likert scale
10. Was the check-in easy to use?	5-point Likert scale
11. How would you rate this check-in overall?	5-point Likert scale

Results

Funding for the VOICE-COVID-19-II trial was obtained in May 2021. The recruitment of participants for the VOICE-COVID-19-II trial started in May 2021, with simultaneous acquisition of data by the Amazon Echo Show 8 device, and is expected to be completed in fall 2022. Data analysis is expected to be completed in early 2023. Subsequently, trial results and analysis are expected to be published by mid-2023.

Discussion

Expected Findings

The study aims to test the concordance of screening for symptoms of SARS-CoV-2 done by Amazon Alexa compared to manual screening done by research coordinators. It also aims to evaluate the perceived comfort of patients when interacting with Alexa. Voice-based technology has the potential to improve clinical treatment for patients affected by SARS-CoV-2 by optimizing rapid and accurate data acquisition and can be extended to allow for screening of other conditions. Before implementing this interactive voice response system, the IRR of the program screening for the virus and overall patient experience, compared to the standard person-to-person screening, must be evaluated.

With standard methods of screening for symptoms and exposures, there is an increased burden on health care professionals that remains strenuous in the context of the pandemic. The use of commercially available digital tools to aid in screening for SARS-CoV-2 symptoms may be instrumental in reducing the burden on health care personnel, as well as minimizing opportunistic spread of disease via person-to-person contact [15].

A number of approaches using available digital health technologies to screen for SARS-CoV-2 symptoms are being explored, including automated text messaging and smartphone apps [16,17]. However, interactive voice response systems remain relatively unexplored. A previous study has evaluated the quality of health information dissemination on cancer screening provided by voice assistants, such as Siri, Alexa, and Cortana, but did not evaluate these devices' ability to screen for cancer [18]. One study evaluated the quality of speech intelligibility of Amazon Alexa and Google Home by providing individuals with intellectual disabilities with smart speaker devices [19]. Another recent study screened patients with major depressive disorder with the Patient Health Questionnaire 9 via randomizing screening with Amazon Alexa compared to manual screening [20]. However, manual screening was done through paper format, and the time between digital and manual screening was 1 month. The potential ease of use of voice-based commands, which, when optimized, would better simulate standard person-to-person interactions compared to requiring digital input, could prove to be optimal in situations where the use of electronic recording of data may be difficult, such as with older participants. Furthermore, the use of Amazon Alexa, a voice response system available at home and other nonclinical environments, could provide additional advantages in terms of remote data collection. A reliable method of rapid acquisition of medical data easily accessible to patients could significantly facilitate future trials and personalizing health care delivery. Similar to other remote digital technology, such as Google Home or Apple's Siri, voice response systems have potential for great scalability for larger participant numbers, given its commercial nature, cloud-based data collection, and easy access.

However, the increasing popularity of remote screening tools during the SARS-CoV-2 pandemic revealed a need for objective measures of the reliability of the data acquired by these tools. In particular, the previous phase of this study did not directly address the risk of bias in the virtual screening question answers when presented with the comparator set of in-person questions beforehand. The strengths of this study are founded upon its design to isolate a verified measure of the accuracy of the screening method and the use of commercial interactive voice response systems. This study aims to examine the reliability of the data acquired by the device while accounting for the priming bias inherent in previous similar studies, where participants would be affected by choices presented by the in-person set of screening questions used as the comparator. In addition, the Amazon Alexa program used in the skill set is based on a widely accessible commercial device designed for home use, which would provide a reasonable simulation of the technology that would be used for widespread public screening.

Limitations

The study does have some limitations. Although the sample size may be adequate in detecting IRR between the virtual screening program and the standard in-person screening questionnaire, it is too small to detect the effectiveness of the questionnaire in triaging patients exposed to COVID-19. While the use a more extensive COVID-19 questionnaire may have increased the amount of data available for analysis, a shorter questionnaire developed with clinical experts was used to enhance patient recruitment. Given that the focus of this study was the accuracy of information obtained remotely compared to an in-person standard and not specifically to screen for SARS-CoV-2, insight into its capability as a screening measure was limited. However, regarding the diagnostic and screening accuracy of voice-based digital screening for COVID-19, a larger-scale study utilizing gold standard diagnostic assays (ie, reverse transcription polymerase chain reaction) would be required. Should a survey evaluating the accuracy of the questionnaire itself be proven to be effective, interactive voice response systems, such as Amazon Alexa, could provide users with a notification for their risk of a positive diagnosis and whether testing is encouraged given a posttest likelihood of illness.

In terms of the questionnaire, it is possible that some questions regarding personal contact with COVID-19 will have some interperson variability secondary to question interpretation. However, given the objective nature of the COVID-19 questionnaire as well as individuals' lived experiences with the pandemic, the overall potential for risk of bias is low. Furthermore, although the study and questionnaire used are limited to recording answers in a 5-point Likert scale and a binary response of yes or no, speech AI is becoming increasingly

XSL•FO
RenderX

sophisticated, with improved speech recognition and more flexible conversations in newly developing propriety speech AI. This could prove to be a unique strength of voice-based screening in future health care delivery, with a possibility of more personalized interactions with patients, nuanced screening questions, and more efficient information dissemination to patients in the form of an interactive question-and-answer program. As remote data collection develops over time, there will be new potential avenues of medical AI research for personalized health care delivery with intelligent voice-based assistants.

Conclusion

In conclusion, the second phase of the VOICE-COVID-19-II randomized controlled trial aims to evaluate the accuracy of data capture by interactive voice response systems, such as Amazon Alexa, compared to health care providers as the baseline. If the study proves to be effective, it could open additional avenues of research and would provide a novel viewpoint on implementing digital health in the context of the pandemic, allowing for screening in both hospitals and at home.

Acknowledgments

Funding for VOICE-COVID-19-II was supplied by the McGill University Health Center Foundation and Canso Investment Counsel Ltd, and in-kind development support was provided by Amazon Web Services (AWS). AWS assisted in the development of the skill but did not have access to any patient data. AS reports receiving support from the Canadian Institute of Health Research (Grant #175095), Fonds de Recherche Santé Quebec (FRSQ) Junior 1 clinician scholars' program, MEDTEQ, McGill University Health Center Foundation, Roche Diagnostics, Boeringer-Ingelheim, Novartis, and Takeda.

Data Availability

In accordance with the approval granted for this study by the McGill Research Ethics Board, the data files will be stored securely and protected by Canadian virtual servers and a secure firewall. Patient level data will not be available. Request for the coding used in the Alexa Skill can be made available upon reasonable request to the corresponding author.

Conflicts of Interest

None declared.

Abstract

Background: Geriatric malnutrition in hospitals is common and can be affected by many things, including poor satisfaction toward hospital foodservice. Hospital foodservice plays an important role in a patient's recovery process by providing adequate nutrients. On top of that, patients' foodservice satisfaction can easily be afflicted by the quality of food served and the overall foodservice experience. Furthermore, malnutrition can occur from poor foodservice quality, especially among geriatric patients.

Objective: This study aims to assess the effectiveness of the Malaysian Geriatric Patients' Hospital Foodservice Protocol (MYGERYFS).

Methods: The protocol comprises 3 phases. Phase One is a cross-sectional study that took place at public hospitals with geriatric wards in the Klang Valley. Univariate data from Phase One were analyzed descriptively. Pearson correlation and chi-square were conducted to find factors associated with foodservice satisfaction. Phase Two involves the collaboration of health care professionals in the geriatric field. In Phase Three, a feasibility study will be conducted to determine the feasibility of the MYGERYFS protocol in a hospital among 60 geriatric patients. These patients will be randomized into control and intervention groups, respectively. Intervention care will be done to ensure the safety of the protocol.

Results: Data collection for Phase One of the study has been completed. A total of 233 geriatric respondents with the mean age of 71.39 (SD 7.99) years were gathered. Approximately 51.5% (n=120) of the respondents were female, while 48.5% (n=113) were male, with a mean BMI of 24.84 (SD 6.05) kg/m2. Their mean energy and protein intakes were 1006.20 kcal (SD 462.03 kcal) and 42.60 (SD 22.20) grams, respectively. Based on the Mini Nutritional Assessment, older patients who scored 12-14 (normal) were 27.9% (n=65), those who scored 8-11 (at risk) were 54.9% (n=128), and those who scored 0-7, which is the lowest (malnutrition), were 17.2% (n=40) of the study population. Hence, most patients were at risk of malnutrition. Although a majority of the patients claimed to have good foodservice satisfaction 26.2% (n=61), they also experienced at least 3 barriers during mealtimes. It was found that dietary intake and mealtime barriers were significantly associated with the respondent's foodservice satisfaction. Data for Phase Two and Phase Three are yet to be collected and analyzed.

XSL•FO
RenderX

Conclusions: This study protocol could potentially benefit the hospital foodservice system and aid in improving geriatric nutritional status.

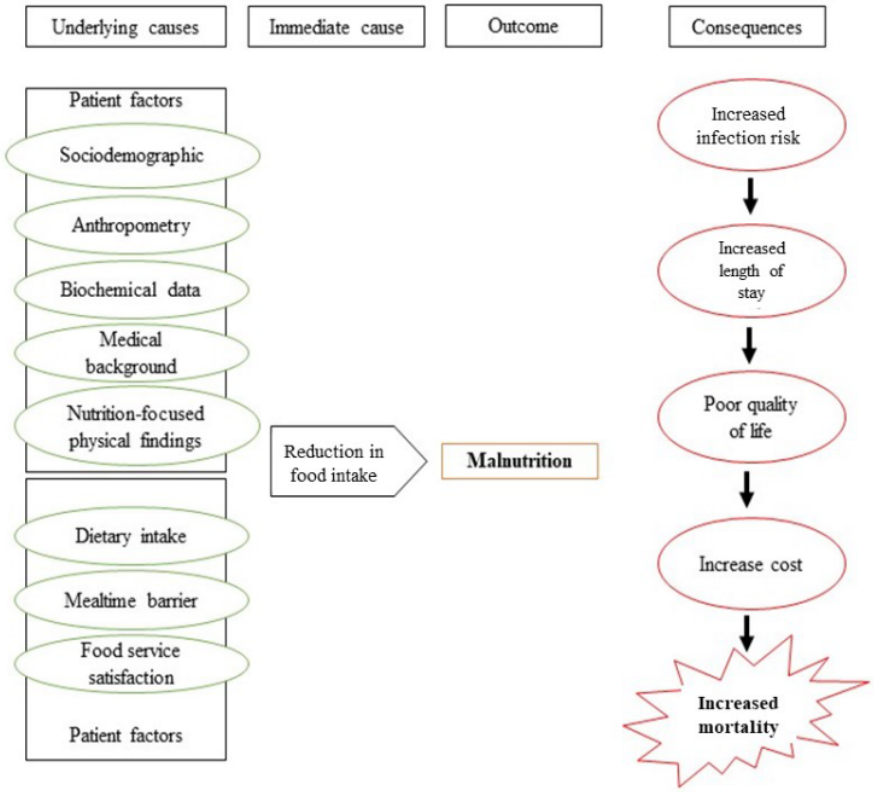
Introduction

"Older people" is defined as individuals aged 65 years or older who are deemed suitable to receive the national pension plan [1]. According to Orimo et al [1], the range of older persons can be divided into two categories. They are (1) "early elderly" (individuals aged 65-74 years) and (2) "late elderly" (individuals aged ≥75 years). In Malaysia, "elderly" is recognized as those aged 60 years and older, due to its policy and program development purposes [2]. The increasing trend of the aging population has shifted the world's demographic patterns [3]. As a developing country, Malaysia is not spared from this phenomenon [4]. The recent National Health Morbidity Survey (2018) estimated that the country's older population is at 2.3 million (6.3% of the total population) and is predicted to double within 23 years [2]. The aging process often relates to health complications [2]. Apart from the presence of comorbidities, malnutrition in older people is also common [5].

The reasons for having compromised nutritional status among older individuals are changes in physical, cognitive, psychological, and social factors (eg, living alone), as well as having limited income [6]. Other risk factors include the presence of comorbidities [7,8], poor dental status [9], and inadequate dietary intake [7,10,11]; moreover, those living in health care institutions often complain of having poor foodservice experience [12,13]. Older people with malnutrition often find themselves in a state of dependency, having prolonged hospital stays, an increase in infection rate that eventually diminishes their quality of life, and an increase in health care costs and mortality [6,7,14].

There are countless studies investigating malnutrition among hospitalized older individuals, and the prevalence is indisputable. The global prevalence of malnutrition in hospitalized older patients ranges from 12% to 75% [7]. Consistent with the worldwide trend, Malaysia also shows a prevalence of malnutrition that ranges from 21% to 55% among hospitalized geriatric patients, which appears to be a matter of concern [15].

Despite the interventions carried out thus far, the prevalence of malnutrition among geriatric patients is still appalling [16]. Most older people view themselves as healthy, in spite of their sociodemographic status (educational level, income status, and daily living activities) [17]. Despite their healthy self-image, older individuals are still vulnerable to malnutrition due to their frail condition [6]. In addition, of 52% of malnourished older patients, 18% were found to be nutritionally compromised even before admission [18]. Surprisingly, these older adults even believe that having inadequate nutritional intake is normal without realizing the consequences that malnutrition carries [6].



Hospital meal is considered as one of the important components of care. Hospital meals are served not only to facilitate well-being and recovery but also to contribute to the patients' satisfactions on their overall treatment experiences [19]. Looking at the hospital foodservice system, oftentimes the patients' nutritional status is impacted by it. For example, hospital-acquired malnutrition is believed to be caused by the poor quality and appearance of the food and its environment [20]. The same study reported that food quality is found to be the best predictor of patients' overall satisfaction, followed by service quality given by staff. A study in Australia has proven this by introducing a room service model to hospitalized patients. The results showed good upturns in the patients' nutritional intake and satisfaction as well as reduced plate waste and patient meal costs after the method was implemented [21].

Another study reported that patients found it tiring to order and eat their food at specific times [22]. On the contrary, these patients were also sensitive to delays and poor service. Further, the study documented that patients appreciated the presence of nonmedical foodservice staff, but at the same time felt pressured by them. According to a study conducted in a military hospital in Turkey, the patients' satisfaction levels on the hospital's foodservice system showed inconsistency. The results showed that 51.3% evaluated the foodservice quality to be adequate, while 32.4% deemed it was of inadequate quality. Accordingly, the remaining 16.3% stated that they were uncertain [23]. The different spectrum of thoughts by the patients only makes it hard to fathom, thus affecting the ways of intervention in many hospitals' foodservice systems. Therefore, the redesigning of hospital foodservice models may be needed not only to drive toward the improvement of patient satisfaction and cost but also to influence clinical outcomes associated with nutritional intake.

Figure 1 shows the conceptual framework of the causes of malnutrition and its possible consequences. This study aims to develop, implement, and evaluate the effectiveness of a Malaysian Geriatric Patients' Hospital Foodservice Protocol (MYGERYFS) in order to improve both the nutritional status of hospitalized geriatric patients and the quality of the foodservice.

Figure 1. Conceptual framework of the causes of malnutrition and its consequences.

Methods

Study Design

The MYGERYFS project is a 2 year and 6 months intervention program, conducted among malnourished older individuals with pre- and postintervention to assess the effectiveness of the protocol. The trial comprises the nutritional status of hospitalized geriatric patients aged 60 years and above in 5 public hospitals in the Klang Valley, which are as follows: (1) Hospital Selayang, (2) Hospital Sungai Buloh, (3) Hospital Kuala Lumpur, (4) Hospital Tengku Ampuan Rahimah, and (5) Hospital Pengajar Universiti Putra Malaysia.

The study comprises the following phases: (1) Phase One—a preliminary study that identified the prevalence and factors associated with hospitalized geriatric malnutrition; (2) Phase Two—protocol development with health care professionals; and (3) Phase Three—testing the feasibility of the protocol. The trial has been registered at ClinicalTrials.gov (NCT04858165) on March 30, 2021.

Phase One

The first phase of the MYGERYFS is a cross-sectional study conducted to assess the recent nutritional status of older hospitalized patients and the factors associated. Phase One has been completed and analyzed in August 2022. Using the proportion formula by Cochran (1963) [19], a total of 233 geriatric patients were gathered as samples for this study.

In this phase, the patients or their respective caregivers were interviewed by the researchers. A series of questionnaires that hold information on the patients' sociodemographic and medical background, anthropometry measurements, dietary intake, mealtime barriers, foodservice satisfaction levels, and nutritional statuses were put together. The collected data were assessed and labeled as preliminary data.

Phase Two

Phase Two of the MYGERYFS protocol studies the current feeding practices and opinions of health care professionals. A group of geriatric health experts, specifically geriatricians, nurses, and dietitians, will be invited to review and discuss the preliminary data. Subsequently, the existing clinical procedures will be audited and improved in line with the recent research. The protocol will be finalized in a consensus meeting.

Phase Three

The newly developed protocol will be tested in a single institution. Altogether, 60 geriatric patients will be recruited. These patients will be divided into 2 groups (control and intervention groups). The control group patients will be given usual hospital care, and the intervention group patients will be cared for according to the developed protocol for approximately 3 consecutive days. Dietary recall of 3 days was thought to be better than 24-hour recall or 7-day recall [24]. This is because a single 24-hour recall could lead to overestimation of intake, while a dietary recall of more than 3 days often leads to lower intake as respondents feel burdened to report their intake further, thus omitting their food items altogether [24]. Details on their dietary adequacy and clinical outcomes will be documented. The feasibility and safety of the protocol will be evaluated. The findings will provide fundamental data to develop a foodservice protocol for Malaysian geriatric patients.

XSL•FO

Participants

Ethics Approval

This study was approved by the National Medical Research Register for Phase One (NMRR-20-308-52632) and was reapplied for Phase Three. In Phase One, a written consent form will be sought from all respondents before the study. Permission from each of the hospitals' clinical research centers was obtained before data collection.

Screening of Nutritional Status

Five public hospitals in the Klang Valley were listed and approached for Phase One of the study. These hospitals were purposely selected due to the availability of their geriatric wards. The selected patients will be screened using the Mini Nutritional Assessment Short Form (MNA-SF). The MNA-SF evaluates 5 components of common geriatric problems, which are food intake, weight status, mobility status, presence of psychological problems, and neurological stress level. These components will be scored based on the patients' conditions and are categorized into the following: (1) normal nutritional status (12-14 points), (2) at risk of malnutrition (8-11 points), and (3) malnourished (0-7 points) [25].

Eligibility and Recruitment

Both Phase One and Phase Three of this study shared similar inclusion and exclusion criteria, as mentioned in Textbox 1.

Textbox 1. The summary of the inclusion and exclusion criteria for Phase One and Phase Three of the Malaysian Geriatric Patients' Hospital Foodservice Protocol (MYGERYFS).

Inclusion criteria

- Patients aged 60 years and older
- Able to understand and speak Malay or English or both
- Patients who are on an oral diet or Oral Nutrition Support or both
- Patients who are admitted for more than 48 hours

Exclusion criteria

- Patients with mild dementia or adjustment disorders that are common in geriatric patients
- Critically ill patients
- Patients who are on full enteral or parenteral feeding

Sample Size Calculation

The sample size for Phase One of the study will be calculated using the proportion formula by Cochran (1963) [19]. A total of 233 geriatric patients will be gathered as samples for this study.

Meanwhile, Phase Two will only require the cooperation of health care professionals; thus, no sample size calculation will be calculated.

In Phase Three of the study, 60 geriatric patients will be recruited and divided equally into control and intervention groups. Therefore, a sample of 30 respondents per arm will be required. As suggested by Cohen [25], a sample size of 30 in each arm is needed to detect the differences between groups, which should lead to about a minimum of 80% power in a study.

Randomization and Allocation

Patients in Phase Three of the study will be randomized into control and intervention groups, respectively. To do so, patients will be allocated with the help of a computer-generated random number sequence.

Intervention

Preceding the development of the MYGERYFS protocol, a feasibility study will be conducted during Phase Three. The study will be carried out in a single institution with a total of 60 geriatric patients. These patients will be screened for their eligibility and separated into control and intervention groups, respectively. Those in the control group will receive the usual hospital care, while the other group will experience hospital care according to the developed protocol. Both groups will be observed for their dietary intake for approximately 2 days from the day of the intervention. All of this information will be compared within the 2 groups.

Outcome Measures

Primary Outcome

Nutritional Status

The nutritional statuses of geriatric patients were assessed using the MNA-SF. The MNA-SF evaluates 5 components of common geriatric problems, which are food intake, weight status, mobility status, presence of psychological problems, and neurological stress level. These components were scored based on the patients' conditions and categorized into the following: (1) normal nutritional status (12-14 points), (2) at risk of malnutrition (8-11 points), and (3) malnourished (0-7 points) [25].

Foodservice Satisfaction

The patients' levels of foodservice satisfaction were documented by the validated Acute Care Hospital Foodservice Patient Satisfaction questionnaire by Capra [26] in 2005 via an interviewing method. The questionnaire weighs 4 main foodservice aspects, which are food quality, meal service quality, staff or service issues, and physical environment. The higher the mean score is, the better the results will be [26].

XSL•FO
RenderX

Dietary Intake

The amount of food consumed by the respondents in 2 days was recorded and analyzed using Nutritionist Pro (version 2.4.1, First Data Bank) [27]. From these data, the patients' energy and protein adequacy was compared against their requirements.

Secondary Outcomes

Anthropometric Measurements

The anthropometric measures considered for this study are as follows:

- Body weight was measured using an electronic scale (digital weighing scale; OMRON HBF-357) according to the standard techniques [28].
- Estimation of weight is done for patients who were unable to stand without assistance using knee height measurement and mid-upper arm circumference. Weight was measured using equations developed by Ross Laboratories [29].
- Height was measured using a stadiometer (SECA height rod) according to the standard techniques [30].
- Estimation of height is done for patients with distinctive conditions (eg, kyphosis, scoliosis) using knee height measurement. Height was calculated using equations developed for older Malaysian people [31].
- BMI was calculated using the following equation: weight in kilograms divided by height in meters squared—weight (kg)/height^2(m^2) [30].

Mealtime Barriers

The patients' mealtime barriers were determined and scored using the Mealtime Audit Tool questionnaire. This questionnaire prioritizes the types of potential barriers during mealtime. Each question is marked with a "Yes" or "No" answer. Scoring for this questionnaire is based on the total "No" responses. This value represents the number of barriers faced by the patients. The higher the "No" responses were, the more barriers were experienced [32].

Statistical Analysis

Data were entered and analyzed using SPSS 25.0 (IBM Corp). In Phase One of the study, descriptive statistics of the continuous data were presented using mean and standard deviation. Meanwhile, categorical data were presented as frequencies and percentages. To analyze the associations of malnutrition, Pearson coefficient correlation and chi-squared test were used. Statistical significance was set at P<.05.

In Phase Two, no analysis will be conducted as it only requires the discussion of health care professionals.

In Phase Three, the descriptive statistics will be presented using mean and standard deviation for continuous data. On the other hand, categorical data will be presented as frequencies and percentages. To compare the control and intervention groups, an independent 2-tailed t test will be used. Statistical significance is set at P<.05.

Results

Phase One of the protocol has already started. A total of 233 older respondents participated in this study. The mean age was 71.39 (SD 7.99) years, where most 51.5% (n=120) of the respondents were female and the rest 48.5% (n=113) were male.

The mean BMI of the older respondents was 24.84 (SD 6.05) kg/m^2. Based on the results showed, most (n=110, 47.2%) participants were classified as underweight, 37.8% (n=88) were normal, and 17.2% (n=40) were either overweight or obese.

The mean energy and protein intakes were 1026.82 kcal (SD 457.66 kcal) and 43.54 (SD 22.66) grams, respectively. The majority of the respondents 70.8% (n=165) had inadequate energy intake (<25-30 kcal/kg). The same trend was shown for their protein intake. Approximately 77.7% (n=181) of them consumed protein below 1.2 g/kg. It was also found that 84.5% (n=197) did not receive oral nutrition support in ward.

The percentage of older patients in hospitals in the Klang Valley who responded to the MNA-SF questionnaire—which was divided into 3 scores of "Normal" (12-14), "At Risk" (8-11), and "Malnutrition" (0-7)—was 27.9% (n=65) normal, 54.9% (n=128) at risk, and 17% (n=40) malnutrition, which is the lowest. Thus, most patients were at risk of malnutrition.

The mean Mealtime Audit Tool score was 3.27 (SD 1.89), showing that the respondents experienced at least 3 barriers during mealtimes. The most common barriers that these patients came across were as follows: (1) respondents were not paid any visits by health care staff midmeal to see if they need anything, (2) respondents were not asked or given other food if they refused to eat their meal, and (3) respondents were not offered to go to the washroom before mealtime. Most of the respondents 74.7% (n=119) experienced good foodservice satisfaction while the other 25.4% (n=59) did not.

Pearson correlation test was done to find the associations between BMI, dietary intake, mealtime barriers, and nutritional status with foodservice satisfaction. According to Table 1, there was no association found between BMI and foodservice satisfaction among hospitalized geriatric patients (r=–0.056, P=.39). As for the dietary intake, both energy (r=0.337, P<.001) and protein (r=0.255, P<.001) were significantly associated with foodservice satisfaction. A statistically significant result was also shown between mealtime barriers and foodservice satisfaction (r=–0.225, P<.01).

A chi-square test was also conducted between nutritional status with foodservice satisfaction. No significant association was found between malnutrition with foodservice satisfaction (χ^2_8=12.778, P=.12).

XSL•FO
RenderX

Table 1. Pearson correlation between BMI, dietary intake, and mealtime barriers with foodservice satisfaction.

Variables	Foodservice satisfaction statistics	
	r	*P* value
BMI	–0.056	.39
Average energy intake	0.337	<.001[a]
Average protein intake	0.255	<.001[a]
Mealtime barriers	–0.225	.07[a]

[a]Correlation is significant at *P*<.001.

Discussion

Principal Findings

Based on the results, it can be seen that the patients' dietary intake was associated with their foodservice satisfaction. Improvement on protein and energy intake to some extent had improved patients' satisfaction within a short period of hospital stay [26].

Next, having mealtime barriers can also affect the overall foodservice satisfaction. This results negatively in the overall experience of services, including foodservice, even though the differences were not statistically significant [33].

This study has its limitations. Phase One of the study was conducted cross-sectionally, which constrained us from finding its causality. Moreover, the feasibility study that will be done may also have its negative impact. This is because feasibility studies often do not identify new concepts as they are based on assumptions. Thus, clear findings must be analyzed during Phase One, and clear decisions need to be made in Phase Two in order to prove them to be realistic.

For all we know, endless research on geriatric malnutrition has been conducted, and the results remain significantly high. To understand the issue, various factors will be studied and addressed with geriatric malnutrition. Thus, the development of the MYGERYFS is considered an unprecedented approach toward delivering a better health care quality for geriatric patients in hospitals, with an ultimate aim to improve the nutritional status of geriatric patients as well as to reduce further deterioration of nutrient intake among this population.

Besides, with the existence of this protocol, there will be a chance to further enhance public hospitals' foodservice system. The provision of a variety of nutritious meals for these patients is believed to be useful with the protocol as an aide. Each meal served to the patient will be tailored to their specific health conditions.

Another strength of this protocol is the encouragement of providing mealtime assistance to those in need. This modified service may enhance the patients' overall foodservice satisfaction. A collaboration between the health care and the foodservice system to improve the well-being of geriatric patients is imaginable.

Conclusions

In sum, the MYGERYFS protocol is designed to suit the needs of geriatric patients in hospitals. With the help of other health care professionals, we assure that this protocol will be able to minimize geriatric malnutrition and enhance the patients' overall foodservice satisfaction. Should this protocol show positive effects, the strategies included may be of help to other Malaysian older populations as well.

Acknowledgments

This research was funded by the Ministry of Higher Education, Malaysia (FRGS/1/2019/SK06/UPM/02/17). The authors would like to thank all the study respondents and their families for their cooperation and confidence in our research team.

Authors' Contributions

NO, SIS, SHN, RJ, SR, ZI, BNMY, HSM, HS, and NSM conceived the study design. NO secured the necessary funding and led the overall project. SIS and SHN are the postgraduate students involved in the overall project and were responsible for the writing of the manuscript. ZI, SR, and RJ acted as cosupervisors of the postgraduate students and contributed to critical input. All authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Parkinson's can impact people's speech, cognition, pragmatics, and language, significantly affecting their conversations with others. The speech and language therapy approach called communication partner training (CPT) is effective for a range of communication difficulties. However, speech and language therapy interventions for people with Parkinson's predominantly focus on impairments, with little provision of CPT for this population. Better Conversations is a CPT approach that involves working with a dyad (the person with the communication difficulty and a conversation partner [CP]) to build conversation skills. It is effective at reducing barriers to conversation, and for some, it significantly increases targeted facilitatory strategies. Some approaches to CPT have been adapted to be delivered via telehealth. This can maximize ecological validity and convenience. Furthermore, telehealth is widely accepted as a delivery method for other interventions for Parkinson's. This study presents the protocol for a pilot feasibility study of a Better Conversations CPT delivered via telehealth to people living with Parkinson's and their CPs, called Better Conversations with Parkinson's (BCP).

Objective: The primary aim is to evaluate the feasibility of the BCP program delivered via telehealth with a treatment group from a collaborating National Health Service (NHS) site to establish for a main trial whether BCP can be delivered as intended in an NHS setting. The aim is to establish: (1) the acceptability of the program for people living with Parkinson's, family members, and speech and language therapists (SLTs); (2) the feasibility of delivering the BCP program; (3) the recruitment and retention rates; (4) a sample size calculation; and (5) the most appropriate primary outcome measure.

Methods: Ethical approval for this study was obtained from London-Central Research Ethics Committee (reference: 22/LO/0332). This case-series feasibility pilot study will recruit 10-12 dyads to ensure 10 complete data sets. Participants will be recruited by a collaborating NHS site located in England. Participants will be involved for 16 weeks (weeks 1-2 preintervention measures, weeks 3-8 intervention, weeks 10-12 postintervention measures, week 16 follow-up interview). Quantitative and qualitative methods will be used to analyze the study data. Speech, communication, and quality of life assessment data will be analyzed statistically to determine a suitably sensitive outcome measure. Descriptive statistics will be used to report on recruitment, attendance, and attrition. Finally, acceptability and feasibility will be evaluated using participant feedback, interviews, and the reflective diary and feedback of the SLT administering the therapy (by the research assistant who is the first author). This data will be analyzed using descriptive statistics and reflexive thematic analysis.

Results: This study was approved for funding from Parkinson's UK. Study recruitment commenced in July 2022. The results of the data analysis are expected to be available by September 2024.

Conclusions: Insights from this study will provide valuable information about the acceptability and feasibility of a remotely delivered Better Conversations CPT approach for people living with Parkinson's and their CPs. An outcome of this study will

XSL•FO
RenderX

be a manualized BCP program coproduced by people living with Parkinson's, their families, and a group of expert SLTs. The study results will guide the next stages of intervention development.

Parkinson's; conversation; speech and language therapy; communication partner training; speech therapy; language therapy; communication difficulty; conversation skills

Introduction

The Impact of Parkinson's on Speech and Communication

Parkinson's is one of the fastest-growing neurological conditions in the world [1], with a recorded UK prevalence of around 22:10,000 women and 32:10,000 men [2]. Parkinson's is associated with a loss of nerve cells in the substantia nigra, resulting in reduced dopamine. Changes to articulation, prosody, respiration, and voice are well attested. Disruption to communication can also occur because of changes in cognition, language, and pragmatics. Self-perception ratings suggest that around 90% of those living with Parkinson's experience some speech-language changes [3,4], with speech among the top 4 concerns for 38% [3].

Current Speech and Language Therapy Provision

Speech and language therapy interventions for people living with Parkinson's have an established focus on intelligibility and volume and principally address speech impairment [5]. Intervention therefore typically focuses on approaches such as Lee Silverman Voice Treatment [6], which involves teaching people with Parkinson's to recalibrate their volume through intensive speech exercises and can result in substantial improvements to vocal loudness and intelligibility [7]. A total of 85% of people with Parkinson's who have had speech and language therapy feel that it has had a positive effect on communication and swallowing [4]. Those for whom speech and language therapy is not helpful cite reasons such as difficulty maintaining gains in day-to-day conversations; difficulty continuing exercises at home; and that therapy does not tackle all the aspects of communication relevant to them. Yorkston et al [8] similarly report difficulties maintaining therapeutic gains, and that therapy does not always address communication problems of concern, such as conversation and cognition. Suggestions for improvements to speech and language therapy include increased focus on the cognitive demands of speaking and psychosocial aspects of communication [9]. These perspectives are also reflected in the views of speech and language therapists (SLTs), who report feeling less able to address maintenance of therapeutic gains outside of therapy sessions [5] and describe lacking the necessary tools to target interaction or conversation in assessment and intervention with this client group [10].

Communication Partner Training

Communication partner training (CPT) is an umbrella term for a therapy approach that involves working with a person with a communication difficulty and their conversation partner (CP; eg, a health professional, a family member, or a friend they regularly converse with) to improve everyday conversations. CPT is effective for a range of communication difficulties, such as aphasia [11], traumatic brain injury [12], and dementia [13]. Evidence suggests that CPT is effective at improving the knowledge, communication skills, and attitudes of communication partners [11,14-16]. Furthermore, CPT can enhance functional communication, accessibility, and participation for people with communication difficulties [11,16,17]. Common components of CPT programs across communication difficulties include the provision of information; building knowledge (eg, about strategies to enhance communication and negative behaviors to avoid), developing behavioral skills (the practical actions of participants in learning and practicing skills), and skill-building techniques [18].

CPT for People Living With Parkinson's

Despite similarities across CPT programs, individual strategies vary for different etiologies of communication difficulty [18]. Thilakaratne et al [19] carried out a scoping review aiming to describe the assessment methods and interventions used to treat conversations between people with Parkinson's and their partners and to identify gaps in the literature. The authors found only 1 intervention study for people with Parkinson's, which treated conversations by implementing CPT. This multiple case study [20] with 3 dyads suggests that CPT adapted for people living with Parkinson's was well received and that the therapy may work well, although its effectiveness remains to be proven. Thilaraktne et al's [19] scoping review highlights a need for further research implementing CPT for people living with Parkinson's and incorporating a participation-based approach to intervention that involves all communication partners.

The Better Conversations Approach to CPT

Better Conversations is an approach to CPT that aims to help people with communication difficulties have more enjoyable and successful interactions in their everyday lives [21]. Rather than working with solely the person with communication difficulties or their communication partner, it involves both parties, referred to as a dyad, in building conversation skills. The SLT supports a dyad to video-record themselves in natural conversations and uses clips from the videos to help them identify what is working well in conversation (facilitators) and what gets in the way (barriers). The dyad sets individualized personal goals and is supported in practicing chosen strategies in order to build their skills in conversation. Behavior change techniques are targeted at both members of the dyad. The most established Better Conversations program is Better

XSL•FO
RenderX

Conversations with Aphasia [22], which significantly reduces barriers to conversation at the group level and, for some individuals, significantly increases targeted facilitatory strategies [23]. Previous successful adaptations of Better Conversations include the coproduced Better Conversations with Primary Progressive Aphasia [13]. This has been deemed acceptable and feasible to deliver, and initial pilot data demonstrates promise as a means to improve self-identified communication behaviors between members of the dyad [24].

Telehealth

Telehealth or telemedicine, the "delivery of health care services where distance is a critical factor" [25], can improve access to quality, cost-effective health services. Despite barriers, in particular for those with cognitive and visual impairments [26], telehealth offers advantages, such as removing issues related to cost, travel, and inconvenience for the service user; increasing access to health care; and being able to observe people in their own environment [27,28]. Better Conversations, and CPT in general, has been adapted to a telehealth form of delivery. Beeke et al [29] introduced the term "teleCPT" to mean CPT delivered via videoconferencing technology. In this case study of a person living with primary progressive aphasia and his partner, the authors demonstrate that Better Conversations delivered via videoconferencing is effective, acceptable, and feasible to deliver. Furthermore, teleCPT can maximize the ecological validity and convenience of therapy [29]. Theodoros et al [30] suggest that telerehabilitation has particular potential to improve services for people with Parkinson's: it allows ready access to treatment, it supports the development of self-management skills, and people with Parkinson's express overall satisfaction with and support for telerehabilitation. There is, however, an absence of evidence exploring interaction-focused therapies or CPT delivered via telehealth (teleCPT) to people living with Parkinson's.

Summary

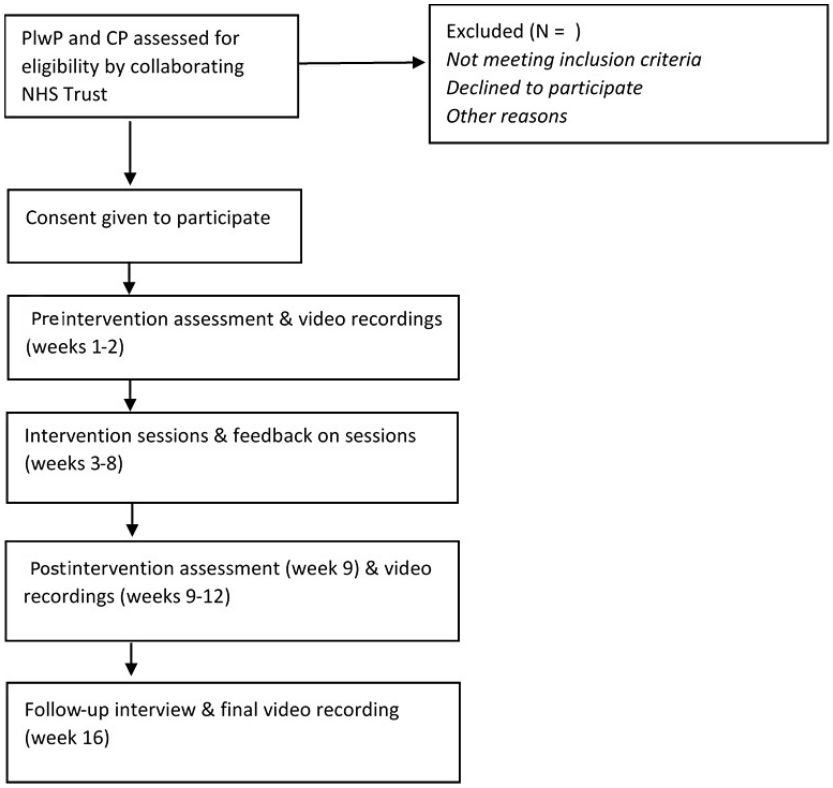
There is demand from people living with Parkinson's for speech and language therapy interventions that address broader aspects of communication beyond speech, involve family members, and consider psychosocial factors. However, there is limited evidence for CPT among people living with Parkinson's. CPT has been effective at improving communication participation for people living with other communication difficulties, and initial research suggests it is acceptable and may be beneficial for people living with Parkinson's [31]. This study presents the protocol for a pilot feasibility study of a Better Conversations CPT for people living with Parkinson's and their CPs, called Better Conversations with Parkinson's (BCP). Telehealth has been chosen as the primary method of delivery for this program due to the high levels of reported acceptability among this client group and its ability to increase access to therapy and support people within their everyday environment.

This feasibility study has been designed in line with Medical Research Council Guidance on developing complex interventions [32]. BCP has been under development through adaptation of existing Better Conversations interventions, identification of key mechanisms of behavioral change, and progressive refinement of the design through coproduction work. The program has been coproduced with people living with Parkinson's, family members, and expert SLTs. A steering group (of people living with Parkinson's, family members, and expert SLTs) was established to provide advice and feedback on all aspects of study management. This study addresses the feasibility phase of development by considering the evaluation design (recruitment, outcomes, and analysis) and the intervention (optimal content and delivery, acceptability).

Aim

The primary aim of this study is to evaluate the feasibility of the BCP program delivered via telehealth with a treatment group from a collaborating National Health Service (NHS) site to establish for a main trial whether BCP can be delivered as intended in an NHS setting.

Specifically, the aims are to establish (1) the acceptability of the program for people living with Parkinson's, family members, and SLTs; (2) the feasibility of delivering the BCP program; (3) the recruitment and retention rates; (4) a sample size calculation; and (5) the most appropriate primary outcome measure.



Methods

Design

This is a case-series feasibility pilot study of the BCP therapy program. Participants will be involved for 16 weeks: preintervention measures (weeks 1-2), intervention (weeks 3-8), postintervention measures (weeks 9-12), and a follow-up interview 4 weeks later (week 16). Figure 1 shows participant flow through the study.

XSL•FO
RenderX

Figure 1. Participant flow through the study. CP: conversation partner; PlwP: persons living with Parkinson's.

Setting

Participants will be recruited by SLTs at a collaborating NHS site located in England. Consent, preintervention measures, and delivery of the BCP intervention will be carried out by a research assistant (a specialist SLT by background; the first author) employed by the study sponsor. The collection of outcome measures and delivery of therapy will be done remotely (ie, via a computer, tablet, or smartphone). Participants will be offered a tablet device to take part in the therapy if required, although an existing internet connection will be required.

Population

The study includes adults (>18 years) with a diagnosis of Parkinson's and related communication difficulties and a chosen CP. Local collaborators (SLTs) at participating NHS sites will use medical notes and a case history to judge potential participants against the inclusion and exclusion criteria (Textbox 1).

XSL•FO
RenderX

Textbox 1. Participant inclusion and exclusion criteria.

Inclusion criteria

1. Being 18 years or older
2. Having a diagnosis of Parkinson's
3. Experiencing intelligibility or communication problems relating to Parkinson's
4. Having some ability to communicate and understand communication in order to participate in the Better Conversations with Parkinson's (BCP) program
5. Being able to see and hear well enough to participate in the program
6. Being functionally able to engage in the program (ie, able to maintain some concentration and remain in a 60-90 minute session; minimal challenging behavior so as to be unlikely to cause disruption)
7. Having English as their language of daily use
8. Having a conversation partner (CP) who is able to and consents to participating in the project
9. Being able and ready to actively participate in conversation therapy at the current time

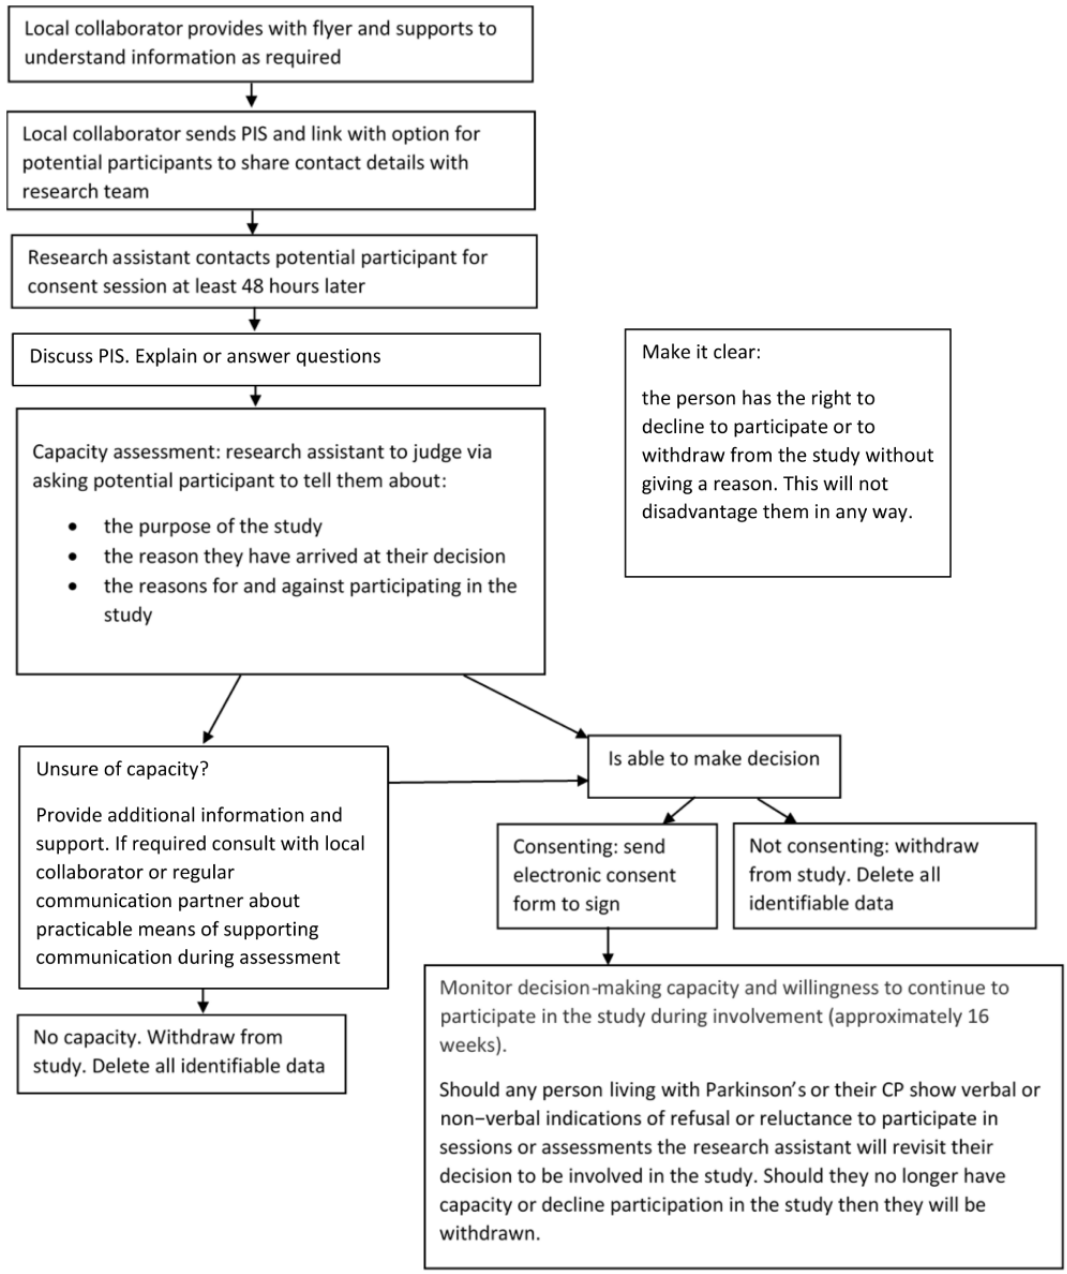
Exclusion criteria

1. Having a history of brain lesions or major head trauma
2. Having a major physical illness or disability that could impact participation
3. Present with a major psychiatric diagnosis
4. Present with prominent behavioral disturbances
5. Present with prominent episodic memory, visual memory, or visuo-perceptual impairments
6. Currently participating in active speech and language therapist (SLT) intervention that may conflict with BCP
7. Participating in or having recently participated in research which may conflict with BCP
8. Having no access to a Wi-Fi connection in order to be able to access BCP remotely

Identification and Recruitment

SLTs at a collaborating NHS Trust will be asked to identify potential participants using the inclusion and exclusion criteria (Textbox 1) and invite them to participate via a flyer. People who meet the inclusion criteria will not be under any obligation to take part in this study, and this will be made clear from the outset. Those who express interest will be given the participant information sheet (PIS) and sent an electronic link. Potential participants can use the link to indicate their consent to being contacted by the research team and to securely share their contact details. Potential participants will be contacted for consent to participate in the study at least 48 hours after receiving the PIS and sharing contact details.

Local collaborators will complete a log to record the number of people with a diagnosis of Parkinson's who do not meet the inclusion criteria and the number of people who are eligible but decline to participate, with their reasons why if provided. Participants will be reviewed by the local collaborator SLT after finishing the study. At this point, participants will resume routine speech and language therapy with the collaborating NHS Trust.



Ethics Approval

Ethical approval was granted by the London-Central Research Ethics Committee (reference 22/LO/0332). Figure 2 depicts the process of consent. Participants in the study are expected to be in the mild to moderate stages of Parkinson's and therefore likely to be competent to give informed consent to participate, provided that sufficient time is allowed for them to reach a decision. Those who are unable to give informed consent will not be able to take part in the study (see Figure 2). Informed consent will be obtained by the research assistant following the current guidance from the Mental Capacity Act [33], Royal College of Speech and Language Therapists guidelines [34], and Good Clinical Practice Standards [35]. The research assistant is a specialist SLT with considerable experience supporting people with communication impairments and issues related to obtaining consent. Potential participants will be given specialist support to understand the information sheets by the research assistant as required.

Participants will not be financially compensated for taking part in this study. All participant data will be deidentified where possible. Identifiable information will remain confidential and will be stored securely in line with the Data Protection Act 2018. See below for further information about data management.

XSL•FO
RenderX

Figure 2. Process of consent. CP: conversation partner; PIS: participant information sheet.

Sample Size Justification

The recruitment of participants will be dealt with pragmatically, within the scope of a small feasibility pilot study. Based on related research and discussions with clinicians at the collaborating NHS Trust, who estimate an active caseload of people living with Parkinson's of approximately 90 cases (inclusive of swallowing and communication difficulties), it is judged that it will be possible to identify and recruit 10-12 couples over a 6-month period. This allows for a slight overrecruitment to ensure 10 complete data sets.

Outcome Measures

Participants will complete preintervention speech, intelligibility, functional communication, and quality of life measures (Multimedia Appendix 1) with the research assistant in weeks 1-2 of the study. Questionnaires will be delivered via a mutually accessible platform (eg, Microsoft Teams or Zoom) or through an electronic questionnaire depending on participant choice, as recommended by the research steering group. Participants will be interviewed to establish a profile of their typical interactions [36], the types of problems with interaction they experience, how often these occur, and in what situations they arise. This will include the perspectives of the person living with Parkinson's and their CP. They will also complete a case history, a rating scale of Parkinson's symptoms, and a cognition and speech assessment to allow a description of relevant individual participant characteristics. This preintervention assessment protocol mirrors routine speech and language therapy practice. Furthermore, it provides the opportunity for the research assistant to build rapport with participants before delivering the intervention.

After intervention, measures (Multimedia Appendix 1) will be repeated (weeks 9-12). These assessments will contribute to the identification of a primary outcome measure for a future trial,

XSL•FO
RenderX

if this is warranted. Final follow-up interviews and the Better Conversations Self Rating Scale will take place 8 weeks after treatment to understand long-term acceptance and the impact of the intervention. This will include the perspectives of both the person living with Parkinson's and their CP. Repeated measures and the follow-up interview will be conducted by junior researchers (student SLTs) with training and support from the chief investigator and research assistant.

Each dyad will be supported to video-record themselves in natural conversation for 15 minutes, 3 times before and 3 times after intervention. They will be recorded via a laptop or tablet by a member of the research team using a mutually accessible platform (eg, Zoom or Microsoft Teams). The team member will set up the remote meeting, start the recording, and then turn off their camera and microphone to leave the dyad to talk unobserved. If the dyad requires it, a list of conversation topics will be provided to support this process. This form of remote data collection replicates methods used in previous teleCPT and Better Conversations research [29] and is designed to facilitate ease of data collection and security of data transfer. The timescales of sample video recordings are shown in Table 1.

Table 1. Schedule of conversation sample recordings.

	Consent session	Preintervention assessment	BCP[a] intervention (6 weeks)	Postintervention assessment	Final data collection	Follow-up interviews or rating scales
Week (expected timescale)	0	1-2	3 -8	9	10-12	16
Conversation sample recording	N/A[b]	1, 2, and 3	N/A	4	5 and 6	7

[a]BCP: Better Conversations with Parkinson's.

[b]N/A: not applicable.

Intervention

The BCP program is described in Multimedia Appendix 2, using the Template for Intervention Description and Replication (TIDieR) checklist. BCP is based on the principles of a Better Conversations approach to CPT [21] and is the first of its kind to meet the specific needs of people living with Parkinson's. It has been coproduced by people living with Parkinson's and SLTs who are experts in this area. Participants' preintervention video-recorded conversation samples will be used to provide short clips for video feedback during intervention sessions. Each member of the dyad will identify personal goals depending on their conversation challenges, but each session's objectives, activities, and types of feedback are manualized. The approach is underpinned by the COM-B model of behavior change [37] and is designed to target behavior change techniques from the Behavior Change Techniques Taxonomy [38], in particular those reliably identified as active ingredients in Better Conversations with Aphasia [39]. The BCP intervention will be administered by the research assistant.

Evaluation of Acceptability

The acceptability of the intervention and study procedures will be evaluated qualitatively. Online anonymous questionnaires submitted after each therapy session will obtain the participants' views and experiences of session delivery, objectives, and activities. Semistructured interviews will be conducted by junior researchers 8 weeks postintervention to explore acceptability, including participant attitude toward and experience of the intervention; the impact of the intervention on activity, participation, and well-being; what participants perceive to be the barriers and enablers to implementing strategies from the intervention; what participants valued about the intervention; and what changes participants might suggest to the intervention. Additionally, the research assistant administering the intervention will complete a reflective diary and feedback questionnaires on the experience of delivering therapy, whether sessions met expectations, adaptations required to sessions, and the perceived helpfulness of therapy for the dyad. This data will be analyzed by junior researchers to enhance objectivity.

Evaluation of Feasibility

Feasibility will be evaluated by collecting data on the following: recruitment and retention rates; time required to recruit to target; attrition rates; feasibility of pre- and postintervention assessment and data collection methods, including completion rates; adverse events.

Data Management

The study is compliant with the Data Protection Act 2018. All personal information (contact details, date of diagnosis, medical and social history) will remain confidential. Each participant will be given a unique research number, which will be used on all paperwork, in the names of video files and electronic records (eg, assessment data), and in analysis documents and subsequent publications. All data will be stored securely on Data Safe Haven, in accordance with the Data Protection Act 2018 and the sponsor's data protection policy.

Video recording of conversation samples between dyads is required as an outcome measure and for video feedback during the intervention. Participants will consent to being video recorded for these purposes. Faces are required to be visible for detailed analysis of the video recordings, as natural human communication is the focus of the intervention being piloted. Only the research team will have access to the full video-recorded data set. Participants will be given the choice to opt in or out of the additional use of short extracts of video recordings for presentations about the research to professional audiences, teaching purposes, and as part of an online therapy resource. It is made clear in the PIS that there are risks of being recognized, and participants will be given a choice as to whether videos are masked (voice and image altered to reduce

XSL•FO
RenderX

recognizability) if used for these purposes. They can opt out of videos being used in this way at any point during the study.

No data management committee will be established as it is felt that this short, small-scale pilot carries minimal risks. If any information is disclosed by the participant that leads the chief investigator to believe that a participant is at risk of harm or harming others, then confidentiality will be broken to ensure the safety of the person or people involved.

Data Analysis

Quantitative and qualitative methods will be used to analyze the study data. Descriptive statistics will be used to report on recruitment, attendance, and attrition. Recruitment and retention rates will be used to support sample size calculations to inform a future full trial and plan the required number of sites to meet this target. To inform a sample size calculation, the mean pre- and postintervention scores, a mean change score, 95% CIs, and SDs will be calculated for each outcome measure. The mean change scores and standard deviations will be entered into the G*Power software, and an effect size will be calculated; this will then inform a 2-tailed sample size calculation for each measure.

Recordings of adverse events and participant feedback will be used to inform future recruitment procedures. The analysis of acceptability data will be based on participant feedback forms, interviews, and adherence data. This data will be analyzed using descriptive statistics and reflexive thematic analysis [40].

Speech, communication, and quality of life assessment data will be entered into a database and analyzed using SPSS (IBM Corp). This information will be used to determine a suitably sensitive outcome measure for a next-stage clinical trial, should this be warranted. Conversation outcomes will be captured using a procedure developed for Better Conversations with Aphasia to identify changes in the use of targeted strategies following intervention [23]. This will involve analysis of frequency counts of barrier and facilitator behaviors linked to people's personal goals for intervention in 5-minute video samples selected from the midpoint of each of 6 pre- and postintervention conversation samples. We hypothesize that dyad management of problems with intelligibility (repair) may be a key site of conversation change. Intelligibility problems typically involve both speakers in a dyad over a series of conversational turns [41]. Given this, a secondary evaluation of conversation data will be conducted using Conversation Analysis [42].

Criteria for Success

The study will be considered appropriate for a next-stage clinical trial evaluating the intervention if (1) the intervention is acceptable to people with Parkinson's and their CP, (2) the intervention is feasible to deliver for the SLT, (3) a suitable sensitive outcome measure is identified, and (4) an appropriate sample size is estimated.

Assessment and Management of Risk

This is a low-risk study. There is a possibility that participants will not experience improvements in their communication, well-being, or quality of life as a result of the intervention. However, there is no evidence to indicate that participants will experience harmful side effects, and the intervention has been coproduced with people living with Parkinson's and expert SLTs to maximize acceptability and relevance. There is evidence to suggest that this kind of intervention is effective at improving communication for adults with other communication difficulties and their partners.

Most assessments and procedures, such as videoing, are routinely used in speech and language therapy clinical practice. It is possible that distress may arise from discussions of communication difficulties and from measures or therapy tasks highlighting existing problems in conversation. The research assistant carrying out the intervention is a highly trained SLT with the ability to manage sensitive situations. The risk of distress is expected to be balanced by the opportunity to discuss communication strengths and strategies, as well as the enjoyment in targeted conversation time with a nominated partner. The process of being recorded on video and watching yourself on video can be confronting. The coproduction group (including people living with Parkinson's, their family members, and specialist SLTs) advised on how to introduce video to participants, so that as far as possible, participants are familiarized with the process and understand why video is vital to changing conversation behavior in a Better Conversations approach.

All study procedures are outlined in the PIS, which has been designed with support from people living with Parkinson's and their partners. Participants will be reminded that they can withdraw from the study at any time. Any adverse events will be recorded in the participant's medical record, and the study sponsor will be informed.

Results

This study was approved for funding from Parkinson's UK in December 2020 following peer review of the proposal by an independent committee (Multimedia Appendix 3). This study was approved for funding from Parkinson's UK in December 2020. Study recruitment commenced in July 2022. The results of the data analysis are expected to be available by September 2024.

Discussion

To the authors' knowledge, this is the first study to investigate a remotely delivered CPT approach for people living with Parkinson's. This study outlines the protocol for the study with the aim of evaluating the acceptability of the BCP program for people living with Parkinson's, family members, and SLTs, and the feasibility of delivering the BCP program in collaboration with an NHS site. The study aims to identify a sample size calculation, recruitment and retention rates, and the most appropriate primary outcome measure to guide the future development of the BCP intervention.

This study involves the adaptation of the Better Conversations approach to CPT for a new client group. There is evidence that a Better Conversations approach reduces barriers to conversation and can increase the use of facilitatory strategies [23]. This study also builds on previous research by Forsgren et al [20]

XSL•FO
RenderX

by further investigating a CPT approach for people living with Parkinson's and, in addition, trialing teleCPT, therefore using a form of delivery that has been found to be highly acceptable for this client group [30]. Despite psychosocial and language issues being flagged as an important reason for referral for people living with Parkinson's, the evidence base and SLT clinical practice are predominantly focused on swallowing, voice, and articulation [5]. This program has the potential to address psychosocial factors and communication difficulties beyond speech and, therefore, fill a gap in research and current clinical practice.

CPT has been shown among other client groups to enhance communication and participation [11] and result in changes to CPs' knowledge, skills, and attitudes [14,15]. This study will provide valuable information about the sensitivity of measures in these areas for capturing CPT outcomes for people living with Parkinson's and CPs. Additionally, this research will provide valuable information about the acceptability and feasibility of the Better Conversations approach for people living with Parkinson's and their CPs. An outcome of this study will be a manualized BCP program coproduced by people living with Parkinson's, their families, and a group of expert SLTs and adapted following the feedback of this study's participants.

The outcomes of this study will be used to guide future phases in the development of the BCP intervention, as per Medical Research Council guidance for developing and evaluating complex interventions [32]. For example, given that this study investigates BCP delivered via telehealth, a future phase of research may compare face-to-face and telehealth delivery. A longer-term aim is to create a freely accessible intervention resource for the benefit of people living with Parkinson's and SLTs working with them.

Limitations

As a small-scale feasibility study with 10-12 dyads from 1 NHS site, the study is limited in scope. The study will therefore not seek to evaluate effectiveness or to generalize results beyond the participants. As a case-series study, which aims to describe the characteristics and outcomes at an individual level of a group of participants with Parkinson's, this study does not include a control group. The results of the study will guide future phases of research into the BCP intervention, which if appropriate may involve a randomized controlled trial design.

A possible risk is a lack of diversity due to recruiting from 1 geographic area and an SLT caseload. Ascertainment bias is also possible: outcomes may be affected by factors (eg, socioeconomic status and cultural and linguistic barriers) that might be limiting access to the local speech and language therapy service. Despite the provision of a device to access the research, exclusion is possible as a result of digital poverty due to the requirement to have an internet connection to take part. Due to resource limitations, the research assistant will carry out the initial assessment and intervention. There is a risk that participants will not feel able to be completely open with feedback following each therapy session as the SLT delivering therapy is a member of the research team. The postintervention assessment and follow-up interviews will be completed by trained junior researchers to ensure that they are unaware of premeasure values and to provide an opportunity for participants to provide feedback they might not want to disclose to the SLT research assistant.

Personalization is a key element of this therapy approach. The coproduction group, which involves people with Parkinson's and SLTs, has created a core set of activities and session plans to be used across all participants but has confirmed that personalization is essential. It is recognized that tailoring the intervention to different dyads and their goals may result in variation in the types of strategies identified and practiced; however, the session objectives, activities, and feedback tasks will be the same for all.

Dissemination

The authors aim to disseminate the results of this study in peer-reviewed scientific journals and via presentations at academic and clinical conferences. Results will also be disseminated via user group publications and will be publicized via the BCP Twitter account and Better Conversations web pages. Opportunities to disseminate outcomes of the study to people living with Parkinson's, SLTs, and researchers will be created through university and NHS Trust links and supported by the study steering group.

Conclusions

This study will provide valuable information about the acceptability and feasibility of BCP—a CPT approach for people living with Parkinson's and their CPs—delivered via telehealth. Outcomes of this study will include a manualized BCP program coproduced by people living with Parkinson's, their families, and expert SLTs, which will be refined based on feedback from study participants. The study results will guide the next phases of intervention development, with the long-term aim of creating a freely accessible intervention resource for SLTs to use with people living with Parkinson's and their regular CPs.

Acknowledgments

The authors acknowledge and thank all the steering group and coproduction group members who consulted on the development of the protocol, coproduced the participant information sheets and consent forms, and coproduced the Better Conversation with Parkinson's intervention program. We would also like to thank the local collaborators and participants at the National Health Service Trust for participating in the study. This study has been funded by Parkinson's UK (grant reference: H-2001) and is sponsored by the University College London Joint Research Office.

Abstract

Background: The intensive care unit (ICU)–ward transfer poses a particularly high-risk period for patients. The period after transfer has been associated with adverse events and additional work for care teams related to miscommunication or omission of information. Standardized handoff processes have been found to reduce communication errors and adverse patient events in other clinical environments but are understudied at the ICU-ward interface. We previously developed an electronic ICU-ward transfer tool, ICU-PAUSE, which embeds the key elements and diagnostic reasoning to facilitate a safe transfer of care at ICU discharge.

Objective: The aim of this study is to evaluate the implementation process of the ICU-PAUSE handoff tool across 10 academic medical centers, including the rate of adoption and acceptability, as perceived by clinical care teams.

Methods: ICU-PAUSE will be implemented in the medical ICU across 10 academic hospitals, with each site customizing the tool to their institution's needs. Our mixed methods study will include a combination of a chart review, quantitative surveys, and qualitative interviews. After a 90-day implementation period, we will conduct a retrospective chart review to evaluate the rate of uptake of ICU-PAUSE. We will also conduct postimplementation surveys of providers to assess perceptions of the tool and its impact on the frequency of communication errors and adverse events during ICU-ward transfers. Lastly, we will conduct semistructured interviews of faculty stakeholders with subsequent thematic analysis with the goal of identifying benefits and barriers in implementing and using ICU-PAUSE.

Results: ICU-PAUSE was piloted in the medical ICU at Barnes-Jewish Hospital, the teaching hospital of Washington University School of Medicine in St. Louis, in 2019. As of July 2022, implementation of ICU-PAUSE is ongoing at 6 of 10 participating sites. Our results will be published in 2023.

Conclusions: Our process of ICU-PAUSE implementation embeds each step of template design, uptake, and customization in the needs of users and key stakeholders. Here, we introduce our approach to evaluate its acceptability, usability, and impact on communication errors according to the tenets of sociotechnical theory. We anticipate that ICU-PAUSE will offer an effective handoff tool for the ICU-ward transition that can be generalized to other institutions.

Introduction

Background

The transition of a hospitalized patient from the intensive care unit (ICU) to the inpatient ward is a particularly high-risk period for the patient recovering from critical illness due to their medical complexity and often residual diagnostic uncertainty. Although transfer from the ICU is indicative of clinical improvement, this process encompasses changes in clinical environments, medical personnel, and reduced monitoring capacity. These complex patient transfers are vulnerable to provider miscommunication, which increases the risk of preventable medical errors and ICU readmissions [1-3]. The transition between medical teams is also distressing for patients and their families, particularly when there is poor communication with and among medical providers [1,4]. Although standardized practices and structured handoff tools reduce these errors and associated negative outcomes [5], these approaches are surprisingly understudied during this high-risk ICU-ward transition [6,7], which remains vulnerable to nonstandard and suboptimal practices [8].

A recent study of several teaching hospitals demonstrated high rates of communication errors—both those of commission and omission—and associated harms, including unplanned ICU readmissions, care delays, medication errors, missed results, and patient and family distress [9]. Residents compensated for suboptimal ICU-ward handoffs by recovering omitted information through the chart review, history-taking, duplicating previously completed tasks, or calling the ICU to clarify information; these inefficiencies and documentation burdens compete for trainee time that could otherwise be spent on patient care and education [2]. Prior studies demonstrate notable gaps in information that is reported by ICU providers and what is understood by ward providers, emphasizing the need for standardized written communication that accompanies the patient during the entire transfer process and mitigates the loss of essential clinical information [10].

These issues indicate the clear need for an evidence-based, standardized ICU-ward transfer tool. Given the variation in ICU systems across medical centers, successful implementation and sustainability of an ICU-ward handoff tool requires user-engaged design with potential institution-specific adaptations. Accordingly, we used human-centered design methods across multiple internal medicine residency programs to create and iteratively prototype a structured ICU-to-ward transfer tool embedded within the electronic health record (EHR) [11]. This template, ICU-PAUSE, comprises the following elements: brief ICU course and reason for admission (I), code status and goals of care (C), uncertainty of working diagnosis and diagnostic pause (U), pending tests (P), active consultants (A), deprescribing unnecessary medications and reviewing pertinent high-risk medications (U), summary of problems and uncompleted tasks (S), and exam at the time of transfer (E) [12].

The ICU-PAUSE handoff tool was piloted in the medical ICU at Barnes-Jewish Hospital (BJH) in 2019 and 2020, and will be implemented across 10 academic hospitals, with each site permitted to customize the tool to institution-specific needs. This mixed methods study will evaluate the feasibility and perceived impact of the novel EHR-embedded ICU-ward transfer tool, ICU-PAUSE, on communication failures and medical errors during the transfer of patients from the ICU to the inpatient ward.

Study Aims and Objectives

This mixed methods study will evaluate the feasibility, acceptability, and perceived impact of a novel EHR-embedded transfer tool, ICU-PAUSE, on communication failures and medical errors during the ICU-ward transfer process. Our specific aims are as follows.

Aim 1

Evaluate the feasibility, acceptability, and adoption of implementing ICU-PAUSE into the ICU-ward physician transfer workflow in a diverse group of hospitals.

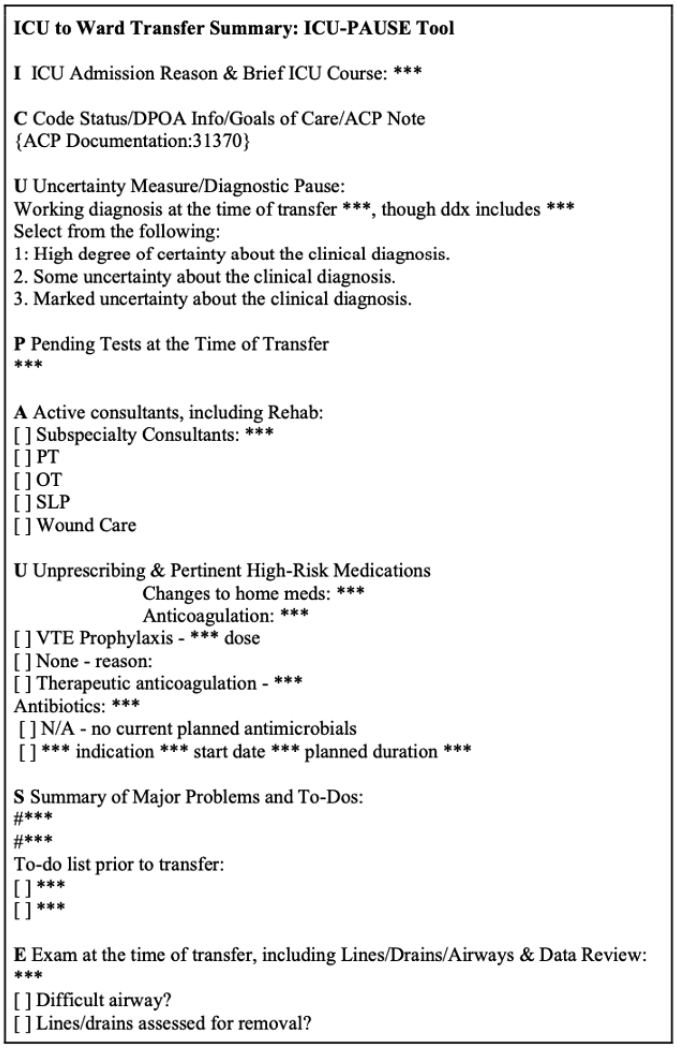
Informed by the Consolidated Framework for Implementation Research (CFIR) model and Sittig and Singh's [13] sociotechnical theory [14], we will conduct quantitative surveys and semistructured interviews of faculty champions and resident trainee stakeholders from multiple institutions that have implemented ICU-PAUSE. Our thematic analysis will be based on dimensions of the sociotechnical model, which offers a framework to evaluate interdependent factors within complex ICU-ward workflows [13]. We aim to elicit perceptions of feasibility, informatics resource needs and constraints, barriers and facilitators to implementation, and cultural changes in safety surrounding ICU-ward handoffs. We will also perform a chart review of ICU-ward transfer notes to assess the frequency of ICU-PAUSE utilization as a measure of adoption.

Aim 2

Examine the perceived impact of ICU-PAUSE on communication failures and associated medical errors during ICU-ward transfers among internal medicine residents, ICU physicians, and ward physicians.

We will conduct quantitative surveys of postgraduate year 2 (PGY-2) and PGY-3 internal medicine residents, ICU attending physicians, and ward attending physicians (n=175) to assess the frequency of self-reported miscommunication events, medical errors, and adverse outcomes during ICU-ward handoffs after the implementation of ICU-PAUSE. We will compare these findings with previously collected preimplementation surveys [9].

XSL•FO
RenderX



This study will provide new evidence on potential best practices for implementation of a novel handoff tool in ICU discharge. ICU-PAUSE can potentially decrease communication failures in the ICU handoff process and be disseminated for adaptation to institution-specific needs, providing a valuable evidence-based transfer tool for ICU systems at other academic medical centers.

Methods

Context

Poor handoff communication between ICU and ward teams may result in unfavorable outcomes: studies have shown that standardization of communication during the handoff process reduces preventable medical errors [5]. We aimed to address the challenges that emerge during the ICU-ward transition period as a result of poor communication between ICU and ward providers by creating a standardized written handoff tool. The ICU-PAUSE handoff tool was developed between July 2019 and July 2020 and contains the key information to facilitate a safe transfer of care as identified through focus groups of residents (Figure 1) [12]. ICU-PAUSE will be integrated into the EHR and implemented into medical ICUs at the following sites between March and August 2022: Cedars-Sinai Medical Center, Kaiser Permanente Oakland Medical Center, Ohio State University, Penn State Health Milton S. Hershey Medical Center, Rutgers University, University of Chicago (UC), University of Iowa Hospitals and Clinics, University of Kentucky, and University of California-San Francisco (UCSF). Each site has a faculty champion, defined as an intensivist who has intimate knowledge of the ICU workflow and who will participate in an education session of the ICU-PAUSE tool to facilitate its implementation at their respective academic institutions. The ICU-PAUSE tool has been in use at our pilot site, BJH (the teaching hospital of Washington University School of Medicine in St. Louis [WUSM]) since late 2019 and is now the standard transfer summary documentation at this hospital.

Study Design

This convergent mixed methods implementation study will use (1) quantitative surveys, (2) a retrospective chart review, and (3) qualitative semistructured interviews to explore the feasibility and perceptions of ICU-PAUSE after implementation at multiple sites [16]. Participants will include internal medicine residents, ICU attending physicians, and ward attending physicians in medical ICUs and inpatient wards across 10 academic medical centers. ICU residents and attendings who make the decision for patient transfer will compose their transfer note using the ICU-PAUSE tool, which will be received by residents and ward physicians on the inpatient wards team. Participants of the quantitative surveys will be recruited by email invitation to a web-based survey platform. Participants of the qualitative interviews will be contacted directly by the research team. For the quantitative arm of this study, we will survey residents, ICU physicians, and ward physicians at least 3 months after successful implementation of the ICU-PAUSE tool at their respective sites. A preimplementation survey of resident trainees was already conducted at UC, UCSF, and WUSM during the 2015-2018 academic years to evaluate the frequency of communication gaps and medical errors related to ICU-ward transfers [9]. We will re-administer this survey across all sites in the postimplementation period to compare survey responses from before and after the implementation of ICU-PAUSE. We will conduct a retrospective chart review of all ICU transfer notes within a 60-day period to evaluate the rate of tool uptake. For the qualitative component of this study, we will conduct pre- and postimplementation interviews of faculty champions who will facilitate implementation at their sites, as well as postimplementation interviews of residents and ICU physicians who have used the tool. The qualitative component of this study will complement our quantitative data by capturing stakeholder experiences surrounding the implementation process that may not be captured within the survey responses. This convergent mixed method approach will allow us to quantify the feasibility and acceptability of the ICU-PAUSE tool while also qualitatively assessing user experiences with the tool using the established implementation frameworks of CFIR and sociotechnical theory [13,14,17].

Conceptual Framework

This study is informed by sociotechnical theory, which offers a paradigm for studying health information technology innovations [13]. The CFIR also provides the basis of our quantitative analysis to evaluate the implementation of ICU-PAUSE [14]. We will use these theoretical frameworks to evaluate ICU-PAUSE at both the user-technical interface and along constructs known to impact the success of implementation [18].

Participants' Inclusion and Exclusion Criteria

Aim 1 participants will include 1 faculty champion and 1 stakeholder (PGY-2 or PGY-3 internal medicine resident trainee or ICU attending physician) from each participating institution. Faculty champions have been identified a priori by word of mouth and will serve as key informants for identifying additional stakeholders for participation. Each faculty champion is an intensivist with an intimate understanding of the ICU-ward transfer workflow and will facilitate ICU-PAUSE implementation at their respective sites. The faculty champions from UC and UCSF, which we will refer to as lead sites, originally conceived of the ICU-PAUSE tool and will therefore be excluded from participation in any surveys or interviews. WUSM's faculty champion at our pilot site was not directly involved in ICU-PAUSE development and will thus provide "early adopter" perspectives in this aim [19]. The remaining participating institutions will implement ICU-PAUSE between March and July 2022 and will be referred to as validation sites.

Aim 2 participants include all PGY-2 and PGY-3 internal medicine residents, ICU attending physicians, and ward attending physicians at all participating sites. PGY-1 residents will be excluded from the study because they infrequently hold primary responsibility for ICU-ward transfer communication at our institutions [9]. Key informants at each site will recruit survey participants, with no specific exclusion criteria.

Intervention

There are 2 components to the intervention: an educational component and the ICU-PAUSE tool. In the educational component, the UCSF faculty champion conducts a 1-hour educational session on ICU-PAUSE implementation with the faculty champion from each participating site. The structured sessions entail discussing the rationale for the tool, describing how ICU-to-ward transitions are high-risk times for patients, walking through the template in detail, giving examples of template use, and answering questions. Once the educational component is completed, the ICU-PAUSE tool is made available as an EHR "dot-phrase" template that will be recreated at each site by the faculty champion (Figure 1). Local champions further the dissemination at the local site through a combination of educational sessions and flyers/handouts provided by the central ICU-PAUSE team. Adaptations will be noted and codified using the Framework for Reporting Adaptations and Modifications-Expanded (FRAME) method of tracking adaptations in our postimplementation interviews [20].

Outcomes

The primary outcome in aim 1 will be the proportion of ICU-ward transfers for which a transfer note is written using the ICU-PAUSE template. Secondary outcomes will be perceptions of acceptability, appropriateness, and feasibility of ICU-PAUSE (as measured by the Acceptability of Intervention Measure [AIM], Intervention Appropriateness Measure [IAM], and Feasibility of Intervention Measure [FIM]) [21], perceived resource needs or constraints, and barriers or facilitators to implementation.

In aim 2, the primary outcome will be self-reported communication failures, the frequency of which will be compared with baseline preimplementation surveys. Secondary outcomes will include the perceived frequency of medical errors and self-reported time spent on tasks related to ICU-ward transfers.

XSL•FO
RenderX

Data Collection

We conducted preimplementation semistructured interviews (n=7) and surveys (n=7) with the faculty champion from each validation site in October and November 2021.

In aim 1, we will re-administer the preimplementation survey to collect postimplementation responses from the same cohort of faculty champions. Survey questions are based on AIM, IAM, and FIM outcome measures to assess the acceptability, appropriateness, and feasibility of the ICU-PAUSE implementation along a 5-point Likert scale (Table 1) [21]. Surveys will be collected using Qualtrics web-based software.

Concurrently, we will conduct a retrospective chart review of patients (n=300) who were transferred from the ICU to inpatient wards between August and October 2022 across all sites. Outcome variables on patient demographics, provider demographics, and note template type will be extracted from ICU-ward transfer notes (Table 2). The adapted ICU-PAUSE template indicates use of the ICU-PAUSE tool with user modifications (Figure 1), whereas the non–ICU-PAUSE template refers to an ICU transfer note that uses any other pre-existing note template. Free text refers to a transfer note written without the use of any template. Each faculty champion will conduct a chart review at their respective institutions. Two co-investigators will independently review and compare a subset of 10 charts to ensure consistency in data collection.

Finally, we will repeat 45-minute semistructured interviews with each faculty champion, along with one additional internal medicine resident or ICU attending physician, for a total of 2 interviewees from each institution (n=14). The postimplementation interviews with the faculty champion will be used for comparison against the preimplementation interviews conducted with the same individual. Interviews with residents and ICU physicians who were not involved in the implementation process will provide an unbiased perspective on barriers or facilitators of ICU-PAUSE implementation. All interviews will be conducted via videoconference by the faculty champion at UCSF [22]. The interview guide was previously developed based on sociotechnical theory and will explore the following key constructs (Table 3): perceptions of usefulness, resource needs and constraints, barriers and facilitators to implementation, culture of safety, and adaptations [13,23]. Interviews will capture any adaptations to the ICU-PAUSE tool based on the FRAME method, such as the timing, participants, and nature of each modification [20]. All interviews will be audiorecorded with participant consent and transcribed verbatim.

In aim 2, we will conduct a postimplementation survey across all 10 sites to assess the frequency of communication failures, handoff errors (eg, rehabilitation needs and intravenous access), and time spent on tasks related to ICU-ward transfers (Table 4). The survey is identical in content to a preimplementation survey of internal medicine residents conducted at BJH, UC, and UCSF in our prior study, which characterized types of miscommunication errors in ICU-ward handoffs [9]. The survey will be administered to house officers, ICU physicians, and receiving ward physicians (n=175). The sample size is based on our work with the preimplementation cohort, and we will aim for at least 30% respondents at each site for the postimplementation surveys [9].

All faculty champions have connections with the internal medicine residencies and will similarly facilitate survey recruitment of residents and attendings at their respective sites. From August to October 2022, we will collaborate with chief residents to recruit PGY-2 and PGY-3 residents who are currently rotating on ICU. As residents rotate through ICU at different months of the academic year, we will email residents to complete the anonymous Qualtrics survey at the conclusion of their ICU rotation. Two follow-up emails will be sent 1 week later and 2 weeks later to maximize the response rate. The faculty champion will also email all ICU and ward attending physicians to complete the Qualtrics survey.

Table 1. Survey measures of faculty champions and stakeholders.

Survey components[a]	Examples of survey items
Acceptability of ICU[b]-PAUSE intervention	• The ICU-PAUSE implementation strategy meets my approval • The ICU-PAUSE implementation strategy is appealing to me
Appropriateness of ICU-PAUSE intervention	• The ICU-PAUSE implementation strategy seems applicable • The ICU-PAUSE implementation strategy seems suitable
Feasibility of ICU-PAUSE intervention	• The ICU-PAUSE implementation strategy seems implementable • The ICU-PAUSE implementation strategy seems possible

[a]Each survey component is graded along the Likert scale (on a scale of 1 to 5): strongly disagree (1), disagree (2), neither agree nor disagree (3), agree (4), strongly agree (5).

[b]ICU: intensive care unit.

XSL•FO

Table 2. Chart review data extraction from ICU[a]-ward transfer notes.

Outcome variables	Items
Patient demographics	• Age • Sex/gender identity • Race
Provider demographics	• Resident • Fellow • ICU attending physician
Transfer note template	• ICU-PAUSE template • Adapted ICU-PAUSE template • Non–ICU-PAUSE template • Free text

[a]ICU: intensive care unit.

Table 3. Postimplementation semistructured interview measures.

Key concepts	Examples of interview questions
Background and current activities	• What are the current efforts related to how handoffs occur when patients are being transferred from the ICU[a] to the ward?
Perceptions of usefulness	• How is the ICU-PAUSE framework helpful to you in improving the transition of care from the ICU to the ward?
Resource needs and constraints	• What resources, personnel, informatics resources, etc. were necessary for you to implement the ICU-PAUSE framework and make this process actionable?
Barriers and facilitators	• What were challenges for you to implement and meaningfully use the ICU-PAUSE framework? • What might be the methods for measuring success?
Culture	• How did the ICU-PAUSE framework change ideas of safety surrounding transition of care from the ICU to the ward?
Adaptations	• Were there adaptations or modifications to the ICU-PAUSE framework at your institution? • When did the modification occur? • Were adaptations planned? • Who participated in the decision to modify?

[a]ICU: intensive care unit.

Table 4. Survey measures of internal medicine residents, ICU[a] physicians, and ward physicians [9].

Survey measures	Survey items
Provider demographics	• Role (PGY-2[b] resident, PGY-3 resident, ICU fellow, ICU attending physician, or ward attending physician) • Age • Gender identity • Geographic region (Northeast, Midwest, South, West)
Frequency of omission or miscommunication of information in ICU-ward transfer note[c]	• Rehabilitation (physical therapy/occupational therapy) needs • Intravenous access and other indwelling hardware • Risk assessment for ICU readmission • Pending results • Nutrition (per oral status, diet orders) • Intravenous fluids • Antibiotics • Pain medications • Insulin needs • Venous thromboembolism prophylaxis and anticoagulation • Vital signs • Oxygen needs • Mental status • Delirium concerns • Goals of care • Health care decision-maker information
Frequency of adverse outcomes as a result of ICU-ward handoff[c]	• Missed results • Medication errors • ICU readmission • Rapid response activation • Delayed discharge • Patient lost in hospital • Upset family • Patient death
Time spent performing tasks related to ICU-ward handoff[d]	• Writing transfer note • Conducting handoff • Chart review and order placement after handoff • Repeating previously completed patient tasks • Recovering information that should have been delivered at handoff • Receiving handoff on an ICU patient who does not ultimately transfer

[a]ICU: intensive care unit.

[b]PGY: postgraduate year.

[c]Likert scale: Never (1), Rarely (<5 times/year) (2), Sometimes (~2 times/month) (3), Often (at least once weekly) (4), Always (nearly every handoff) (5).

[d]Likert scale: <15 minutes (1), 15-30 minutes (2), 30-60 minutes (3), 60-90 minutes (4), >90 minutes (5).

Sample Size Considerations

As per best practices in human-centered design and qualitative inquiry, we have designed this study to include a sufficient number of stakeholders to capture essential design information and attain thematic saturation [24]. At the end of each interview, we will ask stakeholders if they have other stakeholder interviewees to suggest in a snowball-sampling style methodology to ensure that we have had the opportunity to hear new ideas from multiple participants.

Analysis

For quantitative data, we will use descriptive statistics including frequencies, proportions, and measures of central tendency to compare pre- and postimplementation uptake, acceptability, and feasibility of ICU-PAUSE (Tables 1 and 2). We will also compare pre- and postimplementation surveys of self-reported communication failures, handoff errors, and time spent on ICU-ward transfers (Table 3) [9]. Pre- and postimplementation survey data will be compared using paired *t* tests. We will also evaluate for nonresponse bias by comparing the demographic data and survey responses of early respondents and late respondents, under the assumption that late respondents are similar to nonrespondents [25]. Early respondents are defined as participants who complete the survey within the first 2 weeks, whereas late respondents are those who complete the survey after a third reminder email is sent at 2 weeks [26]. Data analysis will be performed with Stata 17; *P* values less than .05 will be considered statistically significant.

We will analyze deidentified interview transcripts according to a deductive approach and perform thematic analysis independently on transcripts of preimplementation interviews and postimplementation interviews [27]. A coding framework rooted in the 8 dimensions of sociotechnical theory has been

XSL•FO
RenderX

developed along the following codes: hardware and software, clinical content, human-computer interface, people, workflow and communication, internal organizational features, and external rules and regulations [13]. Along with the codes derived deductively from sociotechnical theory, we will include any codes that emerge inductively from the data in our final codebook. Two independent investigators will code the transcripts using Dedoose software (Dedoose). We will compare and resolve any coding discrepancies through an iterative process to achieve final consensus. Coded excerpts of the transcripts will be compiled to identify salient themes related to before and after ICU-PAUSE implementation.

Researcher Reflexivity

The primary investigator of this study is a stakeholder in the development of ICU-PAUSE and will be conducting the faculty champion interviews. Two medical student co-investigators will observe the interviews for any bias, and we will regularly meet to discuss how personal or professional biases may impact the interviews and qualitative analysis during our deductive process.

Ethical Considerations

We have received exemption by the institutional review board (IRB) to conduct the survey and interview arms of this study. We will apply for new IRB approval before conducting the chart review. Qualitative and quantitative data will be deidentified to ensure confidentiality. Informed consent for interview participation will be obtained verbally, whereas informed consent for survey participation will be embedded into the Qualtrics survey. Given that the outcome of ICU-PAUSE implementation impacts patient care and safety, we will cease implementation if responses reveal compromised patient safety.

Results

We have already established proof of concept with the execution of ICU-PAUSE at our pilot site, BJH, in late 2019. As of July 2022, implementation of ICU-PAUSE is ongoing at all lead sites and validation sites. We intend to complete the study in mid-2023 and publish our results in the second half of 2023. We expect to identify the factors that facilitate and impede implementation of ICU-PAUSE, as well as a reduction in the frequency of communication failures related to ICU-ward transfers.

Discussion

Currently available handoff tools [5] are informed by external resources and conceptual models [28] and lack the necessary elements to facilitate a safe transfer of information at the ICU-ward interface. These elements were identified and incorporated into our user-engaged creation of ICU-PAUSE, a novel clinical template specific to the ICU-ward transition [12]. Here, we aim to evaluate its acceptability, usability, and impact on communication errors using CFIR and sociotechnical theory [13,14]. Our work is innovative by centering the iterative process of template design [12], uptake, and customization in the hands of users who will implement ICU-PAUSE according to their institution's needs. We anticipate that ICU-PAUSE will offer an acceptable and effective handoff tool that will reduce the frequency of communication failures during the ICU-ward transition.

We hypothesize that ICU-PAUSE will be used in at least 70% of ICU-ward transfer notes [5]. We expect to gain insight into the feasibility of ICU-PAUSE implementation, barriers or facilitators to uptake, any impact on the culture of safety surrounding ICU discharge, and adaptations made to the ICU-PAUSE tool. Our qualitative data will be interpreted according to sociotechnical theory, which provides a multidimensional framework to evaluate the process of ICU-PAUSE implementation within a complex health care system [13]. This interpretation will allow us to identify adaptations and potential problems in all domains, which is pivotal to the success of the intervention. We recognize that user interaction, the EHR interface, institutional workflows, and regulatory policies are all dynamic and interdependent. House officers represent the direct beneficiaries of ICU-PAUSE, whereas faculty stakeholders possess insight into internal institutional procedures and necessary adaptations to facilitate implementation. By interviewing both groups, we aim to capture a continuum of information that ranges from individual user experiences to overarching external regulations that influence the implementation process. ICU-PAUSE also seeks to address the need for brevity, clarity, and deliberate acknowledgment of diagnostic uncertainty in the ICU transfer summary [12]. With respect to our postimplementation surveys of house officers, ICU physicians, and ward physicians, we anticipate that ICU-PAUSE will reduce the frequency of communication errors, adverse outcomes, and time spent verifying information compared with preimplementation measures [9]. Thus, we hypothesize that the use of a structured communication ICU-PAUSE tool at transitions of care from the ICU to the ward will lead to a reduction in communication-related adverse events (frequency of omission or miscommunication of information in ICU-ward transfer notes) and no change or improvements in major adverse events (eg, delayed discharge, patient death, and ICU readmission).

The strengths of our work include the implementation of ICU-PAUSE at geographically diverse hospital systems, which will increase generalizability. The ability of each study site to customize ICU-PAUSE may also lead to higher uptake by providing a tool that meets the unique needs of each institution. We will include multiple perspectives by including house officers, ICU attending physicians, and faculty stakeholders. Our pre- and postimplementation data sets will allow us to compare inefficiencies and communication failures in the transfer process and determine whether they were remedied by ICU-PAUSE.

A notable limitation is the inconsistency of our postimplementation survey cohort of internal medicine trainees and attendings, which will not be identical to the preimplementation cohort from our prior study [9]. However, this is a known limitation of medical education research with resident trainees, and we will control for unpaired groups in our statistical analysis. We presume that residency training programs have remained consistent over the past several years during which the initial survey data were collected. There may also be

XSL•FO
RenderX

selection bias by interviewing faculty champions who may hold personal or professional interests in the success of ICU-PAUSE. We also acknowledge that this study excludes the perspectives of other stakeholders including other specialty practitioners, nursing staff, and patients. We hope to build upon this work with further studies that will include patient and nursing input to gather further stakeholder input in this internal process. Lastly, this study will be conducted at medical lCUs at academic medical centers that may preclude generalizability to specialty ICUs. We considered using patient satisfaction data as a secondary outcome; however, as most patient satisfaction data surveys are collected after discharge, it is extremely challenging to distinguish patient satisfaction data related to the ICU stay or ICU transfer process alone rather than the entire hospitalization.

We intend to disseminate the future results of our multicenter study in a peer-reviewed journal to enable other health professionals to customize ICU-PAUSE to their own institutions and ICU systems. We also recognize the potential for systematic bias with any health technology intervention, and our future research will examine for any patterns of demographic or diagnostic bias in the use of ICU-PAUSE.

Acknowledgments

This study is funded by the National Academy of Medicine Diagnostic Excellence Fellowship.

Data Availability

Transcriptions of deidentified postimplementation interviews will not be available publicly as they could easily be identified and deanonymize a specific site.

Authors' Contributions

EMF and EKM conceived the design of this study with support from LS. EMF, PGL, and LS substantively developed the paper, and all authors contributed to the revision and approval of the final manuscript.

Conflicts of Interest

LS is the primary investigator of this study and employed by the University of California-San Francisco (UCSF). EH is also an employee of UCSF. PGL is a co-author and faculty stakeholder for the Washington University in St. Louis. JCR is also a co-author and faculty stakeholder who is employed by the University of Chicago.

Abstract

Background: Changing current dietary patterns into sustainable healthy diets (ie, healthy diets with low environmental impact and socioeconomic fairness) is urgent. So far, few eating behavior change interventions have addressed all the dimensions of sustainable healthy diets at once and used cutting-edge methods from the field of digital health behavior change.

Objective: The primary objectives of this pilot study were to assess the feasibility and effectiveness of an individual behavior change intervention toward the adoption of a more environmentally sustainable healthy diet as a whole and changes in specific relevant food groups, food waste, and obtaining food from fair sources. The secondary objectives included the identification of mechanisms of action that potentially mediate the effect of the intervention on behaviors, identification of potential spillover effects and covariations among different food outcomes, and identification of the role of socioeconomic status in behavior changes.

Methods: We will run a series of ABA n-of-1 trials over a year, with the first A phase corresponding to a 2-week baseline evaluation, the B phase to a 22-week intervention, and the second A phase to a 24-week postintervention follow-up. We plan to enroll 21 participants from low, middle, and high socioeconomic statuses, with 7 from each socioeconomic group. The intervention will involve sending text messages and providing brief individualized web-based feedback sessions based on regular app-based assessments of eating behavior. The text messages will contain brief educational messages on human health and the environmental and socioeconomic effects of dietary choices; motivational messages to encourage the adoption of sustainable healthy diets by participants, providing tips to achieve their own behavioral goals; or links to recipes. Both quantitative and qualitative data will be collected. Quantitative data (eg, on eating behaviors and motivation) will be collected through self-reported questionnaires on several weekly bursts spread through the study. Qualitative data will be collected through 3 individual semistructured interviews before the intervention period, at the end of the intervention period, and at the end of the study. Analyses will be performed at both the individual and group levels depending on the outcome and objective.

Results: The first participants were recruited in October 2022. The final results are expected by October 2023.

Conclusions: The results of this pilot study will be useful for designing future larger interventions on individual behavior change for sustainable healthy diets.

Introduction

Background

Sustainable healthy diets have been defined as healthy dietary patterns with low environmental impact and being economically fair and affordable and culturally acceptable, which contribute to nutrition security and a healthy life for the present and future generations [1]. Such diets are characterized by being nutritionally balanced patterns, mainly (if not totally) based on unprocessed or minimally processed plant-based foods obtained from fair sources and with minimal food waste [2]. Over the past decades, the way food has been produced and consumed is far from being healthy or sustainable: unhealthy diets are the leading cause of morbidity and mortality worldwide [3]; healthy diets are not affordable and accessible to a large proportion of the world's population [4]; the current food system is among the main drivers of environmental pollution and natural resource use [5]; and from the socioeconomic and ethical perspectives, there are countless cases of forced labor conditions and unfair salaries across the food system [6]. Altogether, changing the current food system toward a sustainable and healthy one is timely. This mission requires large transformative changes in each food system phase, from production to consumption, and all stakeholders, from producers to consumers, should be involved in such a transformation [7].

To encourage the adoption of sustainable healthy diets, structural changes (ie, political actions or nudges) have to be combined with strategies explicitly tailored to individual behavior change [8,9]. To date, most individual eating behavior change interventions implemented have mainly focused on improving health and, to a lesser extent, on the dimensions of sustainable eating behaviors (ie, their environmental impacts and, with even less consideration in the literature, their social consequences [10]). Evaluating all these dimensions at once within interventions is crucial because they are not necessarily aligned. For instance, fish is a healthy food but could be obtained from overexploited fish stocks, exacerbating environmental damage [11]; even if captured from sustainable sources and using environmentally responsible techniques, labor conditions for fishery workers may not be fair, compromising their well-being [6].

Prior Work

Recently, some interventions have been designed with the aim of promoting individual eating behavior change considering different dietary sustainability dimensions. For instance, O'Sullivan et al [12] have designed an intervention to encourage the adherence to a healthy diet with low environmental impact, but they have left aside other relevant behaviors to achieve a sustainable diet, such as food waste, and the socioeconomic consequences of dietary behaviors. An intervention implemented by Monroe et al [13] among US students has targeted food waste reduction and considered the social dimension of individual eating behaviors, such as promotion of the acquisition of local foods from farmers' market. However, this intervention has not tackled the overall dietary pattern of the participants, focusing only on red meat consumption as the main outcome. Besides considering red meat reduction is key to transitioning to sustainable healthy diets, this approach lacks an assessment of the substitution effect and possibility of other changes in untargeted food groups (ie, spillovers), which could offset the overall effect of the intervention [14]. For example, if pork meat is replaced by hard cheese (one of the food products with the highest environmental impact), the dietary environmental impact would increase [15]. Therefore, eating behavior change interventions aimed at promoting sustainable healthy diets as a whole, that is, as a complex interplay of behaviors, are needed [16].

Beyond interventional studies, reviews have documented potential mechanisms of action that motivate or impede behavior change for a healthy and sustainable diet. A diversity of personal and interpersonal factors have been highlighted, such as sociodemographic determinants (ie, gender, age, socioeconomic level, and political orientation), food-related factors (ie, healthiness, taste, and affordability), generic motivational factors (ie, self-efficacy and habit), and specific motives for sustainability (ie, environmental impact, ecoanxiety, and social justice) [17-21]. By contrast, specific barriers have been identified, such as perceiving sustainable healthy food as less tasty [19]. These previous findings are useful for designing interventions (as levers to manipulate and be considered during a study) and for understanding the mechanisms of action that potentially mediate the effect of an intervention on behavior change.

At the methodological level, specific limitations of previous eating and proenvironmental behavior change interventions have also been repeatedly mentioned in the literature. They include the use of long, paper-based food frequency questionnaires that do not allow for frequent and dynamic assessment of the behavior change process [22], short or nonexisting follow-up periods that preclude the appreciation of long-term changes and potential forms of behavioral maintenance over time, and study designs inappropriate for testing causal relationships [23]. To build upon previous research, this pilot trial has been designed to promote individual behavior change for a sustainable healthy diet over a year with measurement bursts of daily eating behaviors digitally implemented through smartphones to better understand and monitor the behavior change process through the study [24].

The primary objectives of this study are as follows:

1.1 To evaluate the effectiveness of a pilot digital behavior change intervention promoting a more environmentally sustainable healthy diet (1.1.a) and relevant specific food outcomes related to dietary sustainability (1.1.b)

By sustainable healthy diet, we refer to a healthy dietary pattern with low environmental impact (objective 1.1.a), that is,

XSL•FO
RenderX

incentivizing the consumption of fruits; vegetables; legumes; nuts; whole grains instead of their refined versions; unsaturated and nonrefined vegetable oils as main dietary fats; and water as the main beverage instead of others, such as sodas or alcoholic drinks, while promoting a reduction in the consumption of meat (especially red and processed meats), dairy products (especially cheese), sugar-added products, products high in salt, and ultraprocessed foods [25], with minimal food waste and the purchase of food from fair and ethical sources.

Specific food groups or relevant food-related outcomes that will be investigated closely (objective 1.1.b) include: the consumption of red and processed meat, fruits and vegetables, ultraprocessed foods, and dairy products, and food waste.

1.2 To examine the feasibility and acceptability of the intervention and collect relevant information for iteratively improving future interventions

The secondary objectives are as follows:

2.1. The identification of mechanisms of action, notably motivational ones, potentially mediating the effect of the intervention on behaviors

2.2. The identification of potential spillover effects and covariations among different food groups (eg, meat, fruits and vegetables, and ultraprocessed food) and dietary outcomes (ie, diet composition and food waste) occurring over the study

2.3. The identification of potential interaction effects between socioeconomic status and intervention effects on behaviors

Methods

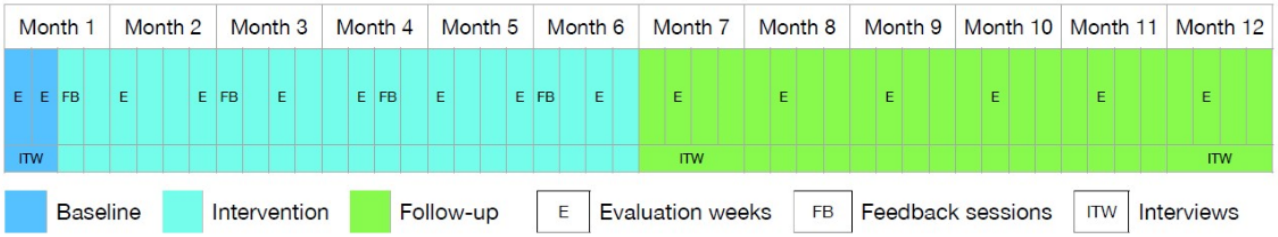
Participants

Potential participants will be approached on the web via email and social media with the support of our institutional communication and outreach activities team (ie, Barcelona Institute for Global Health, ISGlobal). They will be invited to visit a website with a brief description of the study, which will contain a link to a Google form (Google LLC) with questions related to our inclusion and exclusion criteria (provided subsequently) that is to be completed by those interested in participating. Those meeting the inclusion criteria will be classified in 3 groups according to their subjective socioeconomic level. The reason behind this stratification is that socioeconomic level is a major determinant of food choices and individual dietary carbon footprints [26,27]. In addition, deprived populations might benefit less from interventions delivered via digital or mobile means; therefore, it is necessary to include social inequality indicators such as socioeconomic status in the evaluation of interventions to assess their potential differential impact [28,29]. We chose a subjective measure of socioeconomic level and status because it has been shown that socioeconomic status has an impact on how individuals perceive resources beyond their factual resources [30]. This indicator is also strongly associated with physical functioning and health outcomes, beyond objective measurements of socioeconomical level [31]. The MacArthur Scale of Subjective Social Status will be used [32]. This scale ranges from 1 (“perception of low social status”) to 10 (“perception of high social status”). In our study, participants scoring themselves from 1 to 3, 4 to 7, and 8 to 10 will form groups of low, moderate, and high socioeconomic statuses, respectively. Within each group, the first 7 participants meeting the inclusion criteria will be invited to participate in the study after stratification by gender, with the aim of having a balanced number of individuals identifying themselves as women and men in each group. In total, we aim to include 21 participants. The questionnaire used for checking the inclusion and exclusion criteria is provided in Multimedia Appendix 1.

Individuals will be enrolled in the study if they meet the following characteristics: adults aged from 18 to 65 years; residing in Barcelona; speaking and reading Spanish fluently; having a mobile phone supporting the installation of a smartphone app; reporting no history of eating disorders (eg, anorexia nervosa, bulimia nervosa, and binge eating) or any food intolerance or allergy (eg, celiac disease, and nut allergy) or other chronic illnesses that might directly impact eating behaviors (eg, diabetes, cardiovascular disease, cancer, and obesity); following an omnivorous diet; and scoring ≥5 out of 10 points on the dietary questionnaire included in the Google form (refer to Multimedia Appendix 2 for the scoring criteria). The exclusion criteria are being pregnant or planning to be pregnant in the next year, being in a postnatal situation for <3 months, breastfeeding, being professional athletes, following specific diets (eg, vegan, vegetarian, high protein, slimming, gluten free, and low in sugars), reporting any illnesses that might directly impact eating behaviors, and not taking their own decisions about food choices (eg, someone else, such as husband or wife or partner or mother or father, selects what they eat for most of their meals).

Participants will receive financial incentives for their participation. Over the course of the study, there will be 15 evaluation weeks, during which some questions should be answered daily and others once a week (refer to *Measurement* section). For each evaluation week, they will receive €10 (US $10.7) if they complete at least 6 out of the 7 daily questionnaires plus the weekly assessment. Thus, in total, each participant can receive €150 (US $160.4) for full participation in the study. At the end of the study, they will receive their money through bank transfer.

Study Design



We will run a series of 1-year long ABA hybrid n-of-1 trials, with the first A phase corresponding to a 2-week baseline evaluation, the B phase to a 22-week intervention, and the second A phase to a 6-month postintervention follow-up (refer to Figure 1 for an illustration). We labeled the trials as “hybrid” because, in contrast with pure n-of-trials, we will conduct both individual and group-level analyses depending on the hypothesis tested and for maximizing statistical power, as has been done in similar pilot studies previously, for example, the study by Korinek et al [33]. Therefore, we did not rely on the available checklists for n-of-1 trials, such as the SCRIBE (Single-Case Reporting Guideline In Behavioral Interventions) guideline [34]. In addition to the n-of-1 trials, semistructured interviews will be conducted with the participants to collect contextual information that may aid in understanding the mechanisms by

XSL•FO
RenderX

which any individual changes in the participants' outcomes may have occurred, complement the quantitative findings on the intervention's feasibility, and assess the intervention's delivery and acceptability.

We labeled this study as a pilot study because our intention is to generate pilot data to plan further iterations of this intervention in the future and build upon this previous experience. Hence, this study aims to produce generalizable knowledge and cannot be labeled as a full trial; however, benefiting from the within-participant measures, testing the effectiveness of the intervention on some specific outcomes and for some specific objectives will be possible.

Figure 1. Study timeline.

Intervention

The intervention will involve sending text messages and providing brief, individualized, web-based feedback sessions based on the eating behavior assessments completed during the study. The text messages will be distributed on 2 nonconsecutive days per week, that is, Tuesdays and Fridays, through the General Data Protection Regulation–compliant app *m-Path* [35] (the same app will be used for implementing the evaluations; refer to the next section, *Measurements*). An in-person meeting with each of the participants will be set on their first day in the study to help them install the app on their mobile phones and provide training if needed. The text messages will contain brief educational messages about human health and the environmental and socioeconomic effects of dietary choices; motivational messages to encourage the adoption of sustainable healthy diets by participants, providing tips to achieve their own objectives; or links to recipes, providing ideas on tasty sustainable healthy meals. These text messages were developed based on a previous attempt to identify relevant behavior change techniques for changing eating behaviors [14] and the compendium of self-enactable techniques to change and self-manage motivation and behavior v1.0 [36].

The understandability and relevance of each message were pretested. Six individuals from our institution matching our inclusion criteria and not implicated in the development of this study were involved in testing and refining the messages. Initially, the messages were tested for comprehension and relevance. Participants rated how understandable each text message was on a scale of 1 to 10. They also had the possibility of commenting on these as well as suggesting improvements for each text message. After this, and based on end users' suggestions, the text messages were reworded, refined, or even removed. Multimedia Appendix 3 shows the content of the final text messages and how they match specific behavior change techniques.

In addition to the text messages, individualized feedback will be provided via short web-based individual meetings (approximately 15 minutes) at the end of the baseline phase or beginning of the intervention phase and then every 6 weeks during the intervention, after 2 measurement weeks (Figure 1). During the web-based sessions, a member of the research team with extensive knowledge of sustainable healthy diets will review the assessments of the previous weeks with the participants; provide tailored advice to improve their diet with regard to its healthiness and sustainability; and answer any questions, doubts, or additional questions that they may have. No feedback session will be provided during the follow-up period.

Measurements

Both quantitative and qualitative data will be collected (Table 1).

XSL•FO
RenderX

Table 1. Summary table for the study's objectives and their assessment.

Objective and assessment	Measurement
1.1.a Changes in the environmental sustainability and healthiness of the diet	
Quantitative	• Eating behaviors questionnaire

Qualitative	• Baseline interview:
	  • Dietary habits
	  • Healthy and sustainable diet
	• Postintervention interview:
	  • Perceived effectiveness of the intervention

1.1.b Changes in individual food groups and food waste	
Quantitative	• Eating behaviors questionnaire

Qualitative	• Baseline interview:
	  • Dietary habits
	  • Healthy and sustainable diet
	• Postintervention interview:
	  • Perceived effectiveness of the intervention

1.2. Feasibility and implementation of the intervention	
Quantitative	• Relevance of the interventional text messages

Qualitative	• Interview at baseline:
	  • Motivations and expectations from the study
	• Interview after the intervention:
	  • Acceptability of the intervention
	  • Feasibility of the intervention
	  • Elements to improve
	• Interview at the end of the study:
	  • Acceptability of the intervention

2.1. Identifying potential mechanisms of action mediating the effect of the intervention on eating behaviors	
Quantitative	• Mechanism of action questionnaire

Qualitative	• Interview at baseline:
	  • Motivations and expectations from the study
	• Interview after the intervention:
	  • Perceived effectiveness of the intervention
	  • Feasibility of the intervention
	  • Elements to improve

2.2. Identifying potential covariations and spillover effects among food groups and food composition and waste	
Quantitative	• Eating behaviors questionnaire
2.3. Potential interaction of socioeconomic status with the intervention effectiveness	
Quantitative	• Eating behaviors questionnaire

Quantitative Measurements

Questionnaires

Several self-reported questionnaires will be used to collect quantitative data. With the exception of the questionnaire collecting data about baseline characteristics, the questionnaires will be implemented through the study app (*m-Path*). These questionnaires will pop up as notifications in the app.

XSL•FO
RenderX

Baseline Characteristics

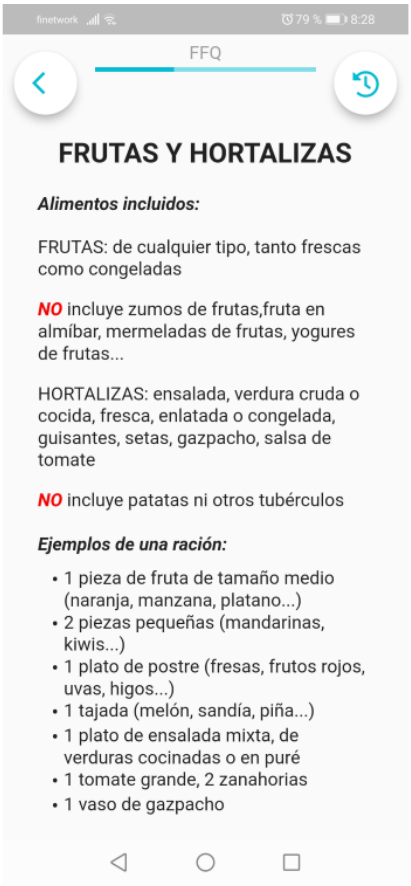
A baseline questionnaire will be used to collect descriptive data about the sociodemographic (ie, gender, age, education, household income, political orientation and postal code, number of people they live with, and if they usually cook for others), anthropometric (ie, height and weight), and health-related (ie, self-perceived physical and mental health, supplement intake, and smoking) characteristics of the participants, together with data about their general motivation for protecting the natural environment (Multimedia Appendix 4). It will be completed once at the inclusion through a Google form.

Eating Behaviors

As shown in Figure 1, eating behaviors will be assessed daily for 15 weeks through a brief questionnaire: participants will have to report their food intake at the end of each day during the 2 weeks of the baseline period; then, every 3 weeks during the intervention period; and afterward, once per month during the follow-up period, representing a total of 105 potential measurement days per participant spread over a year (15 evaluation weeks × 7 measurement days).

A 12-item questionnaire will assess the consumption of specific food groups relevant to environmentally sustainable healthy diets as well as food waste (Table 2) [25]. The present food frequency questionnaire was designed considering the need to minimize the total number of items and make it suitable for daily assessment while adding items about relevant food groups to assess food environmental sustainability and healthiness. For each food group, the number of servings consumed during the day will be asked. Specific foods gathered in the assessed food groups will be detailed, and their serving sizes will be provided with examples that the participants can easily interpret. For instance, a serving of vegetable is reported as a medium size dish of mixed salad, cooked vegetables, or vegetable purée—1 big tomato, 2 carrots, and 1 glass of gazpacho (Figure 2). The size of a serving was established based on the Spanish Society of Community Nutrition recommendations and other Spanish documents [37,38]. The exception will be whole grains and virgin olive oil, which will be assessed in terms of their proportion among all the grains and added fats consumed during the day, respectively. The reason for assessing them as a proportion is because of the priority of healthy fat and carbohydrate intake rather than the total amount of fat and carbohydrate consumed, as the recommended amount of total added fats and carbohydrates depends on the specific energy needs of each person.

Beyond food consumption, daily food waste will be measured with a “yes/no” binary question [39]. As, to our knowledge, there are no previous validated questionnaires to objectively assess the social aspect, changes in this specific sustainability dimension will not be quantitatively assessed but will be explored via the qualitative interviews. An extra open-question item will be added at the end of the 12-item questionnaire to give participants the opportunity to provide any comment or clarification if necessary. To ensure that they understand how their food consumption should be reported, participants will be explained at the initial meeting about the quantification of each food group and provided with an explanatory document showing how to respond to the questionnaire (Multimedia Appendix 5). Eventually, this will also be discussed in feedback sessions.



XSL•FO
RenderX

Table 2. Items for evaluating food consumption and food waste.

Name and item	Answer options
How many servings of the following food groups have you consumed today?	
Red or processed meat	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
White meat, fish or eggs	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
Dairy products	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
Legumes	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
Fruits or vegetables	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
Nuts or seeds	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
Sugary, salty and ultraprocessed foods	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
Alcoholic drinks	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
Sodas, juices, energy drinks, etc	(1) 0 servings, (2) 0.5 servings, (3) 1 serving, (4) 1.5 servings, (5) 2 servings, (6) 2.5 servings, (7) 3 servings, (8) 3.5 servings, (9) 4 servings, (10) 4.5 servings, (11) 5 servings, and (12) more than 5 servings
What proportion of the cereals you have eaten today are whole grains?	
Whole grains	Scale 0-100: 0=no whole grains at all and 100=all cereals I ate were whole grains
What proportion of the oils and fats you have added to your food today is virgin or extra virgin olive oil?	
Virgin or extra virgin olive oil?	Scale 0-100: 0=no virgin olive oil at all and 100=all the added fat I consumed were virgin/extra virgin olive oil
Have you wasted food today? It includes foods that you discard for different reasons: expired foods, that have gone bad, leftovers both at home and in restaurants...	
Food waste	1=yes and 2=no
Do you want to comment or clarify any point? If you want to report any food that you have consumed that is not collected in the questionnaire, please, indicate the amount consumed as well.	
Comment or clarification	Open question

Figure 2. Screenshot of the item aimed at fruit and vegetables consumption.

Eating Behavior Scoring Procedure

In terms of the scoring procedure, we designed an index for assessing dietary healthiness and environmental sustainability for every assessment week based on 10 out of the 12 items provided in Table 1. The item related to white meat, eggs, and fish is not considered in the score to avoid overrating protein groups. However, it will be used in the individual food analysis to assess whether, in the case of a reduction in the consumption of red and processed meat and not a simultaneous increase in legume consumption, red and processed meat is replaced by animal-based proteins (objective 2.2). The second item not included in the present index is the one assessing food waste. This last item will be used as a specific outcome in itself and is not included in our main score.

Therefore, the environmentally sustainable healthy diet score is computed from 10 items, each of which is treated continuously from 0 to 1 point; for example, the scoring of red and processed meat consumption is as follows: 0 points for the consumption of >2 servings of red and processed meat and 0.25, 0.5, 0.75, and 1 points for the consumption of 1.5, 1, 0.5, and 0 servings per week, respectively. Food consumption will be assessed as the average daily food consumed during the entire assessment week. The scoring criteria and rationales are listed in Table 3. The total score of the environmentally sustainable healthy diet index will be the sum of the points for each item. Thus, the environmentally sustainable healthy diet index will range from 0 to 10 points, with 0 points being the lowest score in terms of environmentally sustainable healthy diet and 10 points being the highest (best) score (Table 3). Our overall scoring criteria are based on the recommendations of reference entities in the field of nutrition, mainly the EAT-Lancet Commission, Food and Agriculture Organization, and World Health Organization [25,40,41].

XSL•FO
RenderX

Table 3. Environmentally sustainable healthy diet index: scoring criteria.

Item	What does it assess?	Scoring criteria[a]	Rationale
Red and processed meat	Average daily red and processed meat consumption	• 1 point: 0 serv/w[b] (or <0.15 serv/d[c]) • 0 point: >2 serv/w (or >0.29 serv/d)	Ideally, no red or processed meat should be consumed in a sustainable healthy diet; however, up to 2 servings of red meat per week is acceptable [25].
Dairy products	Average daily dairy product consumption	• 1 point: ≤1 serv/d • 0 point: >2 serv/d	In a sustainable healthy diet, the optimal intake of dairy products should be at the lower end of the range 0 to 500 mL (milk equivalents) [25].
Legumes and soy	Average daily legume and soy product consumption	• 1 point: ≥1 serv/d • 0 point: 0 serv/d	Plant-based proteins should be the main protein source in someone's diet, for their own health and for that of the planet. At least 1 serving of legumes per day should be consumed in a sustainable healthy diet [25].
Fruits and vegetables	Average daily fruit and vegetable consumption	• 1 point: ≥5 serv/d • 0 points: <1 serv/d	At least 5 servings of fruits and vegetable (in total) should be consumed per day [25]. Less than 1 serving per day will be scored as 0 points owing to their crucial daily consumption for a healthy diet.
Nuts (including peanuts)	Average daily nut consumption	• 1 point: 1-2 serv/d • 0 point: 0 serv/d and ≥4 serv/d	Daily consumption of nuts is recommended owing to their health benefits. Indeed, they have been suggested even as a replacement for red meat. However, the quantity should be moderate, as some nut-tree crops are water, fertilizer, and pesticide intensive [15,25].
Sugary, salty, and ultraprocessed foods	Average daily sugary, salty, and ultraprocessed food consumption	• 1 point: 0 serv/w • 0 point: >2 serv/w (or >0.29 serv/d)	These foods should be consumed as less as possible; ideally, they should be avoided or at least consumed no more than once a week [40].
Whole grains	Proportion of servings of whole grains in relation to the total servings of all grains	• 1 point: 100% whole grains • 0 point: 0% whole grains	Whole grains should be prioritized over their refined versions [25].
Oils and fats	Proportion of servings of virgin or extra virgin olive oil in relation to the total added fat intake	• 1 point: 100% virgin or extra virgin olive oil • 0 point: 0% virgin or extra virgin olive oil	Unsaturated and nonrefined oils, mainly virgin olive oil (extra or not) in our context, should be prioritized over other dietary fats [25].
Alcoholic drinks	Average daily alcoholic drink consumption	• 1 point: 0 serv/w • 0 point: >2 serv/w (or >0.29 serv/d)	Ideally, no alcohol should be consumed. According to the World Health Organization, the impact of alcohol consumption on chronic and acute health outcomes is largely determined by the total volume of alcohol consumed [41].
Other beverages: sodas, juices, energy drinks, etc	Average daily consumption of other unhealthy drinks	• 1 point: 0 serv/w • 0 point: >2 serv/w (or >0.29 serv/d)	These foods should be consumed as less as possible; ideally, they should be avoided or at least consumed no more than once a week [40].

[a]Scores will range proportionally from 0 to 1 points. For instance, 0 points will be assigned for the consumption of >2 servings of red and processed meat per week and 1 point for 0 servings per week; 0.25, 0.5, and 0.75 points will be assigned for the consumption of 1.5, 1, and 0.5 servings per week, respectively.

[b]serv/w=servings per week.

[c]serv/d=servings per day.

Mechanisms of Action

Seven items capturing key psychological or motivational mechanisms of action that could potentially play a role in the adherence to sustainable healthy diets will be measured once during each assessment week (refer to objective 2.1 in the *Introduction* and *Statistics* sections). All items are presented in Table 4. Motives for purchasing or eating foods related to dietary sustainability and healthiness (ie, health, environment, affordability, and ethical) will be captured with 4 items adapted from eating motivation validated scales [42,43]. Another item, selected from a validated 12-item questionnaire, will be used to evaluate ecoanxiety, a construct that has been previously described as a relevant mediator of proenvironmental behavior changes [44]. Habit strength of purchasing and eating food while thinking about sustainability will be measured using an item

XSL•FO
RenderX

adapted from the Self-Report Habit Index and Self-Report Behavioral Automaticity Index [45,46], and finally, self-efficacy toward following a sustainable healthy diet will be assessed using another item [47]. The comprehension of these questions was tested by following the same methodology as the one stated earlier for text message content.

Table 4. Items for food-related motives, ecoanxiety, habits, and self-efficacy.

Category and name	Item	Answer options
Motives		
Health	In the last 7 days, how important was the healthiness of your food when choosing what to eat?	VAS[a] 0-10: 0=not important at all and 10=very important
Environmental impact	In the last 7 days, how important was the environmental impact of your food (ie, carbon footprint, water footprint, etc) when choosing what to eat?	VAS 0-10: 0=not important at all and 10=very important
Fair and ethical sources	In the last 7 days, how important was the working conditions of the producers or sellers of your food when choosing what to eat or where to buy?	VAS 0-10: 0=not important at all and 10=very important
Price	In the last 7 days, how important was the price of your food when choosing what to eat?	VAS 0-10: 0=not important at all and 10=very important
Ecoanxiety		
Ecoanxiety	Over the last week, how often have you felt nervous, anxious or on edge, when thinking about climate change?	VAS 0-10: 0=never and 10=almost everyday
Habit strength		
Habit strength	Selecting healthy foods with low environmental impact and from fair sources is something that I do automatically, without thinking about it	VAS 0-10: 0=totally in disagreement and 10=totally in agreement
Self-efficacy		
Self-efficacy	To what extent do you feel capable of following a sustainable healthy diet?	VAS 0-10: 0=not at all confident and 10=totally confident

[a]VAS: visual analog scale.

Relevance of the Interventional Text Messages

Finally, when sending motivational and educational messages as part of the intervention, we will ask the participants to indicate whether the message is "useful, informative or motivating" or "not useful, not informative or not motivating" in a visual analog scale. This will help us refine our messages for future studies and also control for engagement with the messages, given that an absence of answers will indicate that the participants did not read the message.

Qualitative Measurements

We will conduct 3 semistructured qualitative interviews to gain a deeper understanding of the intervention's effect as well as to assess the feasibility, delivery, and acceptability of the intervention beyond the collected quantitative information. We anticipate that the qualitative data will allow us to complement the quantitative data in a way that adequately captures the contextual, social, and cultural factors that determine the intervention's efficacy and perceived influence.

The first interview will be performed at baseline (during the first 2 weeks; refer to Figure 1) to investigate the eating behaviors of the participants (ie, habitual diet; favorite foods; sources of food; frequency of eating out; and the cultural, social, and personal backgrounds that may determine their behaviors), explore aspects related to sustainable healthy diets (ie, conceptualization of a sustainable healthy diet, participants' views on what should change in their daily lives to achieve such a diet, previous attempts to improve their diet, and measures implemented in those attempts), and explore participants' expectations of the intervention and their motivation for participating in the study. The second interview will be held at the end of the intervention (month 7) to examine participants' perceptions of the effectiveness of the intervention (ie, changes in their eating habits and behaviors and other changes beyond diet, such as variations in their well-being and weight) as well as potential mediators that may have influenced outcomes that were not observable in the quantitative part; determine whether the intervention has been feasible (ie, any difficulties with the app, problems completing the questionnaires, understandability of the text messages, etc); identify potential improvements to the intervention's delivery; and examine participants' views on its acceptability, which includes engagement with both the evaluations and intervention's features and any other relevant practical aspects of the study that the participants would like to discuss. The third interview will be conducted at the end of the follow-up period (month 12) and will be less structured than the previous ones, depending on the outcomes for each participant. The objective of the third interview will be to evaluate the persistence of the acquired eating behaviors, focusing on the personal, social, and contextual facilitators and barriers that may influence the persistence of the outcomes over time, as well as the role of the intervention in this persistence. The interview guides are included in Multimedia Appendix 6.

The objectives and procedures of the interviews will be explained at the beginning of the study in the face-to-face meeting for installing the app, in which each participant will

XSL•FO
RenderX

confirm their willingness to participate. The researcher who will conduct the interviews will contact them to schedule an interview at each of the 3 time periods. The same researcher will be in charge of all the interviews. The interviews will be conducted on the web using the preferred platform of the participants (Google Meet [Google LLC], Zoom [Zoom Video Communications Inc], Signal [Signal Messenger LLC], WhatsApp [Meta Platforms Inc], etc), will last between 45 minutes and 1 hour, and will be audio recorded. During the interviews, prompts and probes will be used to collect rich and comprehensive data. All interviews will be digitally recorded, anonymized, and transcribed verbatim. Audio files and transcripts will be imported into the NVivo software (QSR International), which will be used for the data analysis.

Data Analyses

Sample Size and Power Analyses for the Quantitative Side of the Project

The sample size for this pilot study is constrained by financial and human resources. We plan to recruit a total of 21 participants, with 7 participants in each subjective socioeconomic group (refer to the *Participants* section). However, in terms of statistical power, we will benefit from the intensive longitudinal nature of the study, that is, 15 evaluation weeks and up to 105 daily observations per participant. For objective 1.1.a, for which a weekly environmentally sustainable healthy diet index will be used, up to 315 observations will be available in total (21 participants × 15 evaluation weeks) and 105 observations per socioeconomic group (7 participants × 15 evaluation weeks). For objective 1.1.b, for which the daily raw data will be used, up to 2205 observations will be available in total (21 participants × 105 daily assessments), 735 observations in the 3 socioeconomic groups (7 participants × 105 daily assessments), and 105 observations at the individual level (as a general rule of thumb, a minimum of 70 observations are required for conducting individual-level analyses [48]). Given the pilot nature of this trial, we conducted power simulation analyses only for objective 1.1.a (ie, change in the weekly level of food healthiness and environmental sustainability). Considering group-level analyses and the analytical strategy detailed in the next section and assuming an increase of 2 units in the environmentally sustainable healthy diet score per phase, simulated power analysis indicated an adequate power value of 96%. The simulation was performed by generating the response variable as follows:

- Fixed effects: the intercept was set at 6, and the fixed coefficient for the phase was set as −2 for the initial phase and +2 for the final phase based on our average expected change in the main outcome.
- Random effects: it was assumed that each participant would have both a random slope and a random intercept and that both followed normal distributions, with SDs of 2 for the intercept and 0.5 for the slope. The correlation between them was set as 0.2. The random effect for each participant was created by drawing random numbers from a multivariate normal distribution whose covariance matrix was specified using these parameters (R mvrnorm from the package *MASS*).

Then, a linear mixed regression was performed on the data (R lme from the package *nlme*) using phase as a fixed effect and specifying a random slope and intercept for each participant across time. This process was repeated 1000 times, and the significance level for the fixed effect was 0.05.

Quantitative Data Analysis

Analyses for this project will be conducted with the statistical software R (R Foundation for Statistical Computing) [49]. The code and data generated for this study will be made open access when available.

Objective 1.1.a: Changes in the Environmental Sustainability and Healthiness of Diet

To test the main effect of the intervention on the environmental sustainability and healthiness of diet at the group level, linear mixed regression will be performed and expressed as measurement occasions (here, going from 1, first evaluation week, to 15, last evaluation week), using an ordered 3-categories phase variable as a fixed effect, which takes the values of baseline, intervention, and follow-up. Polynomial functions will also be fitted to the time variable to determine whether the index demonstrates any nonlinear patterns across time. If nonlinear patterns are detected, then other patterns (eg, quadratic, cubic, and piecewise) will be examined and selected based on visual inspections and goodness-of-fit indicators. Moderation analysis will be performed by exploring the role of the subjective socioeconomic level (ie, 3 socioeconomic groups entered as fixed effect) with regard to changes in diet. Fixed baseline characteristics will be included as control variables (ie, age, gender, education, income, and political orientation). Individual trajectories will be plotted, and heterogeneity in participants' responses to the intervention will be discussed based on visual analyses using relevant guidelines for n-of-1 trials [50] (individual weekly changes in the whole diet will not be statistically modeled because only 15 observations will be available per participant).

Objective 1.1.b: Changes in Individual Food Groups and Food Waste

An analytical strategy similar to that used for objective 1.1.a will be followed for testing the effect of the intervention on specific food groups, including red and processed meat, fruits and vegetables, ultraprocessed foods, and dairy products, and food waste. A linear mixed model similar to that performed for the first objective will be performed, but time will be expressed as measurement days instead of weeks, thus ranging from 1 to 105. In addition to the group and subgroup analyses performed for objective 1.1.a and maximizing the higher number of observations per participant within those outcomes, individual-level models will also be used to quantify the effect of the intervention on each participant separately from the others by following an idiographic approach.

Objective 1.2: Feasibility of the Intervention

This objective will mainly be investigated through the qualitative data analyses reported in the next section. Simple quantitative analyses will be conducted to examine the relevance of our motivational and educational messages (ie, scores provided to the text messages at the individual and collective levels). We

XSL•FO
RenderX

also report the percentage of missing values for each measurement burst.

Objective 2.1: Identifying Potential Mechanisms of Action Mediating the Effect of the Intervention on Eating Behaviors

Longitudinal mediation analyses will be conducted to understand the processes through which the intervention will potentially affect the environmental sustainability of eating behaviors. These analyses will be conducted independently for the 7 potential mediators presented in the section *Mechanisms of Action* (ie, motives for health, environmental, social, and affordability; ecoanxiety; habits; and self-efficacy) and by following recent guidelines based on longitudinal multilevel structural equation models [51]. These analyses will be performed for the total sample and per socioeconomic subgroup with the environmentally sustainable healthy diet index as the first dependent variable and, in secondary analyses, with the weekly level of the relevant food outcomes mentioned in objective 1.1.b (ie, red and processed meat, fruits and vegetables, ultraprocessed food, dairy products, and food waste). These food groups and food waste will be analyzed here at the weekly level to match the temporal resolution of the mechanisms of action that are also assessed weekly (and not daily).

Objective 2.2: Identifying Potential Covariations and Spillover Effects Among Food Groups and Between Food Composition and Food Waste

Covariations and spillover effects will be examined using network visualizations of the partial correlation matrix by following published guidelines and previous applications in the health behavior domain [52,53]. The within-participant network will be computed by subtracting the mean of each participant's behavior across the 15 assessment weeks from their scores at each time, thus estimating a network of interrelationships centered on each person's "average" behavioral pattern over 12 months. This method allowed us to test whether variations from the mean level for one behavior are associated with variations from the mean for other behaviors and, hence, covariation or spillovers. These networks will be estimated for the total group and the 3 socioeconomic subgroups using the 12 items presented in Table 2. Data from the 3 phases will be combined together to maximize the statistical power.

Objective 2.3: Potential Interaction of Socioeconomic Status With the Intervention Effectiveness

As mentioned in the previous sections, the role of socioeconomic status will be explored in objectives 1.1.a, 1.1.b, 2.1, and 2.2 by conducting group-specific analyses for the low, moderate, and high socioeconomic groups (refer to the above-mentioned sections for further details).

Qualitative Data Analysis

The qualitative data will be analyzed using framework analysis, a thematic-oriented approach to qualitative data analysis that is gaining popularity in the health sciences and is well suited for analyzing data from semistructured interviews [54,55]. The output of this method is a matrix containing the participants in the rows, analytical codes in the columns, and a data summary in the cells. Using this matrix, researchers can compare the participants' views within each participant and across participants, thereby identifying patterns across the data set (ie, code-based analysis) while preserving the context of the participants' views (ie, analysis by case). In addition, because of the structured nature of the method, framework analysis is helpful in studies that involve multidisciplinary research teams with a majority of members having quantitative expertise, such as this study. In this study, framework analysis will be implemented according to the following 6 steps outlined by Gale et al [55]: familiarizing with the interview transcripts, coding the transcripts, developing a working analytical framework by grouping the codes, applying the analytical framework to the transcripts, charting data into the framework matrix, and interpreting the data. Two researchers will independently code and apply the analytical framework. Disagreements between the researchers will be discussed until a consensus is established, if required, with the assistance of a third researcher.

Integration of the Quantitative and Qualitative Data

After completing all the analyses, a back-and-forth process will be used to integrate the quantitative and semistructured interview findings [56]. Joint displays will be used to facilitate this process, an increasingly used visual tool designed for facilitating integration in mixed methods studies [57]. Specifically, using joint displays, both quantitative and qualitative findings for objectives 1.1.a, 1.1.b, 1.2, and 2.1 will be juxtaposed, and the extent to which the qualitative results confirm, reject, complement, or expand on the quantitative results will be assessed. By integrating the quantitative and qualitative findings, a more comprehensive and fine-grained understanding of the effectiveness, feasibility, and implementation of the intervention will be gained.

Ethics Approval

This study was approved by the Drug Research Ethical Committee (CEIm) of Parc de Salut MAR on October 19, 2022 (2022/10304/I), and will be conducted in accordance with the Helsinki Declaration. The participants will be required to provide written informed consent to participate in the study during the baseline visit before any study procedure.

Results

This study was approved by the Ethics Committee on 19 October, 2022. It started in October 2022. The initial results are expected to be published in May 2023. The final results are expected by October 2023.

Discussion

Principal Findings

With regard to objective 1.1.a, we expect environmentally sustainable healthy diet to positively change over time (increasing score for the environmentally sustainable healthy diet index) with small to medium effect sizes, as observed in most previous behavior change interventions [14]. With regard to objective 1.1.b, which focuses on food groups and food waste and reflects the changes in the index, we expect the consumption of meat, dairy products, and ultraprocessed food to decrease

XSL•FO
RenderX

over time and the consumption of unprocessed or minimally processed plant-based foods to increase. However, the rate of change might differ from one food group to another; for example, an increase in fruit and vegetable consumption might occur earlier in the intervention than a decrease in meat consumption, which might indicate that this second behavior is more difficult to change. At the individual level, we also expect the shape of those changes to be heterogeneous across participants, with linear improvements, 1-step changes, and inverse U–shape, for example. Objective 1.2 (feasibility of the study) is not hypothesis driven.

With regard to objective 2.1, we expect substantial mediation effects of motivations, ecoanxiety, habit, and self-efficacy on eating behaviors, with positive changes in eating behaviors being partially explained by positive changes in these variables. More specific hypotheses can also be formulated; for example, we expect motivation for protecting the environment to mediate changes in the food groups with the highest environmental impact (eg, meat) more than those in the food groups mainly relevant for health (eg, ultraprocessed food).

We do not have clear and specific hypotheses regarding the covariations among food groups and among dietary outcomes (objective 2.2) and hypotheses regarding the moderating role of participants' socioeconomic level (objective 2.3), given that only a few studies have examined these dimensions before; overall, the participants from the lowest socioeconomic group may present a less healthy and environmentally sustainable diet than the participants belonging to the higher socioeconomic groups [27,58].

Limitations

Our primary outcome is a weekly score of environmentally sustainable healthy diet created based on daily food measures to avoid recall bias. This specific questionnaire and scoring procedure have not yet received proper validation. However, this does not constitute a limitation to us. The questionnaire gathered common food groups and framed them as in other digital food frequency questionnaires validated for the Spanish population [59]. It provides information about specific foods gathered in each group with the serving size. The reason for using this customized tool instead of any previously validated is that this study is among the first to monitor changes in environmentally sustainable healthy diet as a whole and through dynamic daily assessments (instead of lower resolution measures, eg, monthly assessment), thus justifying the use of a new and shorter measurement tool. Similarly, the lack of validation of our scoring procedure is not a major limitation given that (1) this study is a pilot study and the data gathered will also be used to refine our scoring procedure later in time and that (2) the score is developed in a straightforward manner based on the EAT-Lancet Commission, and Food and Agriculture Organization, and World Health Organization recommendations [25,40,41]. Our team is conducting parallel validation studies of this questionnaire and scoring procedure, and we also expect to use the data from this pilot intervention to examine the sensitivity of the tool to detect behavior changes (with the ultimate aim of refining this questionnaire and scoring procedure for future interventions).

Comparison With Prior Work

We prefer performing n-of-1 trials rather than adopting other traditional designs, such as parallel randomized control trials, because the former present some advantages, including (1) the possibility of developing efficient studies (in terms of time and human and financial resources) with few participants involved but providing forms of causal inference to quantify the intervention's effectiveness for each participant (ie, within-individual randomization and time effect [60]); (2) the possibility of optimizing and refining the intervention over the course of the study based on the empirical data collected from the participants' feedback [61]; and (3) the possibility of exploring heterogeneity between participants given that statistical inference can be produced at the individual level, which makes the tailoring of current and subsequent personalized interventions easier [62].

In recent years, some studies have been designed or implemented with the aim of promoting sustainable healthy eating behaviors [12,13]. However, to the best of our knowledge, this is the first study to address the overall dietary pattern, food waste, and socioeconomic dimensions of food in an intervention. In addition, the brief and continuous assessment implemented through the app will provide, for the first time in the domain of sustainable healthy diet, a high-resolution view of behavior changes useful for improving our understanding of the overall process compared with studies using traditional low-resolution measurement paradigms (eg, baseline and 3- and 6-month follow-ups). If we are able to manage potential technological issues that could happen with the app, the use of technology to monitor participants remotely should also help make this intervention minimally burdensome for the participants, as they do not need to attend in-person meetings.

Conclusions

This study will address the urgent topic of adopting overall sustainable healthy diets, thus filling a gap in the literature and providing pilot data for scaling up the intervention in a full randomized controlled trial. It will provide insights into the effectiveness of the pilot intervention in changing eating behaviors toward a sustainable healthy diet, considering the whole dietary pattern and, hence, spillovers among food groups and among dietary outcomes; it will help to determine the moderation and interaction effects of several individual characteristics, such as socioeconomic level and gender; and it will address its own feasibility to determine the barriers to and enhancers of the intervention, which will help us refine and optimize the intervention for future studies.

Abstract

Background: Primary, basic, secondary, and high school teachers are constantly faced with increased work stressors that can result in psychological health challenges such as burnout, anxiety, and depression, and in some cases, physical health problems. It is presently unknown what the mental health literacy levels are or the prevalence and correlates of psychological issues among teachers in Zambia. It is also unknown if an email mental messaging program (Wellness4Teachers) would effectively reduce burnout and associated psychological problems and improve mental health literacy among teachers.

Objective: The primary objectives of this study are to determine if daily supportive email messages plus weekly mental health literacy information delivered via email can help improve mental health literacy and reduce the prevalence of moderate to high stress symptoms, burnout, moderate to high anxiety symptoms, moderate to high depression symptoms, and low resilience among school teachers in Zambia. The secondary objectives of this study are to evaluate the baseline prevalence and correlates of moderate to high stress, burnout, moderate to high anxiety, moderate to high depression, and low resilience among school teachers in Zambia.

Methods: This is a quantitative longitudinal and cross-sessional study. Data will be collected at the baseline (the onset of the program), 6 weeks, 3 months, 6 months (the program midpoint), and 12 months (the end point) using web-based surveys. Individual teachers will subscribe by accepting an invitation to do so from the Lusaka Apex Medical University organizational account on the ResilienceNHope web-based application. Data will be analyzed using SPSS version 25 with descriptive and inferential statistics. Outcome measures will be evaluated using standardized rating scales.

Results: The Wellness4Teachers email program is expected to improve the participating teachers' mental health literacy and well-being. It is anticipated that the prevalence of stress, burnout, anxiety, depression, and low resilience among teachers in Zambia will be similar to those reported in other jurisdictions. In addition, it is expected that demographic, socioeconomic, and organizational factors, class size, and grade teaching will be associated with burnout and other psychological disorders among teachers, as indicated in the literature. Results are expected 2 years after the program's launch.

Conclusions: The Wellness4Teachers email program will provide essential insight into the prevalence and correlates of psychological problems among teachers in Zambia and the program's impact on subscribers' mental health literacy and well-being.

RenderX

The outcome of this study will help inform policy and decision-making regarding psychological interventions for teachers in Zambia.

Introduction

Background

Teaching is a high-demanding profession, and teachers experience a high prevalence of stress, burnout, anxiety, and depression. In a study, 25.3% of teachers reported mild to moderate stress [1], and high burnout was reported by 33.3% of teachers, followed by 27.6% at risk for moderate burnout [2]. In addition, 38% of teachers reported clinically significant anxiety [3], while depressive symptoms were also found in 35.3% of the teachers in a study [4]. Burnout, also known as professional exhaustion syndrome, is characterized by extreme and prolonged or recurrent stress at work [5-7]. The prevalence of burnout ranged from 25.12% to 74%, stress ranged from 8.3% to 87.1%, anxiety ranged from 38% to 41.2%, and depression ranged from 4% to 77% when only clinically meaningful (moderate to severe) psychological conditions were considered among teachers [8]. When homeostasis is disturbed, stress is produced. According to the stress framework system, there are 3 kinds of stress: sustress (inadequate stress), eustress (good stress), and distress (bad stress) [9]. Eustress may have health benefits, but both sustress and distress may lead to the impairment of normal physiological functions and could result in pathological conditions [9]. Burnout among professionals such as teachers is a stress-related problem and a risk factor for depression and other cardiovascular diseases [10,11]. According to Gluschkoff, school-related stress may lead to depressive symptoms among teachers [12,13], and often, teachers feeling more stressed are also burned out [14]. Various studies have also reported that the type of school, income satisfaction, depression, and perceived stress were all significantly associated with burnout [15,16]. Stress and emotional demands linked with teaching can lead to emotional exhaustion and lower job satisfaction [17]. Symptoms of stress and burnout among teachers directly or indirectly affect their teaching and students' performance [17,18].

Literature has reported several predictors of teacher stress, burnout, anxiety, and depression, including age, job satisfaction, subject taught, and work-related factors [8,16,19-23]. Teachers constantly face increased challenges such as workload, role conflict, and role ambiguity, which cause work stressors and result in mental and physical health challenges [24]. Role conflict and role ambiguity also predict teachers' burnout [25]. Teachers' stress levels increase when their demand exceeds their capability [26-28], leading to burnout and anxiety [29,30]. Several studies have reported a significant overlap between stress, burnout, anxiety, and depression [31-36]. A survey by Besse et al [37] reported that teachers with moderate depressive disorder had higher levels of perceived stress, anxiety, low job satisfaction, and a relatively lower quality of life. Depression among teachers can also significantly affect their health, productivity, and functionality and it typically has persistent effects in both their personal and professional lives [37,38]. Teachers with low job satisfaction are also more susceptible to experiencing burnout, high anxiety levels, and depression [2,39].

Teachers in African countries similarly experience stress, burnout, depression, and anxiety. A cross-sectional study in Egypt by Desouky and Allam [20] reported a high prevalence of occupational stress (100%), anxiety (67.5%), and depression (23.2%) among teachers. This study also indicated that workload had a positive relationship with stress and that occupational stress scores were significantly higher among teachers with an increased workload [20]. A study in Ghana also reported that a poor workplace environment was associated with increased anxiety and depressive symptoms [40]. In Lusaka, Zambia, a teacher survey said that 81% of the participants rated stress levels as often, and 59% of the respondents acknowledged experiencing health-related problems due to stress [18]. Several studies also indicate that sources of stress among teachers include low salaries or income, work-related issues, a heavy workload, poor school climate, and large class sizes [1,18,24]. Another study in Zambia also reported that teachers moderately experienced stress that manifests emotionally in terms of feelings of fatigue, cardiovascular manifestations, and gastronomic manifestations [41]. These work-related psychological problems teachers encounter need to be addressed at institutional and professional levels. One approach to address the above-noted psychological issues is directly providing teachers with mental health support through educational programs that improve their mental health literacy. Teachers need to obtain and sustain positive mental health themselves. They have the skills to decrease the stigma associated with mental health problems and to promote and encourage students to seek timely and appropriate help when necessary [42]. Moreover, teachers play an essential role as partners in identifying, preventing, and intervening in mental health problems among children and youths [43,44]. Hence, improving teachers' mental health literacy will benefit teachers and students.

Health literacy has recently transformed into a broader concept fundamental for improving an individual's health outcome, reducing health inequities in populations, and enhancing the operation and development of health systems and policies [42,45,46]. Mental health literacy, in particular, plays a significant role in improving access to mental health care and reducing stigma related to mental problems [47]. Studies have

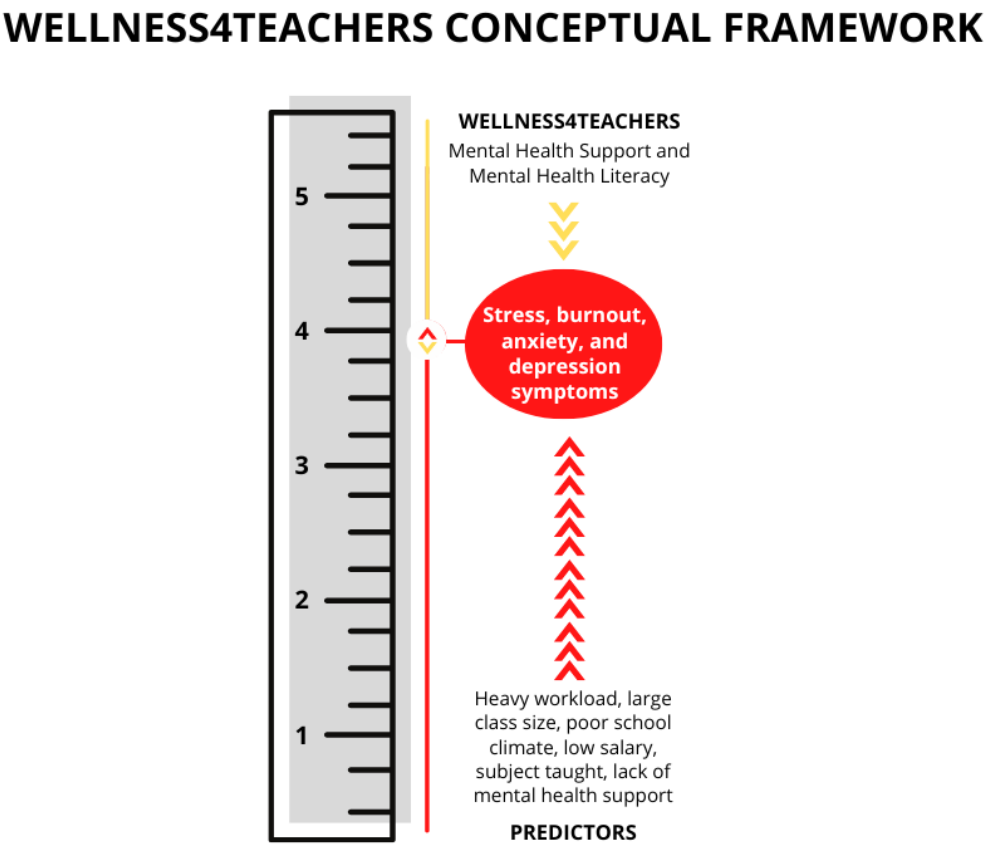
XSL•FO
RenderX

shown that individuals with strong health literacy skills have better health and well-being than those with weak skills [45]. A survey by Kutcher [48] in sub-Saharan Africa noted that there are high stigma levels, poor mental health literacy, and less capacity at the community level to address this health care need. In another study, Kutcher [46] suggested that mental health literacy interventions should be appropriate and delivered within educational settings using modern electronic delivery platforms and strategies that enhance literacy competencies.

In Zambia, the number of frontline mental health workers, psychologists, and occupational therapists is limited and has been declining over time [49]. This has created mental health literacy and psychological treatment gaps that impact teachers and the public. Innovative, human resource-independent and cost-effective ways of delivering mental health literacy and psychological interventions to teachers in Zambia and other low-resource countries, particularly in sub-Saharan Africa, are urgently needed. The use of digital technology–based services such as SMS text and email messaging is an innovative and practical way to deliver mental health intervention and programs to improve access to mental health education and psychological help [50]. Cognitive behavioral therapy–inspired daily supportive messages delivered via SMS text messaging and web-based applications were effectively used to support population-level mental health in Canada during the COVID-19 pandemic and helped to reduce stress, anxiety, and depression [51,52]. Email messaging is another accessible and unique way to deliver low-cost cognitive behavioral therapy–based psychological interventions to the general public with mental health problems [50,53]. Participants' responses on the satisfaction survey associated with the use of supportive SMS text messages in Canada endorsed their desire to receive the same intervention in the form of email [54].

There are about 7 billion mobile phone users globally, and developing countries account for 80% of newly purchased mobile phone devices. Therefore, mobile phone access and ownership are on the rise worldwide, and the advancement in mobile technology has helped shape digital communication [55]. Currently, most mobile phones allow for data plans and internet Wi-Fi connectivity, which makes it possible for individuals to access their emails on their cell phones. Thus, email technology may be easily accessible to teachers with mobile phones who can readily read emails on these devices. Furthermore, teachers who do not have mobile phones can still access emails through personal, institutional, or public computers, making this intervention widely available to all teachers. A study by Shalaby et al [54] also reported that 60% of respondents agreed to receive email messages as part of their health care, an indication of the high level of acceptability of using email as an eHealth tool.

According to Mayeya [49], the mental health services situation in Zambia could be considered critical, requiring immediate attention. To the best of our knowledge, no previous studies have been conducted to assess teachers' mental health literacy levels in Zambia. For this study, 2 cities along the rail line (Livingstone and Lusaka) and 2 cities away from the rail line (Kasama and Solwezi) would be chosen. This would ensure comprehensive and acceptable findings for all teachers' mental wellness in Zambia. A supportive email messaging program for teachers in Zambia seems timely. It can reduce the gaps in psychological interventions available to teachers and improve their mental health literacy.



Study Objectives, Aims, and Purpose
