The study will adhere to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for cross-sectional studies [11]. Descriptive statistics and comparisons between student year groups and other participant characteristics will be used. Appropriate statistical tests will be applied for these comparisons, such as the chi-square test (for categorical variables) and Student *t* test (for continuous variables). For free-text questions yielding qualitative data, a thematic analysis will be conducted using the reflexive approach of Braun and Clarke [12]. Data analysis will be performed using Microsoft Excel and RStudio (version 4.2.1; RStudio, PBC).

Results

Following study completion, teleconferences will be conducted with all collaborators to share and discuss the data analysis undertaken and the study results. Following this, it is intended that results will be presented at local, regional, national, and international conferences. In addition, the results will be disseminated via publication in a peer-reviewed medical journal. All collaborators will be given PubMed-citable collaborative coauthorship under the institutional name "the AIMS Collaborative". We will have a hybrid authorship list of named authors and the institutional collaborative.

Following study completion, medical school collaborators will be able to request their institution-specific data and the analysis performed on said data from the AIMS steering committee. This data will be anonymized. The fully anonymized data set will be made publicly available.

Data collection is currently underway, with the study having launched nationally on January 16, 2023. Data collection was closed on March 27, 2023, and data analysis has commenced. The results are expected to be available later in the year.

Discussion

Previous Literature

Although there have been (1) studies exploring which specialties junior doctors or medical students intend on pursuing [13-18], (2) studies that focused on career intentions of those pursuing one specialty or exploring factors that attract them to one specific specialty [19-35], (3) studies specifically focused on reasons why doctors are leaving the United Kingdom [36-40], (4) studies exploring how medical students and junior doctors feel about specific aspects of working within the NHS [41-44], and (5) studies investigating the desire for a career break post Foundation Year 2 (also known as the "F3") [45-47], there have been no recent, high-powered studies explicitly aimed at medical students, irrespective of current career ambitions or seniority, investigating overall career intentions and correlating it with demographic factors and medical student seniority. There has been one similar study, although it focuses entirely on medical students and their intentions to leave the NHS, which is limited by its low power and lack of subanalysis regarding student seniority and demographic factors [48]. We aim to address these limitations. Additionally, this study will be the first of a series of follow-up surveys of medical students, thus being the first longitudinal study of medical students' career intentions of its kind.

Strengths

Owing to its rigorous collaborator recruitment plans with the aim of high participant recruitment, this study will provide an accurate representation of medical students' intentions regarding practicing in the United Kingdom or abroad, as well as their preferred specialties. This information can be valuable for workforce planning.

The study will determine the current undergraduate consensus on several aspects of working in the NHS, which could help future policymakers prioritize change and better prepare medical schools' junior students for the reality of such aspects.

This study will determine which, if any, of the included demographic factors alter the propensity to pursue different career paths available to a medical graduate, providing insights into potential disparities.

Limitations

The study is limited by its snapshot nature, as it does not capture changes in career intentions over time. However, it is our intention to follow up with consenting participants and determine how their career intentions may have changed.

It is possible that those already intending to exit the profession, emigrate, or are dissatisfied with the current circumstances will be more likely to complete the survey. To mitigate this, we have recruited approximately 200 collaborators who will distribute the survey in their respective medical schools, targeting all medical students. Additionally, the promotional material and the questions have been written not to imply any particular outcome is predicted or sought.

Challenges in recruiting collaborators or ensuring sufficient student responses may impact the achievement of the study's national goals.

The study's response options for each question may be limited, potentially affecting the comprehensiveness of the data. However, an extensive literature review, peer survey testing, and input from senior clinicians provide confidence that the survey will capture the majority of students' career intentions and opinions. Additionally, a free-text box allows participants to express their views more freely.

This study presents a unique opportunity to accurately assess how medical students view their current career prospects and assess the feasibility of potentially implementing a regular, census-like survey of UK medical students to assist the government's efforts in workforce planning and addressing grievances within the workforce, therefore resulting in higher job satisfaction.

Abstract

Background: *Lactobacillus coryniformis* K8 CECT5711 has immune-modulating properties, enhances the immune response to viral antigens leading to the production of specific antibodies, and has anti-inflammatory activity, which may help to prevent uncontrolled inflammatory processes leading to respiratory and other organ failures.

Objective: The purpose of this study is to evaluate the effect of the consumption of a probiotic strain on the incidence and severity of COVID-19 in health personnel who carry out their professional work among patients with infection or suspected infection by SARS-CoV-2.

Methods: This is a double-blind randomized clinical trial in which the experimental group will receive a capsule of *L coryniformis* K8 per day (3×10^9 colony former units/day), and the control group will receive a daily placebo capsule consisting of maltodextrin. A sample size of 314 volunteers was calculated. Volunteers must meet the following inclusion criteria: older than 20 years and active health personnel caring for patients with COVID-19, including all professionals such as medical doctors, nurses, and caretakers at the 2 referral hospitals that treat patients with COVID-19. The main outcome of the clinical trial will be the incidence of symptomatic infection by SARS-CoV-2 in personnel who care for patients with suspected or confirmed COVID-19.

Results: The study had to be extended to the 2 referral hospitals that treat patients with COVID-19 in the province of Granada (Andalusia, Spain); Hospital San Cecilio and Hospital Virgen de las Nieves. A total of 255 individuals met the inclusion criteria and were randomly assigned to one of the 2 groups.

Conclusions: The results of this randomized controlled trial will provide valuable information regarding the administration of *L coryniformis* K8 against COVID-19, including whether there are fewer infectious processes due to this virus or, in case of occurrence, whether the disease is milder in participants taking the probiotic strain.

Introduction

Humans have consumed lactic bacteria throughout history, but it was at the beginning of the 20th century when this consumption was first related to beneficial properties for health [1]. From that moment on, multiple studies both in vitro and in vivo have shown the beneficial effects that the consumption of this type of bacteria, called probiotics, has on health. Effects such as the improvement of intestinal function [2,3], prevention of intestinal infections [4], and immunomodulation have been widely demonstrated [5]. In addition to these beneficial effects, the consumption of probiotics has been related to a reduction in the incidence and severity of respiratory infections [4,6].

Oral administration of lactic acid bacteria has been associated with an increase in innate and acquired immune responses [7,8]. The consumption of certain strains has been shown to induce an increase in IgA related to the anti-infective properties of probiotic bacteria in diarrhea [9,10]. Innate immunity is increased through an increase in the proportion and activity of phagocytic cells of the immune system, such as monocytes and neutrophils. The function of natural killer cells is also enhanced by the consumption of probiotic bacteria [11]. Activation of the innate immune system is essential, as it produces cytokines that will lead to more specialized activation of the specific immune response. It has been suggested that it is through this mechanism that probiotic bacteria activate the immune response, thus being able to function as adjuvants in vaccination processes [12].

The European Food Safety Agency (EFSA) has published guidelines on how studies should be conducted to demonstrate the effect of a probiotic or natural ingredient on the immune system. Among its recommendations is the use of vaccination protocols that demonstrate how the administration of the probiotic translates into an improvement in the response to an antigen [13]. Recently, a study carried out at the Center Institute of Food Science and Technology and Nutrition of the Spanish National Research Council demonstrated that the administration of *Lactobacillus coryniformis* K8 CECT5711 increases the response of specific antibodies against hepatitis A in a vaccination protocol against this virus [14]. In addition, a certain effect on memory T-helper lymphocytes was observed, which increased in the probiotic group with respect to baseline values (mean 660, SD 223 cells/µL vs mean 551, SD 213 cells/µL). These results highlight the potential of this probiotic strain to improve the immune response against viral antigens.

To evaluate this activity that boosts the immune response, another study was carried out in an older population. This population is more susceptible to infections due to the characteristic immunosenescence of age. A total of 98 older people residing in nursing homes participated in this study. The volunteers received a daily capsule of *L coryniformis* K8 CECT5711 (3×10^9 colony former units/day) for 2 weeks prior to being vaccinated against the flu or a placebo. The percentage of seroconversion was higher in the group receiving the probiotic than in the control group (93.1% vs 72.7%; *P*=.04). During the months of October to April, the volunteers were monitored, and the incidence of local symptoms associated with respiratory infections (sore throat, cough, and nasal congestion) was 48% lower in the group that received the probiotic strain than in the control group (*P*=.007). Furthermore, the consumption of analgesics was significantly reduced in this group by 86% (*P*=.008) [15]. This latest study corroborates the strain's ability to improve the immune response against viral antigens even in the older population.

We are currently experiencing a pandemic due to COVID-19 (the English acronym for COVID-19), which started in the Chinese city of Wuhan in December 2019. Having reached more than 100 territories, the disease was declared a pandemic by the World Health Organization on March 11, 2020 [16]. The number of confirmed cases continued to grow until reaching 5,371,660 cases worldwide on May 22, 2020. In Spain, at the end of May 2020, despite the containment measures initiated in early March, more than 235,772 cases were registered, and of these patients, more than 27,940 died [17].

The COVID-19 infection produces flu-like symptoms, including fever, dry cough, dyspnea, myalgia, and fatigue. In severe cases, it is characterized by pneumonia, acute respiratory distress syndrome, and septic shock, which lead to death in approximately 3% of those infected. Transmission occurs through small droplets that are emitted when speaking, sneezing, or coughing by a carrier and pass directly to another person through inhalation or by contact with contaminated objects in the recipient's nasal and ocular mucous membranes. Symptoms start after approximately 7-20 days of exposure, and prevention at the population level consists of frequent hand washing, disinfecting surfaces with alcohol, and avoiding close contact with other people [15].

Some drugs have been proposed as antiviral treatments, such as hydroxychloroquine, lopinavir, ritonavir, and others; severe pneumonia is treated with broad-spectrum antibiotics. There is no up-to-date, effective treatment for the COVID-19 infection.

An article published in March 2020 shows how the immune response to the COVID-19 virus is similar to the response generated by the influenza virus [18]. Some authors propose the use of probiotics as a strategy to mitigate the effects of viruses [19].

Health care workers (HCWs) are at increased risk of COVID-19 infection due to close contact with highly infectious patients as well as exposure to undiagnosed or subclinical infected cases. The stress and physical exhaustion associated with the pandemic may also impact the immune response of HCWs [20]. A recent study examined 97 studies and found that approximately 11% of patients with COVID-19 were people with underlying disease [21]. This represented a considerable percentage of all COVID-19 cases [22]. Although the number of severe cases and mortality among HCWs was lower than in other populations [21], the number of COVID-19 cases has led to a shortage of HCWs, thus adding an extra burden to the fight against this pandemic.

It has been suggested by several authors that probiotics could play a role in preventing and alleviating the severity of COVID-19 due to their immune-modulating, anti-inflammatory, antioxidant, and antiviral properties [23-25]. The *Loigolactobacillus coryniformis* K8 CECT 5711 strain has been

XSL•FO
RenderX

shown to have the immune-modulating capacity in adults [26] and children [27,28]. Research has shown that this strain causes an increase in hepatitis A virus antibody levels after oral administration in healthy adults as part of hepatitis A vaccination [14]. A study in older people found that the administration of *L coryniformis* K8 strengthened the immune response to influenza vaccination and reduced symptoms associated with respiratory infections [15]. A recent randomized controlled trial conducted with nursing home residents showed the benefits of *L coryniformis* K8 in the COVID-19 pandemic. This is because it may enhance the specific immune response following COVID-19 infection and also aid vaccine-specific responses among the older population [29].

In this context, it is proposed that the immunomodulatory properties of *L coryniformis* K8 CECT5711 might be useful for COVID-19 management.

Methods

Aim of the Study

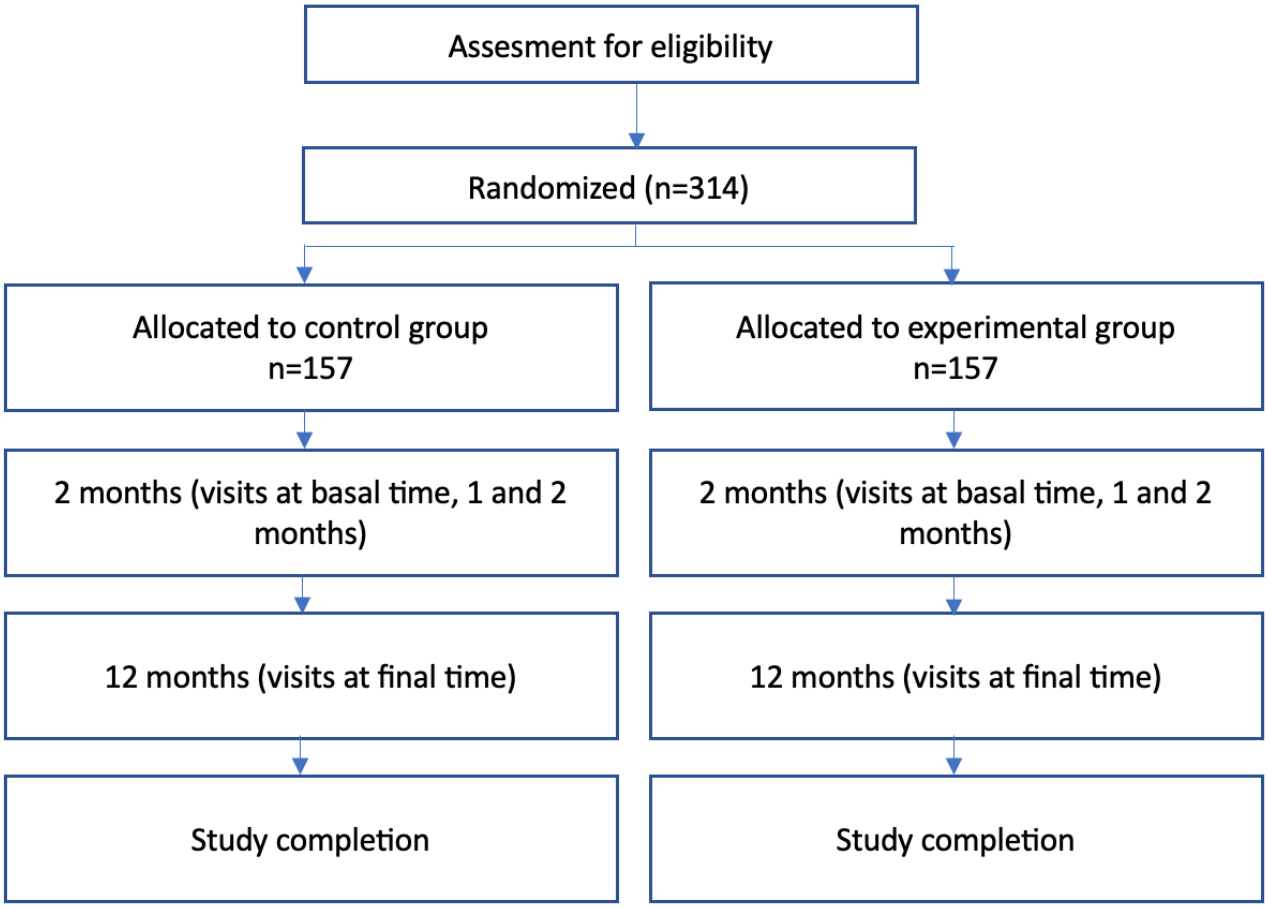
The objective of this study is to evaluate the effects of the consumption of *L coryniformis* K8 on the incidence and severity of symptomatic infection by SARS-CoV-2 and the severity of COVID-19 in HCWs who carry out their professional work among patients with infection or suspected infection by SARS-CoV-2 at 2 referral hospitals that treat individuals with COVID-19 in the province of Granada (Andalusia, Spain).

Description of Treatments

The administration of the experimental product and the placebo will be carried out in the form of a gelatin capsule that will have the same weight, consistency, and color.

The Experimental Group will receive hard gelatin capsules that will contain 3×10^9 colony forming units of *Lcoryniformis* K8 (120 mg), 10 mg magnesium stearate, and 120 mg maltodextrin.

The control group will receive hard gelatin capsules that will contain magnesium stearate (10 mg) and maltodextrin (220 mg). Individuals from both groups will take 1 capsule a day (preferably with dinner).



Capsules for the probiotic and placebo will be provided by Biosearch Life (Granada, Spain).

Study Design

The study is a nutritional, randomized, double-blind, controlled, and parallel-group observational prospective cohort study. Volunteers will be distributed into 2 groups: a control group and an experimental group. The study will be performed as shown in Figure 1.

The trial has been registered on ClinicalTrials.gov (NCT04366180).

Figure 1. Study flowchart.

XSL•FO
RenderX

Ethics Approval

This clinical research protocol has been prepared with full understanding and in accordance with the standards of Good Clinical Practice in accordance with CPMP/ICH/135/95, the Declaration of Helsinki (64th General Assembly, Fortaleza, Brazil, October 2013), ISO 14155, and all relevant national guidelines. All investigators participating in the study are appropriately qualified. The protocol was approved by the Research Ethics Committee for the province of Granada (3/2020_P_054; CEIM/CEI Province of Granada). Volunteers will be included in the study after informed written consent is obtained.

Participants, Intervention, and Outcomes

Inclusion Criteria

The inclusion criteria included individuals older than 18 years and active HCWs, including all professional categories such as medicine, nursing, and caretaking, who attend cases classified as positive or suspicious for COVID-19 in the emergency department, intensive care unit (ICU), or in the wards designated to care for such patients; and the ability to complete the surveys and having signed the informed consent.

Exclusion Criteria

The exclusion criteria excludes individuals with a positive test for COVID-19 confirmed by polymerase chain reaction or serology, individuals with concomitant pathology such as HIV, transplantation, active cancer, or other active immunosuppression, and women who are pregnant or intend to become pregnant in the subsequent months.

Recruitment

The recruitment of participants will take place at the San Cecilio University Clinical Hospital and at the Virgen de las Nieves University Hospital in Granada among HCWs with high exposure to patients with COVID-19.

Randomization, Allocation, and Blinding

Patients will be randomly allocated to a control group or experimental group in a 1:1 ratio by the block randomization method with a block size of 4. Participants and investigators will be blinded to the treatment allocation during the course of the intervention. The blind will be broken after statistical analysis is completed.

Capsules for the control and experimental groups will be provided in white containers labeled with a random number.

Intervention

Participants meeting the inclusion criteria will be randomly assigned to the control or experimental group. During the intervention, participants will be asked to ingest a capsule per day with some food (preferably with dinner). Follow-up visits will be scheduled at the beginning, midpoint (1 month), and end of the intervention period (2 months). At the first visit, baseline data (age, sex, lifestyle, medication, concomitant diseases, and current symptoms) will be collected. At follow-up visits, data about symptoms, medication, and adverse effects will be recorded (Table 1).

Outcomes Measures

Primary Outcomes

The main outcome will be the incidence of symptomatic SARS-CoV-2 infection confirmed by polymerase chain reaction or serology in HCW caring for patients with suspected or confirmed COVID-19 at the San Cecilio Clinical University Hospital and at the Virgen de las Nieves University Hospital.

Secondary Outcomes

Incidence of hospital admissions caused by SARS-CoV-2 infection, the incidence of ICU admissions caused by SARS-CoV-2 infection, the incidence of pneumonia caused by SARS-CoV-2 infection, the incidence of the need for oxygen

XSL•FO
RenderX

support, the incidence of gastrointestinal symptoms, days with a body temperature of >37.5 °C, days of persistent cough, days of persistent feeling of fatigue, and use of pharmacological treatments. Data for mild symptoms will be recorded daily in the notebook of the volunteer, and, in the case of hospitalization, data will be collected by investigators from medical histories.

In addition, the immune response and side effects of the COVID-19 vaccine in these HCWs will be assessed. Data will be collected on the vaccines received by the HCWs, including the name and type of vaccine, doses received, date of vaccination, and immune response of the HCWs.

Withdrawal, Dropout, Discontinuation, and Compliance

Withdrawal will be allowed at any time during the trial. Investigators may recommend discontinuing the trial if, in their opinion, staying in the study would be detrimental to the participant's well-being. This decision must be based on the appearance of an adverse effect that will be duly included in the case report form.

Volunteers will return the unconsumed capsules. Compliance ≤80% of the total will be considered a violation of the protocol and will be considered dropouts.

Adverse Effects

L coryniformis species are included in the Qualified Presumption of Safety list published by the EFSA, which guarantees safety for consumption [30]. On each visit, it will be monitored for adverse effects, which will be recorded in the patient's medical history and evaluated by the principal investigator. In the event of serious adverse events considered related to the experimental product, the researcher will inform the health authorities and the Clinical Research Ethics Committee involved in the clinical trial.

Sample Size

Given that the current rates of infection among health professionals worldwide are very different, the sample size has been based on the comparison of 2 independent proportions for the use of the chi-square test. For an α of 5% and a power of 80%, taking a percentage of affected individuals in the control group of 15% and 10% as the minimum meaningful difference to be detected, a sample of 157 per branch would be necessary, taking into account a loss of 10% of participants.

Statistical Analysis

Due to the urgency of the circumstances of the pandemic, the statistical methods have not been fully planned. A statistical analysis plan will be prepared during the execution of the study and before the closure of the database. The statistical methods to be used, the strategy to be followed in the case of missing values, and the tables and figures to include in the statistical report will be described in detail.

The sample size has been calculated assuming 10% dropouts. It is not planned to replace withdrawal participants. Intention-to-treat analysis will be carried out, taking into account all the data of the recruited volunteers, even if they have not completed the intervention.

In general, the data will be presented as absolute frequencies and percentages in the case of qualitative variables. For the quantitative variables, central tendency statistics, such as the mean and median, and dispersion statistics, such as the SD, IQR, minimum and maximum values, and to indicate the shape of the distribution, shape measures such as coefficients of skewness and kurtosis, will be used. In the case of ordinal variables, depending on the number of categories, one form or another of description will be used. In all cases, a column that includes the number of volunteers with available data must be added to the data presentation table. The analyses will be divided by randomization group.

To analyze the comparisons between groups, parametric tests (Student *t* test or ANOVA) and nonparametric tests (Mann-Whitney *U* or Kruskal-Wallis) will be used for continuous variables according to the characteristics of the study variables (assumption normality), while for categorical variables, chi-square tests or Fisher exact tests will be used.

In the case of between-visit comparisons of continuous variables, parametric tests (Student *t* test for paired data or repeated measures ANOVA) and nonparametric tests (Wilcoxon or Friedman) will be used, as appropriate, according to the characteristics of the study variables (assumption of normality) and the number of visits to be compared, while the categorical variables will be compared using the McNemar test. The effect size will be estimated using CIs.

The significance level of the statistical tests used will be .05. All calculations will be performed with the SPSS statistical software package (version 26; IBM Corp).

For the analysis of adverse events, a descriptive analysis (frequencies and percentages) will be carried out throughout the study, presenting a list of the adverse events grouped according to severity. These events will be listed by volunteer and randomization groups.

Adverse events and concomitant medication will be coded using a standardization system. In the case of adverse events, the most current version of the MedDRA system will be used, and for concomitant medication, the ATC code will be used.

Data Management

To further ensure the accuracy and reliability of the collected data, a thorough process of data cleansing will be implemented before computerization at the coordinating center in Granada, Spain. Any errors or inconsistencies identified during this process will be rectified or clarified with the relevant source documents or database managers. The source documents and databases will also be subjected to regular data cleansing procedures to maintain their integrity throughout the minimum 5-year retention period after the study's conclusion. Additionally, any personal information will be carefully screened and removed as part of the data cleansing process to guarantee anonymity and confidentiality.

Dissemination

Communications and scientific reports that emerge from this study will be carried out under the responsibility of the principal investigator in agreement with the associated investigators.

XSL•FO
RenderX

Publication rules will follow international recommendations. The findings will also be shared with national health authorities.

Authorship will follow the guidelines established by the International Committee of Medical Journal Editors [31], which require substantive contributions to the design, conduct, interpretation, and reporting of a trial.

Results

The study had to be extended to the 2 referral hospitals that treat COVID-19 cases in the province of Granada (Andalusia, Spain), Hospital San Cecilio and Hospital Virgen de las Nieves because the projected recruitment was not sufficient for the objective of the study and it was necessary to expand the sample obtained in order to reach as close as possible to the calculated sample. Finally, 255 volunteers were recruited and randomly distributed into 2 groups: the control group (n=128) and the probiotic group (n=127). In order to measure additional secondary outcomes, the project was kept open by collecting data related to vaccines and immune responses. The study started in July 2020, with the first part of the study ending in September 2020. In order to measure additional secondary outcomes, the project was kept open by collecting data related to vaccines and immune responses until September 2021. We will start analyzing responses in July 2023, with publication of results expected in the second half of 2023.

Discussion

Principal Findings

This study is conducted to evaluate the efficacy of the effects of *L coryniformis* K8 consumption on the incidence and severity of COVID-19 in HCWs working with SARS-CoV-2–infected or suspected patients in referral hospitals for patients with COVID-19 in the province of Granada. This randomized controlled trial aims to study whether the consumption of *L coryniformis* K8 will reduce the incidence of SARS-CoV-2 infection in the staff caring for patients with suspected or confirmed COVID-19 disease at the San Cecilio University Hospital and Virgen de las Nieves University Hospital. For this purpose, the incidence of hospital admissions caused by SARS-CoV-2 infection, both in the general hospitalization area and in the ICU area, will be studied in HCWs caring for SARS-CoV-2–infected patients.

It is important to determine the prevalence of pneumonia caused by SARS-CoV-2 infection and the need for oxygen supply to these patients. The presence of fever will be studied, and the number of days will be quantified, as well as the persistence of cough and feeling of fatigue. On the other hand, it will also be assessed whether these workers have needed pharmacological treatment.

This intervention aims to shed light on the use of probiotics to enhance the immune effect against SARS-CoV-2. In addition, this intervention study aims to contribute to the understanding of the effect of taking probiotics to improve the immune response to vaccines against SARS-CoV-2. An article published in March 2020 shows how the immune response to the COVID-19 virus is similar to the response generated by the influenza virus [18]. When the immune system works properly, the first barrier to SARS-CoV-2 is the innate response. This innate response, characterized by interferon and cytokines, which are small proteins responsible for symptoms such as fever, headaches, and muscle pain, has 2 functions: to slow down the replication and spread of the virus until the specific immune response (which, when it is a virus that has not been previously contacted, takes approximately 2 to 3 weeks) is activated. The specific immune response is what will stop and ultimately eliminate the infection. This specific response also controls the innate response in order to prevent excessive activity from damaging the tissues. When this response works in a correct and coordinated manner, the infection is overcome, showing symptoms more or less similar to those of the flu. However, in an older population experiencing dysfunction of the age-related immune response, called immunosenescence, or in a population in which the response appears to be poorly coordinated, the innate response occurs later or is ineffective, giving the virus time to replicate and spread and delaying the activation of the specific response. Before the massive invasion of tissues, the innate response exaggeratedly damages tissues, causing respiratory failure and failure in other organs, such as the kidney. Given this situation, some authors speak of 3 disease states that require different approaches: an asymptomatic state, a second state with nonsevere symptoms, and a third state with severe respiratory symptoms and a high viral load. During the first 2 states, a specific immune response is required to eliminate the virus and prevent the disease from progressing to state 3. In this phase, strategies to enhance the immune response are important. However, in state 3, when the immune system has failed and the virus has spread, the damage to the tissues causes a massive inflammatory response; the strategy should be aimed at controlling that inflammation [27]. Several clinical trials have evidenced the positive effects of certain probiotic strains on the prevention of respiratory tract infections. In fact, some authors propose the use of probiotics as a strategy to mitigate the effects of SARS-CoV-2 [19]. Mechanisms that would be involved in a positive effect of probiotic treatments on respiratory viruses include enhancement of the intestinal epithelial barrier, competition with pathogens for nutrients and adhesion to the intestinal epithelium, production of antimicrobial substances, and modulation of the host immune system [19]. *L coryniformis* K8 CECT5711 has immunomodulatory properties that could be useful for COVID-19 management. On the one hand, we have previously discussed its ability to improve the immune response against viral antigens, leading to the production of specific antibodies [14,15]. On the other hand, the strain has been shown in animal experiments to have anti-inflammatory capacity in models of inflammation [3,27]. This anti-inflammatory activity would also be of interest in the case of COVID-19, as it could help prevent uncontrolled inflammatory processes from leading to respiratory and other organ failure.

The working hypothesis is that the administration of *L coryniformis* K8 will stimulate the immune response of people exposed to COVID-19, acting as an adjuvant that contributes to developing an effective response against the virus, and therefore fewer infectious cases are presented due to this virus

XSL•FO
RenderX

or, in the event of an occurrence, the disease is milder among the participants taking the probiotic strain.

The high degree of exposure among HCWs puts them at high risk of contracting the virus. If we add to this situation the fact that the stress and physical overexertion caused by the pandemic can affect the immune response, the risk increases even more. The study has been designed to demonstrate if the consumption of these probiotic bacteria might contribute to reducing the level of incidence, or at least the severity of infection, in this population.

Conclusions

Further knowledge in this area could lead to an improvement in the immune response of HCWs to noninfection with SARS-CoV-2 or to a reduction of symptoms in cases of infection. This would ensure that HCW workforces are not impaired in their ability to cope with SARS-CoV-2 and that those infected with SARS-CoV-2 are able to return to work more quickly than those who do not take probiotic supplements.

Acknowledgments

We thank all participants for their valuable contributions. We would especially like to thank the managing directors of the San Cecilio and Virgen de las Nieves University Hospitals.

Data Availability

The data sets generated during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

All authors participated in the writing and reading of the manuscript and approved the final version.

Abstract

Background: Intimate partner violence (IPV) disproportionately affects people in low-and middle-income countries (LMICs), such as Nepal. Women experiencing IPV are at higher risk of developing depression, anxiety, and posttraumatic stress disorder. The shortage of trained frontline health care providers, coupled with stigma related to IPV and mental health disorders, fuels low service uptake among women experiencing IPV. The Domestic Violence Intervention (DeVI) combines the Problem Management Plus counseling program developed by the World Health Organization with a violence prevention component.

Objective: This study aims to implement and evaluate the feasibility, acceptability, and effectiveness of DeVI in addressing psychological distress and enabling the secondary prevention of violence for women experiencing IPV.

Methods: A parallel cluster-randomized trial will be conducted across 8 districts in Madhesh Province in Nepal, involving 24 health care facilities. The study will include women aged 18-49 years who are either nonpregnant or in their first trimester, have experienced IPV within the past 12 months, have a 12-item General Health Questionnaire (GHQ-12) score of 3 or more (indicating current mental health issues), and have lived with their husbands or in-laws for at least 6 months. A total sample size of 912 was estimated at 80% power and $\alpha<.05$ statistical significance level to detect a 15% absolute risk reduction in the IPV frequency and a 50% reduction in the GHQ-12 score in the intervention arm. The health care facilities will be randomly assigned to either the intervention or the control arm in a 1:1 ratio. Women visiting the health care facilities in the intervention and control arms will be recruited into the respective arms. In total, 38 participants from each health care facility will be included in the trial to meet the desired sample size. Eligible participants allocated to either arm will be assessed at baseline and follow-up visits after 6, 17, and 52 weeks after baseline.

Results: This study received funding in 2019. As of December 29, 2022, over 50% of eligible women had been recruited from both intervention and control sites. In total, 269 eligible women have been enrolled in the intervention arm and 309 eligible women in the control arm. The trial is currently in the recruitment phase. Data collection is expected to be completed by December 2023, after which data analysis will begin.

Conclusions: If the intervention proves effective, it will provide evidence of how nonspecialist mental health care providers can address the harmful effects of IPV in resource-constrained settings with a high burden of IPV, such as Nepal. The study

XSL•FO
RenderX

findings could also contribute evidence for integrating similar services into routine health programs in LMICs to prevent IPV and manage mental health problems among women experiencing IPV.

Introduction

Background

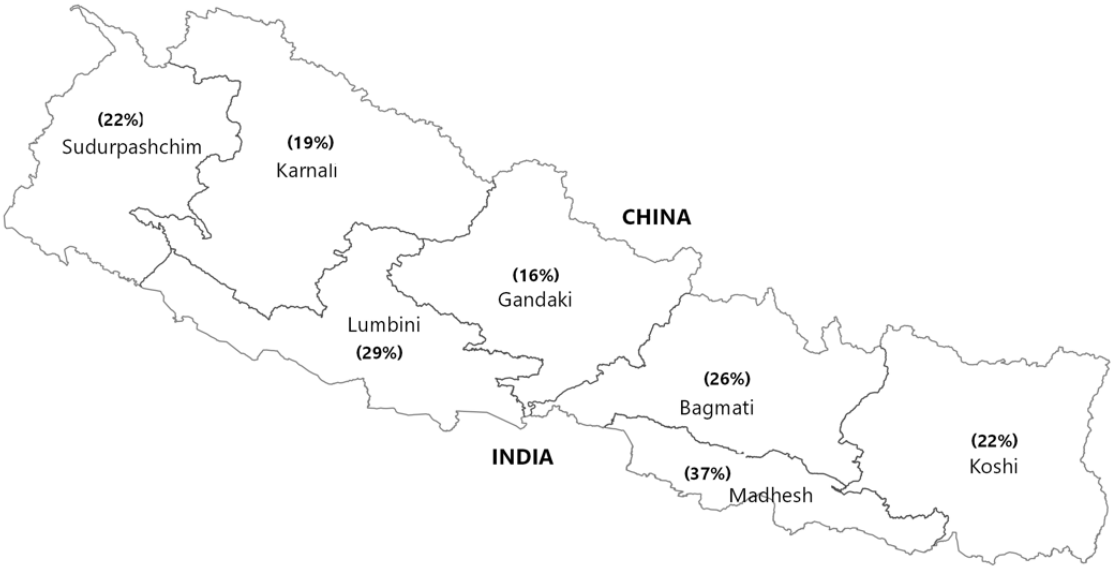
Intimate partner violence (IPV) against women is a significant public health problem worldwide [1]. IPV encompasses various behaviors, such as physical, psychological, and sexual harm or controlling behavior, primarily perpetrated by male partners/husbands, ranging from verbal abuse to assaults and even murder [2]. Worldwide, one-third of women experience physical or sexual violence, often perpetrated by their intimate partners [3]. The COVID-19 pandemic has exacerbated this problem, with approximately 50% of women aged 15-49 years reporting that they either experienced violence themselves or knew someone who did [4]. Low- and middle-income countries (LMICs), including Nepal, witness higher rates of IPV. During the first wave of the pandemic, gender-based violence among women and girls increased by 2.7% in Nepal compared to the prepandemic period [5]. A nationwide survey conducted in Nepal found that 26% of ever-married women aged 15-49 years had experienced physical, sexual, or emotional violence from their husbands/partners at least once in their lives, with physical violence being the most prevalent form (23%) of IPV (Figure 1) [6]. Among Nepal's 7 provinces, Madhesh Province (formerly known as Province 2) has the highest prevalence (37%) of spousal violence/IPV [6].

IPV is a prevalent form of violence against women and is linked to various adverse health and socioeconomic outcomes for survivors. Women who experience IPV are 2.5 times more likely to develop mental and neurological issues, such as depressive symptoms and disorders, suicidal ideation and behavior, and poor psychological adjustment, than those who have not experienced IPV [2]. A systematic review found that pregnant women who have experienced domestic violence (IPV or violence perpetrated by another family member or both) are 3 times more likely to experience postnatal depression [7]. Moreover, there is an increased risk for mental health problems, communicable diseases, health risk behaviors, and reproductive health issues, including pregnancy-related complications [2,7]. A cross-sectional study conducted in Nepal in 2017, involving 397 married women, reported that those who had experienced IPV at any point in their lives were nearly 5 times more likely to have depression compared to those who had never experienced IPV [8]. Common mental disorders significantly contribute to functional impairments and disabilities and severely impact one's quality of life [9]. Recent studies have demonstrated a bidirectional relationship between mental health issues and victimization. For example, research linking depression and posttraumatic stress disorder (PTSD) resulting from IPV also indicates an increased risk for future victimization [10].

Despite increasing recognition of the mental health and social needs of women who have experienced or are experiencing IPV, the programs or interventions aimed to address their needs are still in infancy, particularly in resource-constrained countries. The literature indicates that the shortage of trained health care providers, leading to poor recognition of violence against women, particularly IPV episodes, coupled with the reluctance of women to disclose and seek support for their experiences with violence has made it difficult to manage IPV and its consequences [11-13]. About two-thirds of the women experiencing violence in Nepal never seek help or tell anyone [6] probably due to low expected support, stigma, and fear that the violence will increase. Mental health is not a national priority in Nepal, reflected by the low availability of mental health services (only 1.5 beds per 100,000 people for in-patient care [14]) and almost nonexistent services in rural areas. Investment in human resources for mental health is extremely low: 0.68 psychiatrists and 0.17 psychiatric nurses per 100,000 people (ie, 200 psychiatrists and 50 psychiatric nurses in total to serve almost 30 million people [14]), which is significantly lower than the average of 6 mental health workers per 100,000 population in LMICs and 70 mental health workers per 100,000 population in high-income countries [15]. This indicates an urgent need for developing interventions that are effective in reducing IPV and associated mental health consequences, while improving access to health care services that do not require highly trained professionals.

On a positive note, growing evidence suggests that psychological interventions delivered by nonspecialist mental health care providers are effective in reducing psychological distress among women experiencing IPV [12]. The World Health Organization (WHO) Mental Health Gap Action Programme includes evidence-based psychological interventions for priority mental health conditions to be delivered by nonspecialists in primary health care settings in LMICs. One promising example developed by WHO is a low-intensity 5-session counseling program known as Problem Management Plus (PM+) [16]. PM+ is a nonintrusive technique for managing stress and solving problems, strengthening social support, and sustaining change. This intervention is based on established cognitive behavioral therapy and problem-solving techniques to manage depression, anxiety, and stress regardless of cause and has been evaluated in randomized controlled trials and found to be effective at reducing psychological distress among women experiencing

XSL•FO
RenderX



IPV in Kenya [12] and improving mental health outcomes in conflict settings in Pakistan and earthquake-affected communities in Nepal [17,18].

In high-income countries, several interventions have been introduced to prevent or reduce the effects of IPV [11,19], including counseling interventions, using empathetic listening and psychotherapies, which have demonstrated promising results [11,19,20]. IPV interventions ideally incorporate the development of a safety plan for women to rescue themselves from difficult situations of violence [11,19,20].

The PM+ intervention primarily focuses on managing the consequences of violence on mental health, but it lacks comprehensive components that specifically address the root cause, namely the violence itself. To bridge this gap, the Domestic Violence Intervention (DeVI), proposed in this study protocol, was developed by augmenting PM+ with other violence prevention elements, such as education on the cycle of violence and its impact on health, development of a safety plan, and empowerment-based counseling. Components such as areas of safety, choice making, and problem solving [20,21] were adapted from previous studies [22-24].

The name of the intervention, "DeVI," an integrated, multicomponent tool, is a neutral term that will be used throughout the trial while communicating with the research team and the participants. In Nepali, and originating from Hinduism, *devi* means *goddess* or *supreme woman deity*.

Figure 1. Map of Nepal showing the percentage of married girls and women aged 15-49 years who have experienced physical, sexual, or emotional violence committed by their spouse [6].

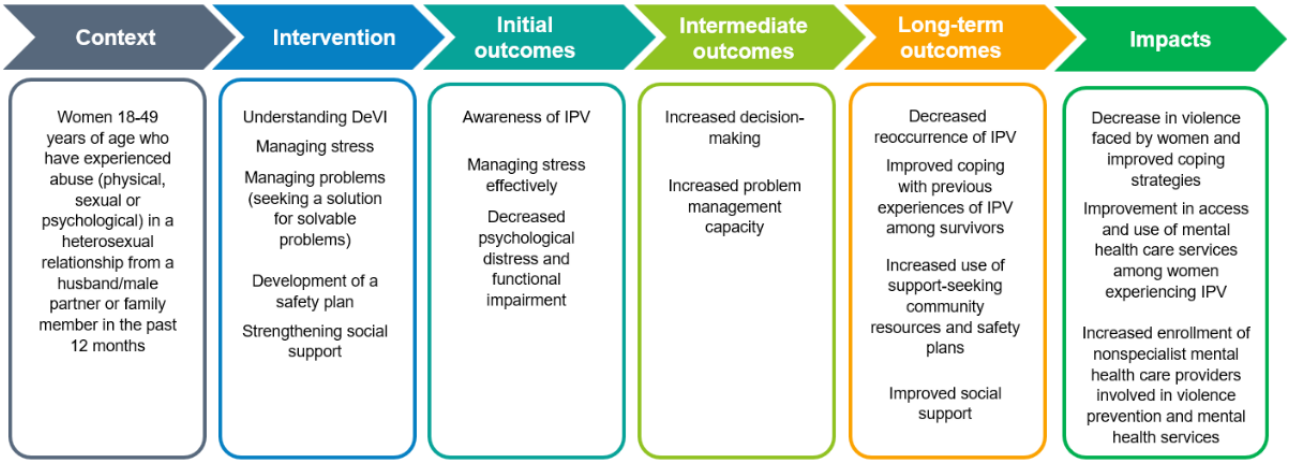
Study Aim

This study aims to implement and evaluate the feasibility, acceptability, and effectiveness of DeVI in addressing psychological distress and enabling the secondary prevention of violence for women experiencing IPV through a cluster-randomized trial. The program will be delivered through nonspecialist mental health care providers in public health institutions to increase the feasibility and applicability of such interventions in an LMIC setting. The study will be conducted in Madhesh Province, Nepal, which has the highest-reported prevalence of spousal violence/IPV [6].

Specific Objectives

The study aims to achieve the following objectives:

- Objective 1: Assess the feasibility of DeVI in health care facilities in Nepal by exploring the views of key stakeholders, health care providers, and local women in the community.
- Objective 2: Train nonspecialist mental health care providers in the delivery of DeVI among women experiencing IPV.
- Objective 3: Explore participants' and health care providers' experiences with DeVI and the opportunities and challenges encountered during implementation.
- Objective 4: Measure the effectiveness of DeVI in addressing and resolving psychological distress, reducing the occurrence of IPV, and developing safety strategies for women experiencing IPV.
- Objective 5: Measure the impact of training health care providers in DeVI on their knowledge, attitudes, skills, and stigma toward IPV and the social and health-related consequences of IPV.



Conceptual Framework of the Study

DeVI will be administered to women who have a history of any form of IPV (physical, sexual, or psychological) and are experiencing or have experienced psychological distress. The primary aim of this intervention is to decrease exposure to IPV and IPV-related distress. The intervention aims to enable women to cope with previous experiences of IPV and manage their situation better, strengthen mental well-being, and prevent revictimization (ie, protect participants from future harm). The intervention also aims to aid in the participants' development of a personal safety plan and strategies, encourage the identification of available support (of any form) in the

XSL•FO
RenderX

community, and use it effectively, when needed. Participants who show severe mental impairment, have suicidal thoughts, or are at risk of suicide after participating in the intervention will be handled per the risk management plan. Figure 2 depicts the conceptual framework of this study in brief.

Figure 2. Conceptual framework of DeVI, including expected outcomes. DeVI: Domestic Violence Intervention; IPV: intimate partner violence.

Methods

Ethical Considerations

This study was approved by the Ethical Review Board of the Nepal Health Research Council (approval no. 852/2019), and permission was obtained from the Ministry of Health and Population, the Health Directorate of Madhesh Province, and all study sites. The study will follow the *Ethical and Safety Recommendations for Intervention Research on Violence against Women* developed by WHO [25]. Participation in the study is voluntary, and participants have the right to refuse or withdraw at any point without providing a reason. Written informed consent will be obtained from all participants. In cases where participants are unable to read or write, a witness will be present during the consent process. Women needing more time to decide will be asked to communicate their decision during their next health care facility visit. Given the sensitivity of IPV/domestic violence, speaking openly about such experiences can be challenging due to shame, stigma, fear, and pressure. To address this, intervention implementers will receive training to create a comfortable environment where survivors of violence can feel at ease sharing their experiences. Further, the intervention will be conducted in a private room.

Study Design and Setting

This study is designed as a 2-arm parallel cluster-randomized trial comparing the study outcomes in the intervention arm to those in the usual standard-of-care (control) arm. The study protocol has been devised in accordance with the Consolidated Standards of Reporting Trials (CONSORT) guidelines for cluster-randomized trials [26].

The trial will be conducted across 8 districts of Madhesh Province, Nepal, which has the highest prevalence of IPV and poorer sexual and reproductive health outcomes indicators compared to other provinces [6]. Although the legal age of marriage under Nepali law is 20 years [27], women in Madhesh Province tend to marry 4 years earlier and are less likely to be literate than women in other provinces [6]. Poor socioeconomic conditions, low awareness of personal and human rights, poor quality of life, and traditional norms are contributors to IPV [28] and are common in Madhesh Province.

The study will be carried out in 24 health care facilities (only public hospitals and selected primary health care centers), both rural and urban, since these types of facilities constitute a major proportion of facilities available in the province that provide a range of services to the public and are visited by patients from diverse backgrounds. Some of the selected public hospitals, typically at the district level or higher, also offer integrated services for survivors of violence through 1-stop crisis management centers. These specialized centers offer a platform for women and care providers to exchange information regarding available measures to combat violence against women, as well as referrals for additional legal services, if necessary, and will enhance our comprehension of the effectiveness of interventions within the current context.

A total of 63 frontline female health care providers (eg, nurses and auxiliary nurse midwives [ANMs]) were trained to deliver DeVI: 33 (52%) health workers from the intervention sites and 30 (48%) health workers from the control sites. Of these, 9 (27%) health workers from the intervention sites and 8 (27%) from the control sites received training to be backups for the intervention implementation or data collection if the primary implementor or data collector was unavailable due to unforeseen circumstances, such as transfer to another health care facility, illness, or pregnancy.

Formative Assessment and Consultation Workshop

A formative assessment was conducted during a preliminary site visit before the commencement of the trial in order to explore the behavior, experiences, opinions, and knowledge of key stakeholders, health care providers, and women experiencing IPV/domestic violence. A qualitative approach using focus group discussions (FGDs), in-depth interviews (IDIs), and key informant interviews (KIIs) was followed to collect data for the formative assessment. The key stakeholders included were women experiencing IPV/domestic violence, local health care providers, women seeking care in the outpatient department,

XSL•FO
RenderX

representatives from various community-based organizations, and individuals/experts from federal and provincial levels. A total of 21 interviews, including 15 (71%) IDIs with health care providers, 3 (14%) IDIs with women visiting the outpatient department, and 3 (14%) KIIs with the stakeholders, and 1 FGD with women experiencing IPV were conducted in Nepali by trained field interviewers.

The FGD explored the women's knowledge, attitudes, and opinions about IPV/domestic violence, as well as personal experiences of violence and its mental, physical, and social impacts. The FGD further explored the challenges these women faced while coping with past experiences of violence, along with barriers to and facilitators of seeking help from a victim's perspective. IDIs with local health care providers focused on existing models of care for women experiencing IPV/domestic violence and their perceptions, experiences, and challenges in managing IPV/domestic violence. IDIs with women seeking care explored their general perspectives of IPV/domestic violence. KIIs with various key stakeholders from different community-based organizations and local nongovernmental organizations (NGOs) explored their role, perceptions, and challenges in preventing and managing IPV/domestic violence. Furthermore, these interviews explored health care providers' suggestions and feedback on DeVI's ability to address psychological distress issues and reduce the recurrence of IPV/domestic violence in communities in which they have been working.

National-level consultation workshops with experts in the field of IPV and mental health were also conducted. Their feedback on the study intervention and tools was acknowledged, and our intervention was updated accordingly. Findings from the formative assessment and consultation workshops were used to adapt the data collection tools and intervention according to the local, social, and cultural context and the participants' knowledge about the topics. Additionally, these findings helped the study team customize the training to be provided to intervention implementers and data collectors at the local health care facilities.

Validity and Reliability of the Tools

All the tools used in this study are standardized and have been used and validated previously in South Asian contexts, including Nepal [17, 29-31]. The tools were translated into Nepali and local languages (Bhojpuri and Maithili), which were reviewed by respective subject and language experts. The validity and reliability of these translated tools were further assessed during pretesting. Pretesting was conducted within a small sample of local working teams, including survivors of violence, and the tools were amended accordingly.

Training of the Study Team

Public health experts, psychiatrists, and staff working on violence against women provided all the field team members (staff nurses and ANMs) involved in the study with specific training in an interactive way, ensuring active participation in the study. The intervention implementers received 10-day training primarily focused on DeVI, the integrated, multicomponent intervention, and were briefed about the types of violence, their prevalence and impact, and the status of women in Madhesh Province. The implementers were also thoroughly trained in implementing the intervention, conducting sessions, and using flipcharts, brochures, worksheets, templates, and forms. In addition, they were trained in the importance and maintenance of confidentiality and ethical considerations. Furthermore, they were trained in how to build trust with the participants, such as approaching them politely, and how to create a comfortable and friendly environment for basic counseling and intervention. While delivering the intervention, the implementers may feel strong emotions and stress, so they were trained to handle their own stress. Although each participant will receive the intervention in a separate, private room at a health care facility, the intervention implementers were also trained to divert the topics to maternal/reproductive health–related issues if interrupted by the person accompanying the participant, such as the woman's spouse/in-laws. Participants will also be informed about such diversions.

Data collectors for both arms received 3-day training in approaching the participants, following ethical guidelines, maintaining confidentially, determining eligibility, using various tools and techniques for data collection, getting oriented with Research Electronic Data Capture (REDCap) data collection software, and sharing data with the central team. They were also trained in using screening, baseline, and follow-up tools.

Participants and Recruitment

Sample Size

Based on the sample size calculation, a total of 912 eligible women (456, 50%, in each arm) will be included in the study. This sample size for the cluster-randomized trial was calculated considering 80% power to detect 15% absolute risk reduction in the IPV frequency in the intervention arm at a statistical significance level of $\alpha<.05$ [32]; we estimated a 50% reduction in mental health problems in the PM+ group, as measured with the 12-item General Health Questionnaire (GHQ-12) [33]. The minimum number of clusters required in each arm was 6, which was later increased to 11 to ensure an efficient trial design [34]. The number of clusters was further increased to 12 to account for dropouts at the cluster level [34]. Finally, a total of 24 clusters (12, 50%, intervention and 12, 50%, control clusters) were included, and 38 eligible women from each cluster regardless of the arms will be enrolled in the study.

Recruitment

Participants will be recruited using different approaches, including direct recruitment by asking women visiting health care facilities for maternal and reproductive health services by trained ANMs and nurses. In addition, women visiting the hospital-based 1-stop crisis management centers will also be approached for the study. Furthermore, female community health volunteers and community leaders may also disseminate information about the study to the community in any gatherings, such as mothers' groups, community meetings, or health-related events.

XSL•FO
RenderX

Eligibility and Screening

The inclusion criteria for the participants are as follows: (1) women aged 18-49 years; (2) those self-reporting experience of abuse (physical, sexual, or psychological) in a heterosexual relationship, involving their husbands/male partners or other family members, occurring within the past 12 months; (3) women who are nonpregnant or in the first trimester; (4) those with a minimum score of ≥3 on the Psychological Distress Scale (measured with sthe GHQ-12) [35]; and (5) those living with their husbands or in-laws for at least 6 months. Women will be excluded if they (1) have severe cognitive impairment, (2) are seeking treatment for life-threatening emergency care, (3) or are at imminent risk for suicidal ideation and attempt. A questionnaire that helps in determining these eligibility criteria will be formulated and used specifically for the purpose of screening women for eligibility. Women who are at imminent risk for suicidal ideation and attempt will be referred to a psychiatrist.

Retention of Study Participants

Contact information of the participants, alternative contact persons, and preferred times for making phone calls for safe contact will be collected in order to keep in touch with them. If a participant absconds from a scheduled session or follow-up, the intervention implementer will try to contact her over the phone and encourage her to attend all sessions and follow-ups. If the participant is still absconding or cannot be contacted over the phone, the intervention implementer will contact female community health volunteers to follow up with the participant personally or over the phone. Female community health volunteers properly informed by the intervention implementer will then personally visit the participant at home following ethical guidelines [25]. All ethical guidelines [25] described in detail in the *Ethical Considerations* section will be considered while following up with participants to continue and complete the intervention. However, participants will be clearly informed that they are free to withdraw from the trial at any time without giving reasons.

Randomization and Blinding

From a sampling frame of 43 health care facilities available in Madhesh Province, a total of 24 (56%) facilities were selected based on the flow of women seeking various health-related services. The selection process involved randomization of health care facilities using a computer-generated random number table, ensuring a 1:1 ratio of intervention and control clusters (12, 50%, intervention and 12, 50%, control clusters). Each health care facility represents 1 cluster.

Participants visiting the intervention sites will be recruited into the intervention arm, while those visiting the control sites will be recruited into the control arm. To maintain blinding, both participants and health care facility staff will be completely unaware of the information pertaining to the 2 different arms, as well as the arm to which their respective health care facility belongs. However, it may not be possible to conceal this information from the study team responsible for the study design. Therefore, the study will be unmasked during data monitoring, evaluation, and analysis.

DeVI: An Integrated Multicomponent Intervention

This intervention is structured into 5 weekly sessions, where each session lasts for about 90 minutes. The first session includes general information about DeVI, components to understand the cycle of violence, and its potential health impacts. Following this, the second session focuses on common health problems caused by IPV, mental health consequences, the purpose of managing stress, and techniques for managing stress. The third session emphasizes on strategies to help women manage their situation and develop their own customized problem management strategies. This session aims to improve participants' ability or skills to solve and manage practical problems that may be influenced by other factors or changed by conflict in the family or unsolvable problems, such as employment. These problems are managed considering the participants' existing personal strengths, resources, or support. This is followed by exploring safety-planning behaviors and preparing a customized safety plan in the fourth session. The last session involves exploring social support and assisting participants in planning to strengthen the social support identified. The contents of DeVI are detailed in Table 1.

XSL•FO
RenderX

Table 1. Contents of DeVI[a].

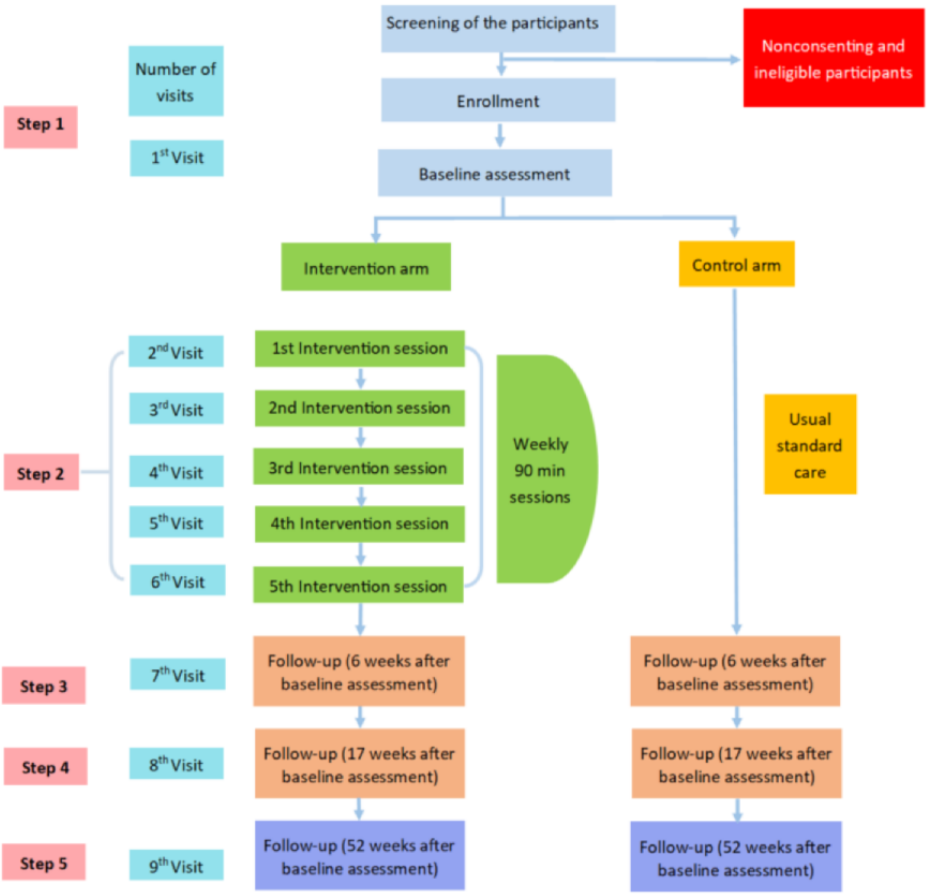
Intervention session	Contents of PM+[b] [16]	Additional components of DeVI
Session 1: understanding the muticomponent intervention	Introduction and confidentiality	General information about DeVI
	Before-intervention PSYCHLOPS[c] assessment	IPV[d] and domestic violence, the cycle of violence, and its common impacts on health
Session 2: common consequences of IPV and domestic violence and managing stress	During-intervention PSYCHLOPS assessment and general review	Information about common health problems associated with IPV/domestic violence
	Purpose of managing stress	Details about the common mental health consequences of IPV/domestic violence
	Explanation and demonstration of some common stress management techniques	Case of a women experiencing IPV/domestic violence
	Strategies to manage stress	
Session 3: managing problems	During-intervention PSYCHLOPS assessment and general review	Behavioral activation, during which participants will be encouraged to gradually re-engage with pleasant and task-oriented activities to improve mood and functionality
	Strategy for managing problems and its usefulness	
	Practice of the problem-managing strategy through a case example	
	Application of the strategy in solving practical problems identified by participants	
	Plan to solve the identified problems	
	Practice of stress management techniques	
Session 4: development of a safety plan	During-intervention PSYCHLOPS assessment and general review	Safety behavior assessment
		Safety-planning behaviors applicable to the participants' context
		Barriers to and facilitators of using safety behaviors
		Preparation of a safety plan in times of need
		Information about applying for legal protection orders
		Filing criminal charges
Session 5: strengthening social support and referrals	During-intervention PSYCHLOPS assessment and general review	Distribution of an information booklet that details updated contact information or locally available organizations that offer different services to women experiencing IPV
	Available social support	
	Assisting participant in making plans and approaches for strengthening social support identified	

[a]DeVI: Domestic Violence Intervention.

[b]PM+: Problem Management Plus.

[c]PSYCHLOPS: Psychological Outcome Profiles.

[d]IPV: intimate partner violence.



Procedure

Trained ANMs and nurses will be referred to as data collectors and intervention implementers, respectively. Their role throughout the study will be to approach women visiting health care facilities and screen them using a questionnaire for willingness to participate and eligibility. The study process is illustrated in Figure 3.

Data collectors will provide detailed information about the study to potential eligible participants and obtain written informed consent for a baseline assessment. Once consent is obtained, data collectors will conduct a baseline assessment. The baseline assessment will take about 30-45 minutes, which will be carried out in a separate room at the health care facilities. Participants will be made aware that refusal to participate will not have an impact on any type of support that they receive outside of the study. The detailed steps of study activities are listed in Table 2.

[c]DeVI: Domestic Violence Intervention.

Intervention Arm

After the baseline assessment, study participants will be referred by data collectors to intervention implementers, whose role is to deliver the intervention package once a week, with each session lasting around 90 minutes. The intervention package aims to prevent the recurrence of IPV/domestic violence and address psychological distress among participants. During each session, intervention implementers will administer the Psychological Outcome Profiles (PSYCHLOPS) form, a mental health and social functioning tool. Before-intervention PSYCHLOPS data will be collected in session 1, and during-intervention PSYCHLOPS data will be collected in sessions 2-5. At the end of each session, the intervention implementer will schedule the participant's next session. The intervention implementers will guide and encourage the participants to develop personalized plans and strategies for managing their problems, create a safety plan, and fully use existing community organizations and social support.

Enhanced Standard Care or the Control Arm

Control arm participants will receive standard care provided by the local health care facilities, depending on what they seek care for, and they will also receive an information booklet. Any participant with severe psychological distress or at risk for suicide will immediately be referred to a psychiatrist. Psychiatrists can provide remote counselling over the phone to the participant and, if necessary, also visit the participant in person. The study team will arrange the time, schedule, and consultation fees for the psychiatrist in both study arms, particularly for severe cases involving suicidal ideation identified during screening. Further, if the participant prefers to visit a psychiatrist herself, she will be provided with the travel cost.

Information Booklet

Both intervention and control arms will receive an information booklet that contains updated contact information for referral services in the study area. Further, they will receive information about the psychological distress resulting from IPV/ domestic

XSL•FO
RenderX

violence and available services in the local context for psychological and legal support. Ahead of the study, the study team contacted and coordinated with concerned NGOs or community organizations working in the field of prevention of violence against women or management of mental health problems in the study area to ensure that women have safe places to visit in case of an emergency or difficulty.

Follow-up Assessments

Follow-up surveys will be conducted at 3 time points: 6 weeks after baseline assessment (ie, 1 week postintervention), 17 weeks after baseline assessment (ie, 12 weeks postintervention), and 52 weeks after baseline assessment (ie, 47 weeks postintervention). The data collection tools for follow-up will be similar to those for baseline assessments. However, in the last follow-up, participants will be asked questions and will be expected to contribute to the assessment of any sustained effects of DeVI on the prevention of revictimization and improvement in coping strategies against IPV. An exit interview will be conducted after intervention session 5.

IDIs will be conducted with health care providers from the intervention arm during or after the intervention to explore their experiences and perspectives of DeVI and program implementation. Health workers will be mobilized to identify suitable participants in the community, and those who provide written informed consent will be contacted for confidential interviews, preferably at the health care facility, both during and after the intervention.

Adverse Events and Risk Management

There are some potential risks to participants, such as escalation of violence, as they reside at the same household as the perpetrator. Participants will be briefed about safety behaviors and contact numbers of local authorities and the study team (ie, health care providers, psychiatrists) that they may seek help from when in need. If any participants are in grave danger and do not want to go home, they will be referred to local shelter homes managed by different community organizations and NGOs.

If any other unprecedented harm or risk arises affecting the involved participants in any study arm, data collectors and intervention implementers from each site will notify the project coordinator immediately and manage the situation per guidance from the study team, depending upon the intensity of the adverse event. Adverse events would include a marked increase in suicidal thoughts, the death of the participants, suicide attempts, serious violence, the need for prolonged hospitalization, disability/incapacity, and any other life-threatening events. The study team will also assess these factors throughout the study period.

Any participant who is at risk for severe injury or who displays severe psychological distress and needs help from a specialist will be referred to a psychiatrist by the study team. Intervention implementers will receive the necessary help and guidance from the study team for risk management at respective sites. If any adverse event is reported by a participant or observed at any stage of the study by the data collector or intervention implementer, the study team will record all the necessary details in an adverse reporting form. This form, which is designed by integrating the adverse event form developed by WHO and the National Institutes of Health (NIH), will be used to capture adverse event details of individual participants throughout the study [25].

Outcomes Measures

Primary Outcomes

The primary outcomes are psychological distress and the frequency and intensity of IPV/domestic violence. IPV/domestic violence will be assessed using the modified WHO multicountry questionnaire [36]. This instrument synthesizes women's experience of physical, sexual, and psychological violence, as well as controlling behavior by husbands/male partners, and also measures the severity of IPV/domestic violence. Psychological distress will be measured with the GHQ-12 [35] and the 9-item Patient Health Questionnaire (PHQ-9) [37]. Both tools have been translated and clinically validated in Nepal. The GHQ-12 has a cut-off score of 0.5, with sensitivity 85.6%, specificity 75.8%, positive predictive value 86.7%, and negative predictive value 84% [38]. Similarly, the PHQ-9 has a cut off score of ≥10, with sensitivity 94%, specificity 80%, positive predictive value 42%, and negative predictive value 99% [39].

Secondary Outcomes

The secondary outcomes are safety planning, use of community resources, social support, impaired functioning, symptoms of PTSD, personally identified problems, and health service use. Health care providers' capacity to identify IPV/domestic violence to provide women experiencing IPV/domestic violence with risk mitigation services will also be assessed. Details of instruments and assessments for primary and secondary outcomes, including follow-up time, are provided in Tables 3-5.

Other Outcomes

Health care providers will be asked to respond to questionnaires, such as the modified Physician Readiness to Manage Intimate Partner Violence Survey (PREMIS), the Mental Health Knowledge Schedule (MAKS), the Social Distance Scale, and the perceived dangerousness of mental health patients pre- and posttraining to assess the impact of training on the health care providers' knowledge and attitude. Further, MAKS and the perceived dangerousness of mental health patients will be assessed during integrated multicomponent supervision (approximately 90 days posttraining). Exit interviews will be conducted among 180 participants by data collectors in the absence of intervention implementers after the completion of all 5 sessions in a separate room by adopting a mixed methods approach. This will help determine changes postintervention and any aspects that need to be changed. This will also help assess the satisfaction and acceptability of DeVI from the participant's point of view.

Quantitative Data Collection for the Trial

Quantitative data will be collected electronically using REDCap software [45] and various data collection tools by data collectors in computer-based tablets at different time points. If any technical problem arises during electronic data collection, paper-based data collection will be performed. Each health care facility will be provided with a computer-based tablet with an updated questionnaire for data collection.

Data collection tools will include structured surveys and standard validated tools. The structured surveys will include questions on participants' personal information (date of birth, ethnicity, address, contact information, and preferred time to call) and sociodemographic characteristics. The data collection tools in this study are standard international tools widely used and validated in different countries. However, some terminologies and contents have been contextualized to suit the Nepali context. The data will be collected at 4 different time points, once at baseline and at 3 follow-up time points (see Figure 3 for details). In addition, the PSYCHLOPS form will be filled in at the 5 intervention sessions.

Qualitative Data Collection

Qualitative interviews will be conducted by purposively selecting participants to learn more about their perspectives toward DeVI. IDIs will be conducted with randomly selected intervention implementers to understand their challenges in implementing the intervention sessions and their suggestions for improving the applicability and sustainability of DeVI. A deeper understanding of their needs will help the study team alter the intervention approach and activities in the future. The qualitative process assessment will also help assess the acceptability of DeVI, which is key for scale-up and integration into routine services.

Data Management and Analysis

Quantitative Data Analysis

Electronically collected data will be securely stored in a central office cloud, accessible only to designated study team members. Paper-based data pertaining to the study will be secured in a locker and retrieved from data collectors during central study team monitoring. Regular checks will be conducted to ensure data accuracy and quality, with necessary feedback provided to the data collectors. The primary measure of intervention effects will be based on intention-to-treat analyses. Multilevel analysis will be conducted to account for DeVI's impact on primary and secondary outcomes, adjusting for clustering at the health center level [46]. The model will consider intervention × time interactions to assess the differential effects of DeVI on changes in outcomes from baseline to the final follow-up. Cluster-level variables will also be compared between intervention and control arms since randomization is based on health care facilities.

XSL•FO
RenderX

Furthermore, the study will assess variations in outcome measures of interest between urban and rural areas.

The knowledge, perception, and preparedness of both intervention implementers and data collectors will be assessed before and after the training through pre-, post-, and follow-up tests. Quantitative data will be analyzed using STATA 15 software.

Qualitative Data Analysis

Qualitative interviews will be conducted in Nepali and audio-recorded with the participants' consent. The recordings will be stored on a password-protected device. Transcription will be carried out in Nepali, and then the transcripts will be translated into English. The transcripts will undergo thorough review and validation against audio recordings to ensure accuracy. Qualitative content analysis will be performed. Independent researchers will initially conduct open coding, followed by discussion within the study team. Agreed-upon codes will be grouped into categories and themes, which will be developed and finalized based on the study objectives.

Monitoring and Evaluation

The monitoring committee will comprise a study principal investigator, coinvestigators, and other independent experts who will oversee the study's implementation and data collection. Any deviations from the protocol will be identified and documented during monitoring. The team will monitor and supervise field activities and communicate over the phone every day and visit all the study sites every month. The monitoring activities will be aided by checklists, tools, and manuals. Regular communication, both oral and written, will facilitate ongoing monitoring and updates among data collectors, intervention implementers, and other study members at the central offices.

Process Evaluation

Concurrently with the trial, we will conduct process evaluation following the implementation component of the UK Medical Research Council's guidance [47] in order to enhance comprehension of the DeVI's acceptability among both women experiencing violence (reach) and health care providers. Additionally, we will assess the study's adherence to the intended plan. The evaluation also aims to explore the barriers to and facilitators of DeVI (adaptations) from the perspective of health care providers, providing information about the possibility of its future sustainability and scalability, considering its effectiveness.

This process evaluation is based on the hypothesis that health care providers can identify women experiencing violence with mild-to-moderate psychological distress and that they can deliver planned counseling sessions and inviting women for further sessions and follow-ups on predetermined dates and times. This evaluation also hypothesizes that health care providers will allocate time for delivering the sessions in intervention sites, as well as conducting baseline and follow-up assessments in both intervention and control sites, in addition to their regular duty.

A mixed methods approach will be used for the process evaluation. Qualitative data will be collected through in-depth interviews with data collectors and intervention implementers at different time points. Quantitative data will be collected using an observation checklist and a 3-month follow-up period. The IDIs with health care providers will explore their experiences in, barriers to, and facilitators of recruiting and retaining women, as well as providing suggestions for improvement. Similarly, the observation checklist will help track their progress and status in the trial thus far, while the practice questionnaire will assess changes in their practice regarding violence identification and management. The practice questions will be derived from the practice section of the PREMIS questionnaire, which was previously used during training as a pretest. Qualitative data will be analyzed using thematic analysis [48], while quantitative data will be simply analyzed using descriptive analysis.

The process evaluation will uncover unforeseen insights, propose solutions, and introduce innovative approaches that encompass diverse aspects and perspectives of health care providers engaged in the trial. Moreover, should the trial deviate from its predetermined trajectory, we will diligently work to enhance the program by addressing areas requiring improvement, facilitating, overcoming barriers, ensuring resource availability, and effectively managing the time of health care providers.

Periodic monitoring will involve conducting site observations, observing intervention sessions with participant consent, and keeping track of participants. Regular meetings will be held between the study team and field teams to exchange updates and monitor progress. Adverse events related to the intervention will be reviewed periodically. The study team will cross-check the collected data for accuracy and completeness. Any identified errors during data monitoring will be promptly addressed through communication with the field teams for correction.

Dissemination of Findings

Study findings, along with policy recommendations for enhanced collaboration between key stakeholders and increased coverage of IPV/domestic violence and mental health services for women, will be disseminated to relevant provincial and national stakeholders and authorities. The study results and recommendations will reach a wider audience through policy briefs, press releases, workshops, conferences, and scientific publications.

Results

The trial received funding from the Swedish Research Council in 2019. The goal is to recruit 456 eligible women in each arm. As of December 29, 2022, a total of 269 eligible women were enrolled from the intervention sites and 309 eligible women from the control sites. The trial is currently in the recruitment phase. Data collection is expected to be completed by December 2023. Data analysis will begin shortly after obtaining all the data following the established plan. Regular data cleaning and monitoring are being conducted every day.

XSL•FO

Discussion

Summary

This cluster-randomized trial aims to implement and evaluate the acceptability, feasibility, and effectiveness of DeVI in addressing psychological distress and enabling the secondary prevention of violence for women experiencing IPV. These interventions will be administered by trained nonspecialist mental health care providers in Madhesh Province, Nepal, at the health care facility level. As of December 29, 2022, the study had enrolled 59% (n=456) of eligible women from the intervention sites and 68% (n=456) of eligible women from the control sites. In low-income settings, such as Nepal, mental health specialists are scarce. Therefore, if this study proves effective, it could provide scientific evidence supporting the integration of mental health services into routine health care facilities in Nepal. This integration aims to prevent the recurrence of violence and address mental health issues among survivors of violence. Additionally, the study can offer valuable insights into how nonspecialist mental health care providers can address mental health problems and violence among women experiencing IPV/domestic violence. DeVI aims to improve access for marginalized women, particularly those who are hard to reach and have experienced IPV/domestic violence, while facing mental health challenges. Throughout the intervention, health care providers and survivors of violence will collaborate actively to address violence and enhance the women's mental well-being. They will develop customized strategies for self-management of these issues. Investing in women's health is considered a cost-effective strategy to improve the nation's overall well-being [49].

We hypothesize that addressing the needs of women experiencing IPV/domestic violence will enhance their mental stability and reduce long-term health risks associated with violence. This study will contribute to bridging existing knowledge gaps by generating scientific evidence for regional policy makers, given the limited availability of data on mental health issues in resource-constrained settings.

The results from DeVI will hopefully support the integration of mental health services into routine health programs in Nepal. It could also add evidence to the global knowledge base on how and whether nonspecialist mental health care providers can be mobilized in addressing mental health problems in settings where IPV/domestic violence prevalence is high and human resources scarce. In addition, if this cluster-randomized trial is proven effective, this concept can be replicated in other LMICs following contextual adaptation and testing in each setting and target population.

Limitations

Women experiencing violence and eligible for our study may refrain from providing consent due to the fear that their husbands or male partners will subject them to further abuse upon discovering their participation. The dropout rate may be higher due to the associated stigma and the fear of family members, society, and perpetrators. In a patriarchal society, such as Nepal, women are typically accompanied by their in-laws or husbands when seeking basic services at health care facilities, which creates reluctance to disclose issues related to violence or participate in the study.

Conclusion

This trial aims to present vital evidence for mitigating the impact of intersecting violence and mental health issues among women in Nepal. If the intervention is found to be effective, the study has the potential to offer significant contributions and insights into how nonspecialist mental health care providers can address problems related to IPV and mental health among survivors in low-income settings.

Acknowledgments

This work was supported by funding from the Swedish Research Council. The funder played no role in study design, data collection, and analysis; the decision to publish; or preparation of the manuscript.

Data Availability

Data sharing is not applicable to this paper as no data sets will be generated or analyzed during this study.

Authors' Contributions

KD conceived and designed the study. RS, DS, DM, and AME made substantial contributions to the study design, and KD and RS drafted the manuscript. All the authors revised the manuscript critically for intellectual content and have read and approved the final manuscript.

Protocol

Effects of Melatonin on Glycemic Variability in Type 2 Diabetes Mellitus: Protocol for a Crossover, Double-Blind, Placebo-Controlled Trial

Abstract

Background: Glycemic variability is recognized as a significant factor contributing to the development of micro- and macrovascular complications in individuals with type 2 diabetes mellitus (T2DM). Numerous studies have shown that melatonin, a hormone involved in regulating various biological rhythms, including those related to glucose regulation, such as hunger, satiety, sleep, and circadian hormone secretion (ie, cortisol, growth hormone, catecholamines, and insulin), is deficient in individuals with T2DM. This raises an important question: Could melatonin replacement potentially reduce glycemic variability in these patients? This warrants investigation as a novel approach to improving glycemic control and reducing the risk of complications associated with T2DM.

Objective: We aimed to investigate whether melatonin replacement in individuals with T2DM who supposedly have melatonin deficiency can positively impact the regulation of insulin secretion rhythms and improve insulin sensitivity, ultimately resulting in a reduction in glycemic variability.

Methods: This study will use a crossover, randomized, double-blind, placebo-controlled trial design. Patients with T2DM in group 1 will receive 3 mg of melatonin at 9:00 PM in the first week, undergo a washout period in the second week, and receive a placebo in the third week (melatonin-washout-placebo). Group 2 will be randomized to receive a placebo-washout-melatonin sequence (3 mg). Capillary blood glucose levels will be measured at 6 different times before and after meals during the last 3 days of the first and third weeks. The study aims to compare the mean differences in blood glucose levels and the coefficient of glycemic variability in patients receiving melatonin and placebo during the first and third weeks. After analyzing the initial results, the number of needed patients will be recalculated. If the recalculated number is higher than 30, new participants will be recruited. Thirty patients with T2DM will be randomized into the 2 groups: melatonin-washout-placebo or placebo-washout-melatonin.

Results: Participant recruitment took place between March 2023 to April 2023. In all, 30 participants were eligible and completed the study. We expect that patients will show different glycemic variability on the days they receive placebo or melatonin. Studies on melatonin and glycemic control have shown both positive and negative results. We hope that there will be a positive outcome regarding glycemic variability (ie, a reduction in glycemic variability), as melatonin has a well-described chronobiotic effect in the literature.

Conclusions: This study aims to determine whether melatonin supplementation can effectively reduce glycemic variability in patients with T2DM. The crossover design is necessary due to the multiple variables involved in the circadian variations of glucose, including diet, physical activity, sleep parameters, and pharmacological treatments. The relatively low cost of melatonin and its potential role in reducing the severe complications associated with T2DM have motivated this research effort. Furthermore, the indiscriminate use of melatonin in current times makes conducting this study essential to evaluate the effect of this substance in patients with T2DM.

type 2 diabetes mellitus; glycemic control; melatonin; randomized controlled trial; cross-over studies; T2DM; glucose; glycemic variability; circadian rhythm

Introduction

Despite recent advances in medical technology and treatments for type 2 diabetes mellitus (T2DM), the prevalence of this disease is still increasing exponentially worldwide [1]. According to the International Diabetes Federation, the number of adults with T2DM globally was expected to rise to 463 million in 2019 and 700 million by 2045, with a significant impact on public health, society, and the economy [2]. Effective treatment of T2DM is crucial in avoiding complications and improving overall health outcomes for patients. In recent years, the management of T2DM has evolved significantly due to the discovery of new therapeutic targets and the development of new drugs with different mechanisms of action [3]. Additionally, nondrug interventions that impact glycemic control have become increasingly important in the management of T2DM [4,5]. Dietary modification, physical activity, weight management, and stress management have long been recommended. In addition to lifestyle modifications and medication, the role of good quality sleep in managing T2DM has become increasingly recognized by health care professionals. The American Diabetes Association's 2017 position statement underscored the significance of adequate sleep in the management of T2DM and brought attention to the detrimental effect that sleep disturbances can have on glycemic control [6]. Melatonin, a hormone linked to the circadian rhythm, may be the pathophysiological link between sleep changes and glycemic control [7]. This hormone synchronizes our waking, sleeping, hunger, and satiety times, as well as other biological functions, such as insulin secretion. Previous studies found that melatonin production is reduced in T2DM [8-10]. While some papers have suggested that melatonin replacement may have benefits for glycemic control, the results of these studies have been conflicting, with some studies not showing significant benefits [11-14]. How can such differences be explained? The impact of melatonin on glycemic control may depend on several factors, including the timing and duration of use, as well as individual genetic variations, such as *MT2* melatonin receptor polymorphisms [15,16] Mutations in the *MT2* receptor gene have been associated with altered glucose metabolism and insulin sensitivity and may impact the effectiveness of melatonin supplementation in improving glycemic control. Some studies have suggested that individuals with *MT2* receptor mutations may experience an increase in glycohemoglobin levels following melatonin use, unlike those without this mutation.

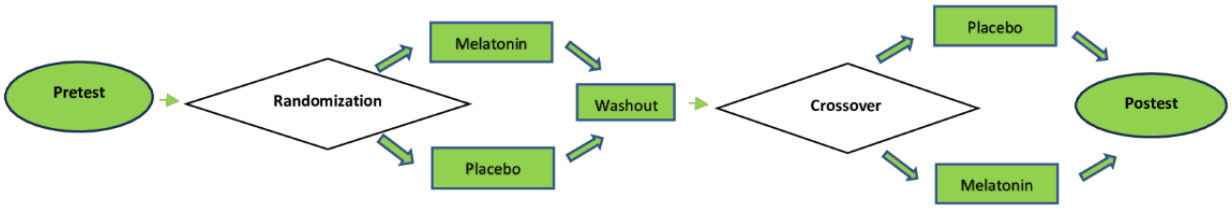
Assessing variations in glucose throughout the day, instead of just the average glycohemoglobin level, is an important aspect of investigating the potential impact of melatonin on glycemic control. In this work, we will not evaluate the role of melatonin in average glucose (glycohemoglobin) level, but on variations in glucose level throughout the day. Our proposal is to determine whether melatonin influences the circadian rhythm of glucose in patients with T2DM. Currently, no study has evaluated whether melatonin has such a role.

Glycemic variations throughout the day depend on central and peripheral control of insulin secretion and sensitivity. Previous studies have linked the action of melatonin on *MT1* and *MT2* receptors to insulin secretion and sensitivity [17]. Our hypothesis is that melatonin replacement in people with T2DM who are melatonin deficient may have a positive role in the regulation of insulin, cortisol, and the rhythms of other secretions. If this hypothesis is correct, melatonin replacement may reduce the range of blood glucose variation throughout the day. It has already been demonstrated that wide circadian glucose variation in patients with diabetes mellitus can be a stress and inflammation factor and lead to chronic complications of the disease that occur when glycohemoglobin is elevated [18,19]. Thus, this study asks, Could melatonin replacement in these melatonin-deficient patients attenuate these glycemic oscillations? The objective of this research project is to assess whether melatonin supplementation can reduce glycemic variations throughout the day in patients with T2DM.

Methods

Study Design

This prospective, crossover, double-blind, randomized, placebo-controlled study was approved by the ethics committee of the Federal University of Minas Gerais. The study will be conducted at an endocrinology outpatient clinic run by the research physician (WM) in the city of Belo Horizonte, Brazil. Thirty patients will participate in the initial phase of this work. These patients will be randomized to 2 groups: a placebo-washout-melatonin (3 mg) group, which will receive a placebo for 7 days, followed by 7 days without the study medication (washout period) and 7 days of melatonin (3 mg); and group 2, the melatonin-washout-placebo group, which will receive melatonin (3 mg) for 7 days, followed by 7 days without the study medication (washout period) and 7 days of placebo. When 15 patients are allocated to one of the possible intervention orders (placebo followed by melatonin or melatonin followed by placebo), 15 patients will be allocated to the other, not-yet-complete intervention order. Patients will be instructed to use the study medication at 9:00 PM. Patients will receive guidance on diet and physical activity to be followed during these 3 weeks. On the fifth, sixth, and seventh days of the first week and the fifth, sixth, and seventh days of the third week, the patients will use a glucometer to monitor fasting capillary



XSL•FO
RenderX

blood glucose before breakfast, 2 hours after breakfast, before lunch, 2 hours after lunch, before dinner, and 2 hours after dinner. The primary outcome analyzed in this study will be the variability of pre- and postprandial glycemia. The result will be compared between 2 periods: with placebo and with melatonin.

Blinding

Medicine bottles containing melatonin or placebo will be numbered 1 and 2, not necessarily in that order. The individual responsible for assigning the numbers will be the sole person with knowledge of which bottles contain melatonin and which contain placebo. All other people involved in this project (patients, medical researchers, statisticians, and assistant personnel) will be blind in relation to the substances. Upon completion of the statistical analysis, the researchers will be informed as to which bottle contained melatonin and which contained placebo. Figure 1 shows a flowchart of the study.

Figure 1. Flowchart.

Glycemic Variability and Crossover Studies

Crossover studies present an advantage over parallel group studies: comparing 2 or more interventions in the same individual reduces possible biases related to differences between groups. Such a design is suitable for chronic diseases and for testing drugs that control a disease but do not cure it. Curing a disease in one period of the study would make it meaningless to use another drug or even a placebo in the following period. When studying an outcome that is influenced by several variables, this design allows for a more reliable comparison with a smaller sample. This is the case for assessing glycemic variability in patients with T2DM. Glycemic variability in patients with T2DM can be influenced by several factors, including medications, duration of diabetes, age, diet, and physical activity. In the evolution of the treatment of diabetes mellitus, there has been an effort to develop drugs that reduce variability in glycemia: dipeptidyl peptidase 4 (DPP-4) inhibitors, GLP1 (glucagon-like peptide 1) analogues, and ultra-slow insulins. Patients with T2DM are treated with a diverse combination of the available drugs. For this reason, pairing groups for a comparison of glycemic variability would be a complex task. Added to this are individual differences in diet and physical activity. Thus, a crossover study is more suitable for the purpose of this work.

Melatonin and the Carryover Effect in Crossover Studies

Crossover studies should include an adequate washout period, that is, a period in which there is a break from the initial intervention until the beginning of the next intervention. In this work, we propose a period of 1 week for the washout. Questions to examine include whether that time is adequate and whether effects of the initial intervention in the first week remain in the third week. As melatonin has a short half-life (10 to 60 minutes), we believe that its influence will not be present in the third week of the study in the group that uses it initially; a washout period of 1 week thus seems sufficient [20]. Therefore, after a week without using any substance, the initial intervention will not influence the proposed intervention in the third week.

Glycemic Variability

Glycemic variability refers to fluctuations in blood glucose levels over time. It can be short-term, in self-monitored evaluations of (pre- and postprandial) capillary blood glucose; it can also use the gold standard method, continuous blood glucose monitoring, in which nocturnal blood glucose fluctuations are recorded every 5 minutes [21,22]. There is little correlation between the average variability in glycemic amplitude measured by continuous glucose monitoring and by self-monitoring; however, the latter method can be used for structured assessments of short-term glycemic variability in a day and between different days. The calculation of glycemic variability by this method can also be performed using SDs or even the coefficient of variation. A glycemic variation coefficient of less than 36% is considered level E evidence to separate stable from unstable glycemic control [21]. This measure is considered most effective to assess glycemic variability; however, comparing glycemia between different days is more effective with the mean of daily differences (MODD). This measure is obtained by determining the difference in blood glucose measured at the same time in a 24-hour interval. An additional computer program is used for this measurement, and it cannot be obtained only by continuous capillary blood glucose monitoring devices [21]. In this work, we will use pre- and postprandial capillary glycemia monitoring to determine the glycemic variability of patients with T2DM. In addition to the low cost of the method, we believe that this method gives the work an aspect of a real-life study and therefore greater clinical relevance.

Inclusion and Exclusion Criteria

Patients will be included in this project according to the following criteria: (1) T2DM duration more than 1 year, (2) age greater than or equal to 40 years, (3) family history of T2DM, and (4) glycohemoglobin between 7% and 10%. Inclusion criterion 1, a T2DM duration of more than 1 year, was chosen because in the first year after diagnosis, patients might not yet have achieved baseline glycemic control. Some patients may have significant improvement in beta-cell glucotoxicity in the first year, with reduced blood glucose levels, and therefore have

XSL•FO
RenderX

very wide blood glucose variations from one week to the next because of this improvement. Inclusion criterion 2, the age limit, was established based on the fact that most individuals with T2DM are aged over 40 years. In this way, we avoid including individuals who have autoimmune or genetic diabetes in the study. Item 3 is important because it further homogenizes our patients. We know that T2DM has a strong hereditary component, unlike other types of diabetes. Item 4, limiting the glycohemoglobin value range to 7% to 10%, was established with the objective of homogenizing glycemic variability among our patients, as it is known that glycemic variability increases with an increase in glycohemoglobin.

The following patients will be excluded from this study: (1) pregnant women, (2) patients who have recently (within 3 months) used corticosteroids or other hyperglycemic medications, (3) patients who have conditions that significantly alter glycemic stability (such as renal failure, recent acute coronary syndrome, and other diseases, such as cancer and liver failure). Also excluded will be (4) patients who refuse to participate in this research at any point and (5) patients who have uncontrolled diabetes with symptoms of polydipsia, polyuria, or weight loss that require other measures, such as the use of insulin for glycemic control, in addition to diet, physical activity, and medications already in use. Finally, we will exclude from this study (6) patients at high risk for severe sleep apnea, (7) patients with depression, (8) patients with alternating work shifts, and (9) patients who have epilepsy, a condition that can worsen with the use of melatonin.

Most of these exclusion criteria function to limit conditions that generate very high glycemic variability. It is unlikely that the use of melatonin will be able to reduce glycemic variability induced by corticoids, for example. Patients at high risk for sleep apnea, patients with depression, and patients with alternating work shifts were excluded due to studies that show the negative influence of these conditions on glycemic control. Specific studies with these populations seem more adequate for the purpose proposed here.

Ethical Aspects

Participants involved in this study will be required to sign an informed consent form that has been drafted in compliance with the Declaration of Helsinki [23]. The wording of the consent form was initially sanctioned, together with the entire project outlined herein, by the ethics committee of the Federal University of Minas Gerais (CAAE: 31990720.7.000.5149). The invitation to participate in this study will be extended during routine consultation at the office of an endocrinology physician (WM). Participants, if they meet the inclusion criteria, will be volunteers. There will be no payment. All research objectives, as well as potential risks pertaining to the use of melatonin, will be explained. We will emphasize, however, that melatonin is a low-risk substance with few side effects. A possible risk is daytime drowsiness, but this is unlikely given the very short half-life of the drug and the low dose used.

Randomization

Patients will be randomized into two groups. Group 1 will use the substance contained in bottle 1 in the first week, will not use any substance in the second week (the washout period), and will use the substance contained in bottle 2 in the third week. Group 2 will use the substance contained in bottle 2 in the first week, will not use any substance in the second week (the washout period), and will use the substance contained in bottle 1 in the third week.

Patients will be divided into these groups according to the result of rolling a die. Those who roll a number from 1 to 3 will be in group 1, while those who roll a number from 4 to 6 will be in group 2. When the number of participants in a group reaches 15, patients will be automatically allocated to the other group until it includes 15 participants. The project researcher will know which patients will use bottle 1 or 2 in the first and third weeks but will not know which bottle contains placebo and which contains melatonin.

Interventions

Patients will use melatonin in the first week and placebo in the third week or placebo in the first week and melatonin in the third week, according to the randomization described. On days 5, 6, and 7 of the first and third weeks of the study, patients will measure fasting capillary blood glucose levels 2 hours after breakfast, before lunch, 2 hours after lunch, before dinner, and 2 hours after dinner. Patients will also receive guidance on diet and physical activity to be followed during these 3 weeks. In the second week, patients will undergo a washout period. At the end of the study, the patients will return to the office with their capillary blood glucose results. At this point, they will be asked whether they experienced excessive daytime sleepiness at any point in the study and whether they suspected at any time whether a substance was the placebo or melatonin.

Procedures

Patients with T2DM will be selected to take part in this study during routine consultations held in an outpatient endocrinology clinic. At the end of the consultation, the endocrinologist, when verifying that the patient meets the inclusion criteria, will ask the patient if they are interested in participating in research on diabetes and melatonin. This question will be followed by reading the informed consent form. All stages of the research will be explained to the patient. This includes the research period, the use of a placebo substance and melatonin, the need to perform capillary blood glucose measurement 6 times a day for 3 days in the first week and 3 days in the third week, the washout period, and the delivery of capillary blood glucose results after the 3 weeks of the project. If the patient agrees to participate in the project, the researcher will ask them to sign the free and informed consent form. A copy of this form will be given to the patient. Next, the researcher will ask the patient to roll a die. Patients who roll a number from 1 to 3 will be in group 1 and will be included in the group that uses the following sequence: bottle 1, washout, bottle 2. Those who roll a number from 4 to 6 will be included in group that uses the following sequence: bottle 2, washout, bottle 1. After allocating the patient to one of the groups, the project researcher will fill in the research record, which will contain the epidemiological, clinical, and laboratory data of the patient, including age, gender, duration of diabetes, history of epilepsy, insulin use (or not), STOP-Bang (snoring, tiredness, observed apnea, high blood

XSL•FO
RenderX

pressure, BMI, age, neck circumference, and gender) questionnaire results, weight, height, BMI, abdominal circumference, and glycohemoglobin value. After this step, the patient will be guided on the diet and physical activity regimens to be carried out during the 3 weeks of the project. Patients will be instructed to perform 30 minutes of physical activity 5 times a week during the 3 weeks of the project. After this guidance, patients will receive a glucometer, strips for measuring capillary blood glucose, and lancets to take home. In addition, patients will be given a form to record capillary blood glucose values. At the end of the third week, the patient will return with the blood glucose values.

Primary and Secondary Outcomes

The primary end point of this study will be the difference in mean variability of the patients' blood glucose levels between the first and third weeks of the study. The data will be acquired by computing the average of the variance between the total blood glucose levels obtained in these weeks.

As a secondary outcome, we will evaluate the mean disparities in glycemia at each time interval, namely fasting, 2 hours after fasting, before lunch, 2 hours after lunch, before dinner, and 2 hours after dinner. This assessment aims to determine whether the use of melatonin has any discernable impact on blood glucose fluctuation at specific times of the day.

In order to analyze the effect of melatonin after a greater number of days of use, we will perform a specific analysis of the glycemic variability measured on the last day of glycemic measurement in the first and third weeks.

We will also perform a categorical analysis that will take into account the coefficient of variation of blood glucose levels during the use of placebo and during the use of melatonin. We will consider this value to be stable if it is less than 36% and unstable if it is higher than 36%. We will evaluate whether the coefficient of variation was stable or unstable in the week in which melatonin was used.

Sample Size

The sample size will be 30 patients. As referenced in the literature, when the SD and population frequencies of a given variable are not known, a pretest should be performed with 30 to 40 patients, and data from this group should be considered a population estimate [24]. After collecting blood glucose data for the first and third weeks, the mean glycemic variability and the SD will be calculated so that the sample size can be recalculated. This is necessary because there are no similar studies in the literature. If the recalculated sample size is less than 30, no new participants will be needed and the study will be concluded. If the new sample size is greater than 30, new patients will be recruited until the new, larger sample size is reached.

Statistical Analysis

If quantitative variables adhere to a normal distribution, as represented by the Gaussian curve, their central tendency will be expressed as mean and their dispersion will be quantified by the SD. If the distribution of these variables does not follow a normal distribution, then their central tendency will be described by the median and their dispersion will be characterized by the 25% and 75% quartiles. The Shapiro-Wilk test will be used to assess normality. Categorical variables will be presented using both absolute frequencies and percentages.

Statistical analyses of normal quantitative variables, both before and after the intervention, will be conducted using a paired 1-tailed *t* test. When the distribution is not normal, the Wilcoxon test will be used. The study will have 2 intervention tails: placebo-washout-melatonin and melatonin-washout-placebo. Comparison of blood glucose levels will be performed between the time when the patients used melatonin and the time they used placebo.

The patients will be compared with one another based on the capillary blood glucose results obtained during the first and third weeks.

The epidemiological, clinical, and laboratory data of the patients will be compared between groups 1 and 2 in order to evaluate whether the randomization process has generated groups that lack statistical differences that may influence the research results.

The significance level will be .05 and the software of choice will be SPSS (version 20.0; IBM Corp).

Results

Participant recruitment took place between March 2023 to April 2023. In all, 30 participants were eligible and completed the study. Upon selection of these patients and completion of the 3-week research period, a statistical analysis was conducted on the variability of capillary blood glucose levels during the first and third weeks. Subsequently, these data were used to determine the required sample size (n) necessary to draw valid conclusions regarding the proposed research objectives. Furthermore, in addition to the capillary blood glucose values, the data types presented in Table 1 will be scrutinized to ensure the absence of statistical discrepancies between groups 1 and 2. The study was approved by the Brazilian Registry of Clinical Trials (RBR-6wg54rb) on March 7, 2023. Figure 2 shows a sample table of how the results will be presented.

Table 1. Epidemiological, clinical, and laboratory data (n=30).

Characteristics	Values
Participants	n
Age (years)	Mean or median
Sex (female)	n, %
Insulin users	n, %
BMI (kg/m^2)	Mean or median
Abdominal circumference (cm)	Mean or median
Duration of diabetes (years)	Mean or median
STOP-Bang[a] (score)	Mean or median
Glycohemoglobin (%)	Mean or median

[a]STOP-Bang: snoring, tiredness, observed apnea, high blood pressure, BMI, age, neck circumference, gender.

Figure 2. Sample table showing how results will be reported. Unpaired-sample *t* tests or Wilcoxon tests will be used.

Results	Placebo	Intervention	*P* value (95% CI)
Sum of the differences between all pre- and postprandial blood glucose levels			
Sum of the difference between pre- and postprandial blood glucose levels (breakfast glucose level)			
Sum of the difference between pre- and postprandial blood glucose levels (lunch glucose level)			
Sum of the difference between pre- and postprandial blood glucose levels (dinner glucose level)			
Sum of the difference between all pre- and postprandial blood glucose levels on the last day of blood glucose measurement			
Glycemic variability coefficient			

Discussion

Anticipated Findings

The role of melatonin in the glycemic control of T2DM patients has been studied for a number of years [25]. However, studies on the role of melatonin in glycemic variability are not available. Our work does not aim to assess the impact of melatonin on glycohemoglobin levels, but rather its effect on glycemic variability. The hypothesis was tested based on the fact that melatonin, as a hormone, plays a crucial role in regulating circadian rhythms. This notion is logical to us, given that a hormone whose secretion is primarily nocturnal, such as melatonin, governs numerous biological rhythms [26]. Our findings could signify a great advance in the management of T2DM, as it would provide a new therapeutic target: deficient melatonin production in affected individuals. The primary aim of this work is present a new approach toward managing and preventing chronic complications in patients diagnosed with T2DM.

Limitations

The limitations inherent in this study pertain to an analysis of glycemic variability conducted over a short span: only a few days after intake of melatonin or placebo. The effectiveness of melatonin in reducing glycemic variability might occur with longer use.

A second limitation of this study is derived from the fact that endogenous melatonin peaks in the middle of the night. The exogenous melatonin administered to patients in this study will not reproduce the physiological rhythm of endogenous melatonin.

A third limitation is the fact that patients may have diet and physical activity fluctuations between weeks 1 and 3 of the study, despite the guidance given initially, which might interfere with glycemic variability.

A fourth limitation of this study is the fact that we will not assess the prevalence of the *MTNR1B* mutation, which can determine a poorer glycemic response to melatonin use.

XSL•FO
RenderX

Conclusions

The study of glycemic variability in patients with T2DM is fundamental for the prevention of chronic complications of the disease. Melatonin is a substance involved in biological rhythms, including those related to glucose control, such as insulin secretion. The existing knowledge that patients with T2DM produce a smaller amount of melatonin motivated us to test the replacement of this hormone as an instrument for greater glycemic stability. As glycemic variability is influenced by several variables, we conclude that a crossover design will be more suitable than a paired-group design for this study to evaluate the role of melatonin in glycemic stability.

Abstract

Background: Incidence of and mortality from colorectal cancer (CRC) can be effectively reduced by screening with the fecal immunochemical test (FIT) or colonoscopy. Individual risk to develop CRC within 15 years varies from <1% to >15% among people aged 50 to 75 years. Communicating personalized CRC risk and appropriate screening recommendations could improve the risk-benefit balance of screening test allocations and optimize the use of limited colonoscopy resources. However, significant uncertainty exists regarding the feasibility and efficacy of risk-based screening.

Objective: We aim to study the effect of communicating individual CRC risk and a risk-based recommendation of the FIT or colonoscopy on participants' choice of screening test. We will also assess the feasibility of a larger clinical trial designed to evaluate the impact of personalized screening on clinical outcomes.

Methods: We will perform a pilot randomized controlled trial among 880 residents aged 50 to 69 years eligible to participate in the organized screening program of the Vaud canton, Switzerland. Participants will be recruited by mail by the Vaud CRC screening program. Primary and secondary outcomes will be self-assessed through questionnaires. The risk score will be calculated using the open-source QCancer calculator that was validated in the United Kingdom. Participants will be stratified into 3 groups—low (<3%), moderate (3% to <6%), and high (≥6%) risk—according to their 15-year CRC risk and randomized within each risk stratum. The intervention group participants will receive a newly designed brochure with their personalized risk and screening recommendations. The control group will receive the usual brochure of the Vaud CRC screening program. Our primary outcome, measured using a self-administered questionnaire, is appropriate screening uptake 6 months after the intervention. Screening will be defined as appropriate if participants at high risk undertake colonoscopy and participants at low risk undertake the FIT. We will also measure the acceptability of the risk score and screening recommendations and the psychological factors influencing screening behavior. We will also assess the feasibility of a full-scale randomized controlled trial.

Results: We expect that a total sample of 880 individuals will allow us to detect a difference of 10% (α=5%) between groups. The main outcome will be analyzed using a 2-tailed chi-squared test. We expect that appropriate screening uptake will be higher in the intervention group. No difference in overall screening uptake is expected.

Conclusions: We will test the impact of personalized risk information and screening recommendations on participants' choice of screening test in an organized screening program. This study should advance our understanding of the feasibility of large-scale risk-based CRC screening. Our results may provide insights into the optimization of CRC screening by offering screening options with a better risk-benefit balance and optimizing the use of resources.

Introduction

Background

Colorectal cancer (CRC) is the third most common cancer after breast and lung cancers [1]. In 2020, CRC affected approximately 2 million people worldwide and caused 900,000 deaths. In Switzerland, every year, 4500 people are diagnosed with CRC, of whom 1760 die from CRC [2]. However, CRC can be effectively prevented by screening that allows detection and removal of early-stage cancers and precancerous lesions [3-5]. The 2 most frequently offered screening options are colonoscopy and the fecal immunochemical test (FIT). Colonoscopy is more sensitive, especially for polyps [6,7], but it carries risks of bleeding and perforation [8,9]. It also requires an onerous bowel preparation; can be embarrassing for patients; and, as a population-level screening test, requires a large number of gastroenterologists. The FIT is less costly and noninvasive, can be performed at home without preparation, and has higher acceptance [6,10]. The impact of the FIT on CRC mortality over multiple rounds of screening is likely similar to colonoscopy [7,10], and it seems to decrease CRC incidence by approximately 33% [11].

Major risk factors for CRC are advanced adenoma, increasing age, and a small number of rare genetic syndromes [5]. Multiple other factors related to environment and lifestyle influence CRC incidence and can also contribute to one's risk of developing CRC [12]. One of the best-performing risk calculators is the open-source tool QCancer [12], developed in the United Kingdom and validated on 2 large cohorts of 3.6 million and 2.1 million patients [13,14]. It performed well in comparison with other algorithms [14,15].

Currently, in Switzerland and many other countries, the population is divided into 2 groups: people at average risk of CRC and those at very high risk of CRC because of a personal history of advanced adenomas or CRC, a familial history of CRC, symptoms concerning for cancer, or rare genetic syndromes [5]. Individuals at very high risk are offered regular surveillance colonoscopies and are not part of organized screening programs. However, the population at average risk is not homogeneous and could be broken up into at least 3 groups: high, moderate, and low risk. In 2019, the BMJ Rapid Recommendations team [12] made a weak recommendation against screening for individuals with a CRC risk of <3% in the next 15 years using the QCancer calculator [12]. However, because zero risk does not exist, recommendations against screening are questionable. Nevertheless, the threshold of <3% risk can be used to recommend the FIT and not colonoscopy. In clinical practice, patients with a risk of >6% in the next 15 years are generally offered colonoscopy surveillance. Thus, 6% risk can be considered a threshold for the high-risk level. These cutoffs could optimize the use of colonoscopy resources, which are limited. The majority of people are at low risk (approximately 60%; J Usher-Smith, PhD, email, June 21, 2020). Offering them colonoscopy results in its overuse and risk of complication for the individuals who are less likely to benefit from screening. On the contrary, reorienting individuals at low risk to the FIT would reduce the number of individuals who choose colonoscopy as a screening test and, therefore, reduce waiting time for those at high risk. Given that the ultimate aim of screening is to diminish mortality, colonoscopies should be reserved for people at high risk because differences in risk reduction between colonoscopy and the FIT become more pronounced for this population [16].

However, the impact of personalized screening on the screening test choice remains unclear. A meta-analysis has shown that personalized risk communication alone does not improve the overall uptake of screening tests [17]. Indeed, communicating personalized risk without giving clear screening recommendations may have no influence on screening behavior or even decrease it. This is in accordance with the view that providing people with threatening information only can decrease desired health behaviors if people cannot cope with the threatening information. However, the studies included in the meta-analysis did not address the choice between the FIT and colonoscopy and contain some important methodological discrepancies.

Objectives

In summary, personalized screening may offer people better risk-benefit balance in CRC screening and optimize the use of limited colonoscopy resources. However, there is limited knowledge about how the communication of risk and screening recommendations affects CRC screening behaviors. The primary aim of this trial is to study the effect of communicating individual CRC risk score and screening recommendations on appropriate screening uptake at 6 months in individuals stratified into 3 groups: low, moderate, and high risk of developing CRC in the next 15 years. Screening will be considered appropriate if the participant undertakes the test that is adapted to their risk level. Our hypotheses are as follows:

- Compared with the control group, individuals at low risk receiving the intervention will be more likely to undertake the FIT.
- Compared with the control group, individuals at high risk receiving the intervention will be more likely to undertake colonoscopy.
- Individuals at moderate risk receiving the intervention will have the same screening behavior as the individuals in the control group, that is, approximately 50% will be more likely to undertake the FIT, and approximately 50% will be more likely to undertake colonoscopy [18].

XSL•FO
RenderX

We expect no difference in overall screening uptake.

Moreover, we will calculate the participation rate and proportion of individuals eligible for our study. We will also perform subgroup analyses and explore anxiety related to the information about the participants' risk level.

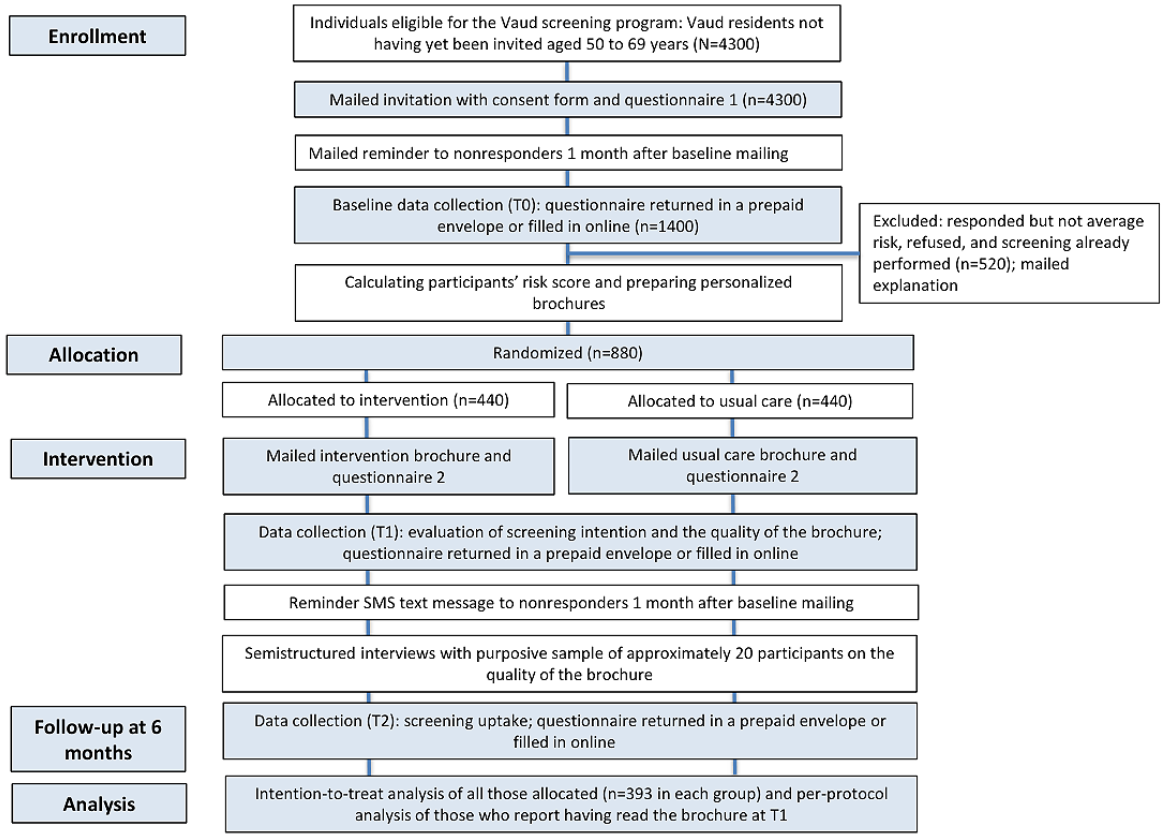
Methods

The trial's protocol follows the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) guidelines and the CONSORT (Consolidated Standards of Reporting Trials) statement for randomized controlled trials, as well as the CONSORT-EHEALTH (CONSORT of Electronic and Mobile Health Applications and Online Telehealth) checklist [19,20] (Multimedia Appendix 1). The trial was registered on ClinicalTrials.gov (NCT05357508) on May 3, 2022, before the enrollment of the first participant.

Study Design and Setting

We will perform a 2-arm randomized superiority controlled trial with participants randomized 1:1 in 2 arms: intervention and usual care. Participants, but not the investigators, will be blinded. The statistician performing the primary outcome analyses will be blinded to group assignments. The trial will be nested in the Vaud CRC screening program.

We used a *patient and public involvement in research* approach throughout by involving 5 members of the target population (residents of the canton of Vaud, Switzerland, aged between 50 and 69 years) in all aspects of the project. This collaboration allowed us to develop materials for our participants that were acceptable, easily understood, and pretested before the trial started. These 5 members will participate in the interpretation and dissemination of the results.



Participants

We plan to send out 4300 invitations to recruit 880 eligible participants (Figure 1). Refer to Textbox 1 for the inclusion and exclusion criteria.

Our exclusion criteria allow for the exclusion of individuals at very high risk of CRC (Textbox 1), enabling us to avoid inviting to the study those who are ineligible for the Vaud screening program. Individuals at very high risk are identified using a questionnaire to screen for current symptoms of possible CRC, personal history of CRC or polyp requiring surveillance, inflammatory bowel disease, and genetic syndromes.

Participants can stop their participation at any time without providing any justification. They will be informed that screening uptake is not mandatory and that withdrawal of consent will not affect their subsequent participation in the Vaud screening program.

Figure 1. Planned CONSORT (Consolidated Standards of Reporting Trials) diagram for the pilot randomized controlled trial. T1: intervention and secondary outcome data collection; T2: follow-up at 6 months (primary outcome and secondary outcome data collection).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Being a resident of the Vaud canton, Switzerland
- Aged between 50 and 69 years
- Not having yet been invited to the Vaud colorectal cancer (CRC) screening program (this program was gradually rolled out between 2016 and 2022)

Exclusion criteria

- Current new symptoms suggestive of CRC
- Personal history of CRC, inflammatory bowel disease, or advanced adenoma or other polyps requiring colonoscopy surveillance at intervals of <10 years
- High-risk familial syndromes for CRC (ie, Lynch syndrome or familial polyposis)
- Having undergone colonoscopy within 9 years or having undertaken the fecal immunochemical test within 1.5 years
- Being unable to participate in follow-up at 6 months

Procedure

The study will be conducted in the following 3 phases:

- T0: recruitment and baseline data collection
- T1: intervention and secondary outcome data collection
- T2: follow-up at 6 months (primary outcome and secondary outcome data collection)

At T0, an invitation letter, a consent form, and the baseline questionnaire (questionnaire 1) that allows us to verify the eligibility criteria and calculate the CRC risk score will be sent to the potential participants by the Vaud CRC screening program. The ID codes for the participants will be generated using the IDGenerator, a software tool that was specifically developed for epidemiological and clinical trials [21]. The risk score will be calculated for all eligible individuals who return the signed consent form; subsequently, they will be randomized to either the intervention group or the control group. All individuals who do not respond within 1 month after the first mailing will receive a reminder.

At T1, enrolled participants will receive the intervention or a usual care brochure (in accordance with their group allocation), questionnaire 2, and an information sheet that they can provide to their general practitioner and pharmacist regarding their participation in the study. The participants who do not respond to questionnaire 2 within 2 weeks will be sent a reminder. Qualitative interviews will be conducted with willing participants at this time.

Six months after the intervention, at T2, participants will be contacted again to measure their screening behavior using questionnaire 3. Their responses will be accepted up to 8 months after the intervention. In case of nonresponse within 2 weeks, they will receive a reminder.

All 3 questionnaires, information materials for the participants, and the consent form will be available in both paper and electronic formats. Participants can choose the format that is more convenient to them. All data will be entered into the REDCap (Research Electronic Data Capture; Vanderbilt University) platform [22,23].

Refer to Table 1 and Figures 1 and 2 for procedure details.

Figure 2. Detailed procedure of the study. T0: recruitment and baseline data collection; T1: intervention and secondary outcome data collection; T2: follow-up at 6 months (primary outcome and secondary outcome data collection).

Outcome Measures

The primary outcome measure is the self-reported appropriate screening uptake 6 to 8 months after the intervention (T2), measured using a short self-administered questionnaire. As waiting times can be long for screening colonoscopies [18], participants who have fixed a colonoscopy appointment will be counted as having undergone a colonoscopy. For the secondary outcome measures, refer to Textbox 2, and for the additional measures, refer to Textbox 3.

Refer to Multimedia Appendix 2 for the English version of the questionnaires and Multimedia Appendix 3 for the French version.

Textbox 2. Secondary outcome measures.

- Self-reported overall screening participation measured at T2 (follow-up at 6 months): on the basis of the participants' responses at T2, we will calculate the proportion of those who have completed any colorectal cancer (CRC) screening test (fecal immunochemical test or colonoscopy)
- Participation in the study at 6 weeks after the invitation letter was sent out: we will calculate the number of fully completed electronic or paper questionnaires
- Eligibility for the Vaud CRC screening program at 6 weeks after the invitation letter was sent out: we will calculate the proportion of those who are eligible for the Vaud screening program (eg, not up to date with screening, not in colonoscopy surveillance, and no personal CRC history)
- Self-reported anxiety related to the intervention and control materials measured at T1 (intervention) using 6 items inspired by the State-Trait Anxiety Inventory [24]
- Linkage to the Vaud CRC screening program assessed at 3 to 6 months after the primary outcome measurement: we will calculate the proportion of study participants who consent and whose screening status is obtained from the Vaud CRC screening program
- Linkage to the Vaud cancer registry up to 10 years after the primary outcome measurement: we will calculate the proportion of study participants who consent and whose cancer status is obtained from the Vaud cancer registry (a long time frame has been chosen in view of the delay in updating the cancer registry records and interest in cancer outcomes several years after the primary outcome measurement)

XSL•FO
RenderX

Textbox 3. Additional measures.

At T0 (baseline)

- Intention for screening
- Preferences for screening test
- Capacity to participate in screening (no serious health conditions preventing participants from undergoing screening)
- Previous screening recommendations of general practitioner
- Knowledge about screening for colorectal cancer (CRC)
- Demographics

At T1 (intervention)

- Perceived susceptibility to CRC
- Perceived benefits of, and barriers to, screening
- Perceived self-efficacy for screening tests
- Participants' opinions regarding the quality of the brochure
- Acceptance of the provided screening recommendations

At T2 (follow-up at 6 months)

- Participants' barriers to screening (only those who were not screened)

Theoretical Framework for Understanding the Choice of Screening Test

Several of our outcomes are based on the health belief model [25], which posits that people are more likely to adopt a health-related behavior if they believe that they are vulnerable to the illness (perceived susceptibility) and that the illness is dangerous (perceived severity). Indeed, according to a recent meta-analysis [26], risk appraisals had a small to moderate effect on both the intention to adopt a health-related behavior and the behavior itself. However, the effect sizes for intention and behavior were nearly doubled in size when the interventions aimed at increasing participants' self-efficacy and perceived efficacy of the recommended behavior [26].

We believe that participants' screening behavior will largely depend on their perceived susceptibility to CRC as well as their beliefs about their self-efficacy and the efficacy of screening. These elements have been included in our intervention materials.

CRC Risk Calculation and Risk Levels

The personalized 15-year CRC risk score will be calculated using the QCancer calculator [27]. The QCancer calculator is an open-source algorithm that was developed in the United Kingdom and validated on 2 large cohorts of 3.6 million and 2.1 million patients [28,29]. The QCancer algorithm is based on variables that were available from the patients' primary care electronic health records. This covers many risk factors for CRC such as age, sex, and personal and family histories of cancers. However, diet and physical activity, which are 2 potentially important CRC risk factors, were not included in the algorithm because the information about them was not routinely collected and included in electronic health records [14]. The QCancer score was chosen because it was developed on a European population, it predicts CRC instead of advanced neoplasia, and it performed well in a large prospective validation study [13]. Despite some limitations, a systematic review showed that the QCancer score allows assigning an individual to the correct risk group with a probability of approximately 70% [14,15]. Although its predictive performance is not perfect, the QCancer risk score gives a good estimation of an individual's risk level and allows the delivering of personalized recommendations for screening.

For this study, we modified the original algorithm slightly. Our adapted version includes the following factors to calculate the participants' risk score: age; sex; tobacco and alcohol consumption; family history of CRC; personal history of breast cancer, uterine cancer, cervical cancer, or ovarian cancer for women and personal history of lung cancer, oral cancer, or blood cancer for men; having type 2 diabetes; and BMI values.

Ethnicity, postal code, ulcerative colitis, and colonic polyps will not be used in our adapted algorithm. Ethnicity and postal code have not been validated by studies for use in Switzerland and likely have different effects on CRC risk here than in the United Kingdom. For this reason, the option "White or not stated" will be used by default for all participants, and the field for postal code will be left blank. As our exclusion criteria include advanced adenoma and inflammatory bowel disease, we will indicate that our participants had neither ulcerative colitis nor colonic polyps. We have conducted tests to ensure the robustness of the QCancer score without these elements.

The obtained participant risk scores will be divided into 3 risk levels: low risk (<3%), moderate risk (3% to <6%), and high risk (≥6%).

These cutoffs are related to screening recommendations made to the participants and were based on the evaluation of risk and benefits related to the screening options.

XSL•FO
RenderX

Intervention and Usual Care Materials

The intervention consists in communicating to the participants their 15-year CRC risk score and recommending the screening test most appropriate for their risk level using specially designed brochures (refer to Multimedia Appendix 4 for the English version of the brochure and Multimedia Appendix 5 for the French version). The intervention brochure is available in the following 3 categories: low CRC risk (<3%), with a recommendation to undertake the FIT; moderate CRC risk (3% to <6%), with a recommendation to either undertake the FIT or colonoscopy; and high CRC risk (≥6%), with a recommendation to undertake colonoscopy.

The intervention brochure provides the 15-year CRC risk score in comparison with that of an *average person* who has a similar profile; for example, an individual who has a CRC risk of 2% (low risk) receives the following message: "According to our estimations, 2 out of 100 people with the same profile as yours will get colon cancer in the next 15 years."

This message is accompanied by a graphic representation of the risk score and the risk level. Refer to Multimedia Appendix 4 (English version) and Multimedia Appendix 5 (French version) for more information.

Clear screening recommendations presented in the intervention brochure aim to increase participants' perceived self-efficacy for screening tests. We thus expect that participants at high risk will perceive that they are more susceptible to CRC and, therefore, will be more likely to undertake colonoscopy, which is the most accurate CRC screening test. By contrast, the participants at low risk are expected to perceive their susceptibility to CRC as lower and opt for the noninvasive FIT. To prevent the participants at low risk from declining screening, the brochure informs that zero risk does not exist and strongly recommends undertaking the FIT. No strong recommendations will be made to participants at moderate risk; therefore, the FIT and colonoscopy will be presented in the brochure as equal screening options.

To increase the participants' perceived response efficacy, our intervention materials emphasize information about the advantages of the recommended test for their risk level. However, the intervention brochure does present an alternative to screening, thus offering a choice to the participants. Moreover, all intervention group participants will receive an information sheet suggesting that they discuss their risk level with their general practitioner.

The intervention brochure will contain recommendations corresponding to the risk level of each participant only. We expect that this will facilitate the understanding of the provided information, minimize reading effort, and enhance adherence to our recommendations. Refer to Table 2 for more information about the content of each brochure category. For the sake of brevity, the intervention brochures will not communicate the side effects or sensitivity of the tests. Both the FIT and colonoscopy are screening tests commonly used in Switzerland and are considered safe and efficient to significantly reduce CRC mortality if undergone within the recommended period (the FIT every 2 years and colonoscopy every 10 years).

The control brochure represents the usual brochure that the Vaud screening program provides to individuals eligible for CRC screening. This brochure recommends screening to all individuals beginning at age 50 years and presents both the FIT and colonoscopy as equal options. This brochure does not include either a personalized risk score or specific screening recommendations. This suggests that, in the control group, the screening tests will be chosen according to the participants' preferences or after discussion with their primary care physician rather than in accordance with their risk level.

[b]FIT: fecal immunochemical test.

Qualitative Interviews

Semistructured qualitative interviews will be conducted by telephone with a purposive sample of approximately 20 participants using a previously elaborated interview guide until we achieve thematic saturation. The interviews are based on the user-experience "honeycomb" framework described by Morville [30], and they aim to obtain detailed information about the quality of the brochure and the acceptability of the provided screening recommendations. We will be especially interested in the following information: (1) whether the brochure is useful for decision-making about the screening tests; (2) whether participants feel that the brochure improved their knowledge about CRC and screening; (3) whether the information is clear, easy to understand, and credible; and (4) whether the brochure satisfies the participants or whether they have suggestions to improve it.

Purposive sampling will be based on study arm, sex, age, risk level, knowledge of the French language, and reported preferences for the screening test.

Randomization and Blinding

Randomization will be carried out automatically via the REDCap randomization module programmed by the trial statistician. We will apply a stratified block randomization strategy with a block factor of 8 to prevent a possible imbalance between the control and intervention groups, especially among participants at high risk. The participants will be blinded to the group allocation. They will be told that the study compares 2 slightly different brochures about CRC screening options; however, the nature of the intervention will not be disclosed. The investigators will not be blinded, but, owing to the automatic randomization, they will not be able to influence the participants' group allocation. The analysis of the main study outcome will be performed by the trial statistician who will be blinded to the participants' allocation.

Ethics Approval

The study protocol (project ID 2021-02431) was approved by the ethics committee of the canton of Vaud on March 2, 2022. All the important protocol modifications will be documented and communicated to the ethics committee along with the intermediate and final reports.

Steering Committee and Trial Monitoring

The trial is supervised by a steering committee composed of a gastroenterologist, a general practitioner, an epidemiologist, and psychologists, as well as experts in shared decision-making and statistical modeling. The members of the steering committee are in charge of approving the trial's methodology and data analysis plan, and they also contribute in the preparation of oral and written communication materials.

The trial is monitored by an institutional team for trial monitoring that is independent from the trial sponsor and competing interests. The monitoring team will check the quality of collected data as well as conformity with the study protocol. At least 3 site visits are planned, following recommendations from the Swiss Clinical Trial Organization for low-risk trials.

XSL•FO
RenderX

Statistical Analyses

Sample Size Estimation

We expect that 60% of the eligible individuals will be at low risk for CRC, 30% at moderate risk, and 10% at high risk, based on approximate calculations carried out with the UK biobank cohort. The actual distribution of CRC risk factors, and hence 15-year risk scores, in the Vaud population eligible for the screening program is not known.

We also expect that in the intervention group, individuals will be more likely to undertake the appropriate screening test, whereas in the control group, the choice of screening test will not differ among the risk levels (Table 3).

Thus, to detect a difference of 10% (ie, between 46% and 56%) at α=5%, a sample size of 392 individuals in each arm is required to reach 80% power. Assuming approximately 10% attrition, we plan to recruit 440 individuals in each arm (a total of 880 individuals). Our estimation of 10% attrition is based on the results of previous longitudinal studies conducted in the canton of Vaud.

We will invite individuals who have not previously been invited to the Vaud CRC screening program. At the time of sending out the invitation, we will not know whether they are eligible for screening, principally because they may already be up to date with screening or may have had a high-risk polyp needing colonoscopy surveillance. Thus, we plan to send out approximately 4300 invitations; we expect 1400 (32.56%) to respond. Of these 1400 participants, we anticipate that 880 (62.86%) will be eligible for the study (Figure 1). In case of a low response rate, we will send out an additional 2000 invitations.

Table 3. Hypothesized size of each group as a proportion of the eligible population and predicted changes in screening choices with personalized recommendations. Group sizes have been chosen to provide sufficient statistical power.

Arm and risk level	Eligible population, %	Choose colonoscopy, %	Choose FIT[a], %	None, %	Colonoscopy, n/N	FIT, n/N	None, n/N	Overall uptake, %	Appropriately screened, % (n/N)	Overall proportions by randomization

Data Collection

Trial personnel will be trained in good clinical practices and data management. The research team will be provided with the precise guidelines for the inclusion and exclusion criteria, data collection and analysis, and the handling of missing data.

For data collection, we will use 2 validated questionnaires or questionnaires pretested in previous studies. All study materials, including questionnaires, have been reviewed and approved by our citizen advisory group.

All answers to the questionnaire in paper format will be manually entered into the REDCap platform, and 20% of the entries will be checked by another member of the research team. Qualitative interviews will be conducted by a trained team member, recorded, and transcribed. For quality assurance, dual independent coding will be used for 20% of the transcripts, purposively selected. Data triangulation will be used as relevant. Investigator triangulation will also be conducted.

Quantitative and qualitative data will be coded using unique participant identifiers previously generated via the IDGenerator [21]. Paper questionnaires and consent forms will be stored in the investigator site file. Coded data and participant identification lists will be stored separately. Participants' data will be accessible to authorized personnel only.

Although our trial presents low risk for participants, we will collect information about adverse events; for instance, we will collect information about rectal bleeding or hospitalization after colonoscopy and participants' anxiety related to the intervention and control materials, as well as the adverse events registered by the Vaud screening program. Serious adverse events will be documented and reported within 24 hours to the sponsor-investigator of the study. Serious adverse events that

XSL•FO
RenderX

could be attributable to the trial intervention will be reported to the ethics committee within 15 days.

Quantitative Data Analysis Plan

The study data will be summarized across all participants by group and by risk level. Continuous and count variables will be summarized as mean (SD) or median (IQR) and categorical variables as number (percentage). To test randomization quality, differences on the baseline variables will be examined using a 2-tailed *t* test for continuous variables and a 2-tailed chi-squared test for categorical variables.

Self-reported appropriate screening uptake will be analyzed using a 2-tailed chi-squared test and controlled for the CRC risk level. Data analysis will be performed using R statistical software (R Foundation for Statistical Computing) [31] and Stata 16 software (StataCorp LLC) [32].

For the primary outcome, participants lost to follow-up will be considered as having refused to participate in screening. If there seems to be differential loss to follow-up between the intervention and control groups, we may perform multiple imputation based on baseline factors as an exploratory analysis. For other secondary outcomes, data will be considered missing completely at random.

Qualitative Data Analysis Plan

For qualitative analysis, we will use the user-experience "honeycomb" framework described by Morville [30]. This approach was used to test health education applications, a decision aid tool [33-36], and the systematic review library of the Cochrane Collaboration [37]. For the purposes of our study, we will use the following 5 (of 7) dimensions:

- Useful: whether the brochure is useful for decision-making about the screening test
- Valuable: whether the brochure improves participants' knowledge about CRC and screening
- Credible: whether the information in the brochure is perceived as credible
- Usable: whether the information is clear and easy to understand
- Desirable: whether the participants are satisfied by the brochure or whether they have suggestions about how to improve it

The qualitative data will be analyzed using MAXQDA software (VERBI Software GmbH) [38].

Results

Overview

As of September 2022, a total of 515 participants had been enrolled in the trial and sent intervention or control materials. Six months later, 98.8% (509/515) of the enrolled individuals were sent the follow-up questionnaire. Data collection was completed on July 24, 2023 (6-8 months after the intervention).

We expect that the proportion of participants who complete the screening test appropriate to their risk level will be higher in the intervention group than in the control group, except for the individuals at moderate risk. The proportion of participants at moderate risk in the intervention group is expected to be the same as that of the participants in the control group in screening test choice because both tests are suggested as equal options.

We do not expect any difference in anxiety between the intervention and control groups. A Cochrane review of interventions similar to ours has shown that there was a nonsignificant trend toward decreased anxiety with risk information (standard mean difference in anxiety 0.13, 95% CI −0.29 to 0.03) [17].

Our intervention does not aim to enhance overall screening uptake; therefore, we do not expect any difference between the groups.

Dissemination of Results

We plan at least 5 open-access publications based on the trial data. Intermediate and final reports will be sent to the funding institution and to the ethics committee. Participants will be informed about the results of the trial on request. We communicate regularly with the Vaud organized CRC screening program and will encourage it to implement components of this approach if it is found effective.

Suggestions for oral communications and publications as well as names of authors will be discussed during the meetings of the steering committee. The principal investigator should be considered for the role of lead author. Disputes regarding authorship will be settled by the principal investigator and the steering committee.

Discussion

Testing the Impact of Risk Communication and Recommendations on Screening Behavior

Although many experts have recommended personalized CRC screening as a means of optimizing the risk-benefit balance for individuals and improving the use of scarce gastroenterology resources, this approach has not been implemented to date in an organized screening program. This study aims to demonstrate the effect of personalized information materials on individuals' choice of screening test to assess the feasibility of a larger trial evaluating the effect of personalized screening recommendations on clinical outcomes such as advanced neoplasia detection rate and CRC screening uptake. The trial addresses a current need of the Vaud screening program to demonstrate to the public and to physicians that individuals at low risk can be safely directed toward the FIT.

This trial is one of the rare studies that tests the impact of risk communication and recommendations on screening behavior. Although it may seem evident that communicating individuals' risk level would influence their screening behavior, previous studies have shown increased knowledge but little effect on test choice [17]. This presents a potential limitation in the implementation of personalized screening programs: unless these programs restrict the choice of participants, risk calculation may have no effect.

There are other means of personalizing CRC screening. Several strategies rely simply on participants' sex or race. In Sweden

XSL•FO
RenderX

and Norway, different cutoffs are used to define a positive FIT result requiring colonoscopy [39]. In Germany, colonoscopy screening is recommended at age 50 years for men and age 55 years for women. The American Gastroenterology Society recommends screening at a younger age (45 years) for African Americans. Another approach is to use quantitative FIT results below the positivity threshold but above 0 to define shorter intervals between FITs [40]. We chose to use multiple factors to define baseline risk following recommendations from the BMJ Rapid Recommendations team [12] and because of the strains on colonoscopy capacity in the canton of Vaud [18].

The strengths of this study include its *patient and public involvement in research* approach for the development of study materials; nesting within an organized screening program; population-based sampling to obtain the estimates of participation in the general population; both quantitative and qualitative evaluations, which should permit us to obtain a preliminary estimate of not only efficacy but also acceptability and potential improvements; the use of theory (the Health Belief Model [25]) to inform the intervention and evaluation; and randomization and rigorous design for a pilot study.

Potential weaknesses include the need for informed consent beyond what is typically needed in an organized screening program, which could decrease participation and increase selection bias. As such, we might underestimate eventual participation and overestimate acceptance, assuming that we preferentially include persons motivated to be screened. This selection bias could exclude populations considered more vulnerable, such as individuals with poor health literacy. However, the study materials were written, to the extent legally possible, using plain language. We did not translate the study materials into other languages, but all invitations from the screening program are also in French, with other languages only available on request. The Vaud screening program requested that we not invite individuals already participating in screening at regular intervals with the program because screening recommendations made in the study may differ from those made by the program and thus create confusion. We sought to avoid inviting for this study individuals who had not participated after being sent an invitation to the program, fearing that our participation rate would be too low. As a result, our sample population is heavily weighted toward younger age groups (those aged 50-54 years), and we may have a larger-than-expected proportion of participants at low risk of CRC.

Conclusions

We are evaluating the effect of communicating individualized CRC risk information and screening recommendations on the choice of screening test in an organized screening program that currently performs the FIT and colonoscopy in a ratio of approximately 50:50. We hypothesize that we can increase FIT use among individuals at low risk and increase colonoscopy use among individuals at high risk, improving the risk-benefit balance of CRC screening. These results will be valuable to screening programs around the world with either a high use of colonoscopy, such as in the canton of Vaud, or FIT programs that may fail to recognize individuals at high risk who could derive additional benefit from colonoscopy over the FIT.

Acknowledgments

The authors would like to thank Cyril Ducros, head of the Vaud cancer screening program; Sandra Mordacci-Boldini, administrative coordinator of the program; and all program team members for their contribution in the development of the original concept of the study and study logistics. The authors would also like to thank the members of the citizen advisory group who greatly contributed in the development of the study materials for participants.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Conflicts of Interest

M-AD has contributed to the development of Option Grid patient decision aids. EBSCO Information Services sells subscription access to Option Grid patient decision aids, and M-AD receives consulting income from EBSCO Health as well as royalties. RA is the main recipient of 2 grants related to colorectal cancer screening from the Swiss Cancer Research Foundation (Health Services Research; HSR-4366-11-2017) and the Swiss National Science Foundation (National Research Program 74; NFP74 407440_167519) “Smarter Health Care.” RA is also an unpaid member of the expert committee of the organized screening program in Bern, Switzerland, with an advisory role as expert. IL-V has received several grants evaluating (risk-based) colorectal cancer screening from nonprofit organizations.

Abstract

Background: Emerging evidence at the international level suggests that the Housing First approach could improve the housing stability of young people experiencing homelessness. However, there is a dearth of literature in Canada on whether the Housing First intervention for young people experiencing homelessness can improve outcomes including housing stability, health and well-being, and access to complementary supports. Adapted from the original Housing First model, Housing First for Youth (HF4Y) was developed in Canada as a rights-based approach tailored specifically for young people aged 16 to 24 years who are experiencing or are at risk of homelessness.

Objective: The Making the Shift Youth Homelessness Social Innovation Lab is testing the effectiveness of the HF4Y intervention in Canada. The objective of this study is to determine whether the HF4Y model results in better participant-level outcomes than treatment-as-usual services for young people experiencing homelessness in 2 urban settings: Ottawa and Toronto, Ontario. Primary outcomes include housing stability, health and well-being, and complementary supports, and secondary outcomes include employment and educational attainment and social inclusion.

Methods: The HF4Y study used a multisite, mixed methods, randomized controlled trial research approach for data collection and analysis. Eligible participants included young people aged 16 to 24 years who were experiencing homelessness or housing precarity. The participants were randomly assigned to either the treatment-as-usual group or the housing first intervention group. Survey and interview data in Ottawa and Toronto, Ontario are being collected at multiple time points (3-6 months) over 4 years to capture a range of outcomes. Analytic strategies for quantitative data will include mixed-effects modeling for repeated measures and logistic models. A thematic analysis will be used to analyze qualitative data based on participants' narratives and life journeys through homelessness. Furthermore, program fidelity evaluations are conducted within each HF4Y program. These evaluations assess how well the intervention aligns with the HF4Y model and identify any areas that may require adjustments or additional support.

Results: The HF4Y study has received human participant research ethics approval from the Office of Research Ethics at York University. Recruitment was conducted between February 2018 and March 2020. Data collection is expected to be completed at both sites by March 2024. A preliminary analysis of the quantitative and qualitative data collected between baseline and 24 months is underway.

XSL•FO
RenderX

Conclusions: This pilot randomized controlled trial is the first to test the effectiveness of the HF4Y intervention in Canada. The findings of this study will enhance our understanding of how to effectively deliver and scale up the HF4Y intervention, with the aim of continually improving the HF4Y model to promote better outcomes for youth.

Introduction

Background

Youth homelessness has become a social problem in Canada that does not lend itself to a straightforward solution. Young people who experience homelessness (aged 13-24 years) account for approximately 20% of the total population experiencing homelessness in Canada, with 6000 to 7000 young people experiencing homelessness on any given night [1]. Pathways into youth homelessness are diverse and essentially emerge as the outcome of a complex and intricate interplay between individual and relational risk factors (eg, family crises and trauma), structural circumstances (eg, poverty and the lack of affordable housing), and systems failures (eg, fragmented service and program delivery) [2,3]. To effectively reduce and end youth homelessness, it is necessary to identify best practices and program interventions that address the unique needs of developing adolescents and young adults.

To date, studies have mostly focused on evaluating the different models of housing and support programs that serve adults experiencing homelessness, particularly those with mental health and substance use disorders [4]. Among such programs, the Pathways model known as Housing First gained currency in the 1990s, largely because of its demonstrated efficacy in reducing homelessness for individuals experiencing chronic homelessness and serious mental illness [5]. The underlying premise of the Pathways model was that individuals experiencing homelessness should be placed in housing as quickly as possible without conditions or prerequisites such as sobriety or medication adherence. The well-established, evidence-based body of research on the Pathways model lent further support to its success, with many cities adopting the model to address homelessness [6-9].

Within the Canadian context, the national At Home/Chez Soi project initiated in 2008 the largest randomized controlled trial (RCT) of the Housing First intervention, with many studies stemming from this research project [10-15]. The Mental Health Commission of Canada implemented the Housing First model in 5 cities (Vancouver, Winnipeg, Toronto, Montreal, and Moncton) with >2200 individuals who were experiencing homelessness. The 1-year and 2-year findings of the At Home/Chez Soi project across various sites provided compelling evidence that the Housing First intervention is an effective approach that helps individuals experiencing homelessness and who have serious mental illnesses exit homelessness more quickly compared with other treatment-as-usual (TAU) services [11,12,16,17].

However, as discussed by Goering et al [10], it remains unknown whether the Housing First intervention is effective and can be replicated among young adolescents with diverse racial and sociodemographic backgrounds, particularly within the Canadian context where Indigenous youth experiencing homelessness are overrepresented [3]. In addition, although Kozloff et al [14] presented promising results that the Housing First model can be "a viable intervention to promote housing stability in homeless youth with mental illness," they suggested that modifications be made to the model to better meet the needs of youth, as their findings indicated that the application of the model to young people did not significantly improve other primary outcomes in the treatment group (eg, community integration and substance use).

With these considerations in mind, Housing First for Youth (HF4Y) was developed in Canada as an adaptation of the original Housing First model and is based on the understanding that the causes and conditions of youth homelessness are distinct from those affecting adults; therefore, the solutions must likewise be youth focused [18-22]. This means that HF4Y is designed specifically to meet the needs of young adults who are at risk of or experience homelessness by providing them with age-appropriate supports including housing. As a rights-based approach, HF4Y rests on the philosophy that "all people deserve housing and that adequate housing is a precondition for recovery" [23]. The core principles of the HF4Y model provide a framework for developing the interventions that are needed to help young people successfully transition to adulthood in a safe and planned way. These core principles are as follows [20]:

1. A right to housing with no preconditions: as a rights-based and youth-centric approach, HF4Y does not require youth to fulfill any precondition, such as sobriety or abstinence, to qualify for receiving housing support.
2. Youth choice, youth voice, and self-determination: this principle speaks to providing opportunities for youth to be in control of their own lives and encouraging them to make informed decisions when it comes to deciding where they want to live, rather than having this imposed on them (in real-world practice, eg, if a young person cannot live in cooperative housing with shared rooms, case workers need to discuss and work on a solution to accommodate the youth

XSL•FO
RenderX

living on their own by finding a place that is suitable for the young person and within their budget).

3. Positive youth development and wellness orientation: as a strength-based approach, the HF4Y model extends beyond assessing risk and vulnerability by recognizing the assets and strengths of young individuals to build self-esteem and a positive sense of self.
4. Individualized, client-driven supports with no time limits: as youth have diverse pathways into homelessness, the program model is client-driven to ensure culturally appropriate services are offered to youth that also accommodate the spectrum of sexual orientation and gender identities with no time limits.
5. Social inclusion and community integration: HF4Y promotes social inclusion by building youth's life skills and strengthening their existing relationships or by providing opportunities for them to meaningfully participate in community activities and engage with school and the labor market.

There is emerging evidence on the effectiveness of HF4Y at the international level [24-26]; however, little is known about the effectiveness of the HF4Y model in Canada, particularly considering that interventions and programs based on the HF4Y model must strictly adhere to the model's core values and principles to qualify as an HF4Y intervention [20]. This paper describes the research protocol of a 4-year comprehensive study that will contribute to the evidence base on the effectiveness of HF4Y through a rigorous program of developmental and outcomes evaluations. This will enhance our understanding of how to effectively deliver the HF4Y intervention and what outcomes are likely to be expected, with the aim of continually improving the HF4Y model to promote better outcomes for youth.

Making the Shift Youth Homelessness Social Innovation Lab

A key challenge in addressing youth homelessness is to determine what works, for whom it works, and in what context [27]; thus, how we frame "youth homelessness" is of paramount importance. In the Canadian context, youth homelessness refers to "the situation and experience of young people between the ages of 13 and 24 who are living independently of parents and/or caregivers, but do not have the means or ability to acquire a stable, safe, or consistent residence" [3]. The youth population experiencing homelessness is diverse, with Indigenous, 2SLGBTQA+ (2-spirit, lesbian, gay, bisexual, transgender, queer [or questioning], asexual, and additional groups), and Black youth being overrepresented, meaning that our interventions need to be implemented with a focus on equity, diversity, and inclusion [3].

Focusing specifically on the prevention of youth homelessness (ie, reducing inflow into homelessness and returns to homelessness), the Making the Shift (MtS) Youth Homelessness Social Innovation Lab is coled by A Way Home Canada and the Canadian Observatory on Homelessness, which is housed at York University. MtS supports the facilitation of sustainable exits from homelessness by identifying, developing, prototyping, testing, evaluating, and mobilizing innovations in policy and practice through the implementation of demonstration projects. Blending experimental program delivery with research and evaluation, the demonstration projects include 15 sites across Canada in 12 communities in Alberta, British Columbia, Newfoundland and Labrador, and Ontario. These projects are intended to expand the knowledge and understanding of innovative approaches to preventing and ending youth homelessness by using design thinking and producing scientific evidence to truly meet the needs of those served. The demonstration projects also help determine how and whether a proposed policy or intervention works—known as establishing "proof of concept"—which can later be used to inform policy and provide knowledge for "scaling" successful models beyond the original communities.

As part of the MtS Youth Homelessness Social Innovation Lab, 3 demonstration projects on HF4Y are currently being implemented by community agencies in Ottawa, Toronto, and Hamilton in Ontario, Canada. In each of the cities, agencies that work with youth experiencing homelessness are implementing and operating the HF4Y program, consistent with the model developed by Gaetz et al [21]. Each testing site focuses on specific populations of young people experiencing homelessness. Although Ottawa focuses on youth currently experiencing homelessness, Toronto focuses on youth exiting the child welfare system as a preventive intervention.

In Hamilton, an RCT design is not being used as it does not align with the values of Indigenous knowledge and traditions. Instead, a hybrid model is being implemented; it is called *Endaayaang* and combines the core principles of HF4Y with Indigenous ways of knowing and cultural practices. In Canada, Indigenous youth include 3 distinct cultural groups, that is, First Nations, Metis, and Inuit. Youth from these communities are overrepresented in the population of youth experiencing homelessness because of the history of colonialism (including practices aimed at eradicating Indigenous cultural traditions such as residential schools and the 1960s Scoop); involvement with child protection services; and the presence of intersecting forms of oppression, intergenerational trauma, and marginalization [28-30]. The adaptation of the HF4Y program necessitates the inclusion of Indigenous leadership in the program for it to succeed. Therefore, an Indigenous-led methodology that adopts a hybrid approach combining Western and Indigenous methodologies and ways of knowing is being used [31]. This approach combines elements from the settler-developed HF4Y model with Indigenous ways of knowing and cultural practices, rooted in the understanding that Indigenous youth must experience a sense of belonging within their community and have access to cultural and spiritual guidance from Elders and Traditional Knowledge Keepers to achieve positive outcomes.

The demonstration projects intend to help build an evidence base for youth homelessness prevention in Canada and to inform work on youth homelessness internationally. The research protocol described in this paper focuses on the models being implemented at the HF4Y sites in Toronto and Ottawa. The *Endaayaang* program model, which incorporates Indigenous epistemology, vernacular knowledge, and Indigenous-led research methodologies, will be described separately.

Study Objectives

The HF4Y study seeks to engage relevant stakeholders and communities in a collaborative research and knowledge translation process throughout all stages of the project. The stakeholders include young people with lived experiences of homelessness, Indigenous communities, the agencies engaged in the homelessness sector and delivering interventions, and the broader network of service providers for youth experiencing homelessness in each city. On the basis of an equity lens, this study also intends to address the intersectional needs of racialized, Indigenous, and 2SLGBTQA+ youth populations as well as youth with disabilities. Together, this collaboration aims to achieve the following objectives:

1. To determine whether the HF4Y model results in better participant-level outcomes than TAU services for young people experiencing homelessness in 2 urban settings (Ottawa and Toronto) with respect to (1) housing stability; (2) health and well-being; (3) complementary supports such as social functioning and life skills (4) engagement in education, training, and employment; and (5) social inclusion.
2. To identify the critical components of the HF4Y model and what modifications are needed to effectively serve particular communities and subpopulations (eg, youth exiting the child welfare system, Indigenous youth, and 2SLGBTQA+ youth).
3. To identify the main pathways into youth homelessness or precarious housing situations and understand the key challenges young people experience in terms of recovery, the ability to thrive, and housing precarity. This will allow policies, practices, and program interventions to be improved to better serve the needs of youth experiencing homelessness.

It should be noted that the relationship between these objectives can be framed in a complementary manner, which helps improve the HF4Y program to better respond to the needs of youth experiencing homelessness.

Methods

Study Design

The HF4Y study uses a longitudinal, multisite, mixed methods RCT research approach for data collection and analysis. The choice of using an RCT design was consistent with the relevant body of clinical trials at the intersection of homelessness, social policy, and health [16,32,33], particularly the At Home/Chez Soi national project [10]. RCT studies are widely regarded as the highest standard for studying causal relationships between interventions and outcomes [34,35]. Despite their limitations, such as population availability, missing data, and participant dropouts [36], RCTs can successfully minimize a substantial portion of the inherent biases commonly observed in other study designs.

There is a growing recognition of the importance of integrating qualitative approaches in RCTs [37]. The choice of incorporating a qualitative inquiry in this study was intended to gain insights from youth participants during the implementation phase to better understand the effects of the HF4Y interventions and how they are experienced by recipients. Therefore, the results of the qualitative inquiry and RCT can be integrated to draw meaningful conclusions about the efficacy of the HF4Y intervention.

Each of the 2 site-specific HF4Y demonstration projects was tailored to reflect the needs of the target population as well as the unique local environments and cultural contexts at hand. At both the Ottawa and Toronto sites, 2 groups were created: an intervention group that received housing first (HF intervention) and a control group that received TAU services. At both sites, the participants randomized to the HF intervention group receive housing and support, consistent with the HF4Y program model [20,21], including the provision of a housing subsidy for the duration of the study (4 years). Youth participants are offered a range of housing options with no treatment preconditions (eg, in-place crisis, transitional, supportive, or scatter-site housing with mobile supports), and they receive an array of case management services related to housing retention, well-being, income and employment, education, and social inclusion as well as complementary supports. Participants randomized to the TAU group do not receive the HF intervention but generally have access to supports and regular housing programs in the community that are available for young people, potentially including income support, drop-ins, physical and mental health clinics, emergency shelters, and transitional housing or longer-term housing. Participants in this group are provided with an information package about both housing and supports and are invited to use the field office or participating service agency as a resource.

Partnership and Public Involvement

The HF4Y research study actively engaged community partners and youth with a lived experience of homelessness throughout the design and implementation process. Forming a partnership with key stakeholders, including community agencies, was pivotal to advancing the goals of the study while allowing for a more meaningful collaboration between researchers and service providers. It was important that the study be delivered in partnership with local agencies, as the ultimate aim was to build practical knowledge and an evidence base for the HF4Y intervention. Combining on-the-ground knowledge with insights provided by a large body of stakeholders, including service providers, policy makers, researchers, and youth with lived experience, was an underlying ethos that undergirded the development of the original HF4Y program model guide [20].

The collaboration between researchers and 2 key organizations, namely, the Street Youth Planning Collaborative (Hamilton) and the National Learning Community on Youth Homelessness, played a central role in shaping and executing this study. In particular, the input from young individuals with lived experience was crucial and highly valued during this collaborative process. The findings of this study will also be shared with the youth participants and community partners who actively participated in the research.

Ethical Considerations

The study's human participant research protocol was approved by the Office of Research Ethics at York University (2017-382).

The eligible participants are provided with informed consent forms that contain information about the study, participants' rights, expectations, potential risks and benefits, the amount of compensation, and the resources and services available for them during the study. Informed consent is also solicited from participants for each follow-up survey or interview. Participants are compensated for their participation in the research depending on the length of the sessions they attend. For the intervention group, 90-minute appointments are being remunerated with CAD $50 (US $37) per session, and shorter appointments of 30 minutes are being remunerated with CAD $25 (US $18.5) per session. For the TAU group, 90-minute appointments are being remunerated with CAD $60 (US $44.4) per session, and shorter appointments of 30 minutes are being remunerated with CAD $35 (US $25.9) per session. Qualitative interviews last approximately 60 to 90 minutes, and participants in both the intervention and control groups receive CAD $50 (US $37) per interview.

The privacy and confidentiality of participants will strictly be followed to the fullest extent possible by the law. All identifying information collected will be treated as strictly confidential. The names of the participants will not be used to identify the data at any stage of the research. Each participant will instead be identified by a number code on every survey, recording, and transcript to ensure privacy. The participants ID list, linking the participants' names with their unique identifiers, will be kept electronically on a password-protected computer in the locked office of the principal investigator at the Canadian Observatory on Homelessness at York University. This participants ID list will be kept separate from all other data and will only be accessible to the research team enlisted in the study's human participant research protocol. The participants ID list will be kept in the event that any participant wishes to withdraw from the study following data collection. In terms of data analysis, the research team will only be working with deidentified data, and all findings will be presented at the aggregate level. For the purpose of research dissemination, no identifying information about the participants themselves or the names of participating agencies and organizations will be shared in publications or presentations.

Participants' Recruitment

The recruitment process began by identifying eligible youth across the demonstration sites, which included young people aged 16 to 24 years who were experiencing homelessness or housing precarity consistent with the Canadian definition of youth homelessness [3]. However, because of concerns over participants not reaching the age of majority to be able to participate in the HF4Y research study, the age range was set between 16 and 24 years. Owing to different operational procedures, each community agency included additional criteria in terms of recruiting participants.

Potential study participants came from the pool of young people who accessed homelessness services and associated sectors (eg, child protection services, youth mental health or addictions services, law enforcement, or corrections). Each site determined additional inclusion criteria to address existing gaps in local service delivery as well as individualized recruitment strategies based on local prioritization processes and budgeting limitations. For example, the Ottawa site recruited youth aged 18 to 24 years who were experiencing homelessness, including young people living in a shelter, couch surfing, or sleeping outdoors. The Toronto site recruited youth experiencing homelessness (or at risk of experiencing homelessness) aged 17 to 24 years who had been in or were transitioning out of the provincial child welfare system.

To identify eligible participants to be recruited for the study, outreach activities began with local agencies and providers who were in contact with young people experiencing homelessness in Ottawa. Community representatives from each site developed a strategy to work with potential referral sources and inform them about the study. Strategies to ensure adequate participation in the study included seeking referrals from a wide range of services accessed by each site population. In Ottawa, these included local youth shelters, drop-in centers, city prioritization lists (ie, by-names list), and other local service agencies delivering programs for youth experiencing homelessness. In Toronto, youth were primarily referred by Youth in Transition workers who work with youth exiting the child welfare system, in addition to the types of referral sources used in Ottawa. Researchers and service delivery teams followed site-specific strategies for informing referral agencies (eg, outreach, posters, and meetings with key staff), identifying prospective participants, making contact to ascertain participant interest, and carrying out screening processes.

Recruitment for the study started in February 2018 in Ottawa and was completed in November 2019, with 86 participants enrolled in the study. In Toronto, the first participants were recruited in June 2018, and the final group of youth was admitted to the study in March 2020, with 62 youth participants in total. At the initial interview, participants were guided through an informed consent process and then asked to complete a baseline evaluation (interview and survey) before receiving a notification of the group assignment.

Data Collection and Randomization

Survey and interview data in Ottawa and Toronto are being collected at multiple time points over the course of 4 years to capture a range of outcomes, as listed in Table 1. Data collection is expected to be completed at both sites by March 2024. The data collection procedures follow a sequential, mixed methods design [38], which involves a 2-phase process starting with the quantitative data collection, followed by a qualitative phase to help provide a deeper understanding of the survey responses and quantitative results based on participants' personal narratives and life journeys through homelessness.

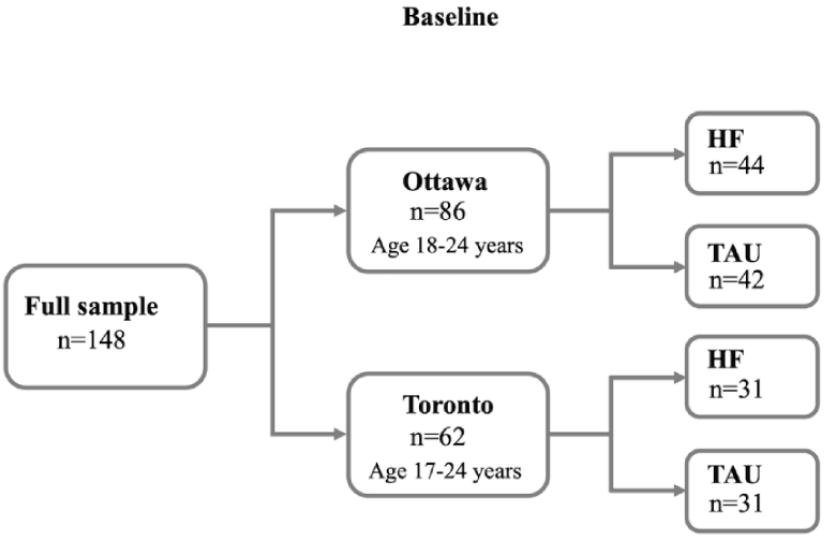
Sense of belonging to the community	Psychological Community Integration Scale [49]	6 months
Engagement in cultural and meaningful activities	Physical Community Integration Scale [50]	6 months

[a]Primary outcomes domains.

[b]The residential timeline follow-back (RTLFB) is designed to assess various aspects of housing status and stability. In this study, it serves to incorporate point-in-time assessments and longitudinal evaluations of participants' housing stays and transitions. It allows building a chronological record of each respondent's residential history between successive interviews. In addition, the RTLFB collects information about the type of residence, the individuals the participants are living with, and the reasons for moving in and moving out during the specified period. The records obtained from the RTLFB will be analyzed to gain insights into the specific places where young people stayed during the study, as well as the reasons for their moves in and out of different residences. This information will contribute to a comprehensive assessment of the effectiveness and impact of the HF4Y intervention on their housing stability and overall well-being.

[c]The measures and intervals listed will be used at the interval indicated to collect data over 48 months (eg, the residential timeline follow-back is being used every 3 months for 48 months).

[d]VTLFB: vocational timeline follow-back.



It was expected that baseline differences would exist across sites, reflecting the diverse demographic, socioeconomic, and ethnoracial background of participants based on regional characteristics. To achieve representativeness in the RCT sample, homogeneous sampling was used [38], which targeted several shared characteristics including age range (youth aged 16-24 years) and those who were experiencing homelessness or were at risk of homelessness. For each site, a minimum of 63 participants needed to be recruited for the study to be able to detect an effect size of 0.5 between the TAU group and the intervention group for the primary outcome domains, given α=.05 and β=.20. However, the total number of participants recruited was 148 to account for an attrition rate of 25%, following similar RCT-designed studies [11,17].

The participants were assigned through strict randomization to either the TAU or HF intervention groups. Research assistants sealed assignments in envelopes ordered by participant identification number according to a randomization sequence generated through a web-based random sequence generator.

XSL•FO
RenderX

Once the baseline interview was completed, the participants received a notification of the group assignment in a sealed envelope along with an information sheet. In Ottawa, 44 youths were assigned to the HF intervention group and 42 were assigned to TAU group. In Toronto, the number of participants in the HF intervention and TAU groups was equal (n=31; Figure 1). After group assignment, research assistants connected the participants assigned to the HF intervention group to the program service provider. Participants randomized to the TAU group were informed about the available services in the community. All participants were informed of the schedule of research follow-up appointments and were invited to use the research field office or the participating service agency as a resource center. All participants were provided with a pamphlet on existing services in the community.

Figure 1. Housing First for Youth randomized controlled trial study design HF: housing first; TAU: treatment-as-usual.

Housing and Supports Services

Participants randomized to the HF intervention group receive housing and support in accordance with the HF4Y model's framework and core principles [20,21]. The program staff were extensively trained on the intervention requirements to ensure fidelity to the model. Supports offered include the provision of a housing subsidy, such that participants spend ≤30% of their income on housing based on the private rental market. Participants may also live in social, supported, or alternative housing with no treatment preconditions (eg, in-place crisis, transitional, supportive, or scatter-site housing with mobile support), in which case the rent supplement is not required. The provision of support services is not bound by any preconditions (eg, housing readiness, sobriety, and engagement in other treatment), although participants agree to be visited in their unit a minimum of once per week by program staff for a length of time that is appropriate to their level of need.

It is important to note that although a range of housing options is available in both Ottawa and Toronto, the immediate access to specific options may vary. Factors such as demand, capacity, and funding influence the availability of each option. Resource limitations or eligibility criteria may result in some options being more readily available than others.

The intervention services young people receive within the HF4Y model, including a housing rent subsidy and a range of supports delivered via housing-based case managers, are designed to bridge the financial gap and enhance young people's ability to secure suitable housing, such as private market rentals, which they may not be able to afford on their own. In addition, housing-based case managers provide support in navigating housing processes while ensuring that young people are aware of their housing prospects. These supports include providing young people with comprehensive information about the various housing options available in the community as well as facilitating discussions with youth on the advantages and disadvantages of each option, including any potential constraints in accessing their preferred types of housing. Through these conversations, young people actively participate in the decision-making process, enabling them to select the type of housing, neighborhood, and level of services that best align with their individual needs and preferences. This means that young people can also reassess their needs and make adjustments to their housing options as required. This approach empowers young individuals, promotes informed decision-making, and supports their personal growth and development.

The HF4Y model offers a wide array of support services related to housing retention, well-being, income and employment, education, and social inclusion as well as complementary supports such as peer support that are offered by providers who are based off-site. These support services are individualized and tailored specifically to participants' needs, preferences, and cultural backgrounds. Adapted from the Pathways model [5], the support services are provided in the home or community, using mostly intensive case management, which is appropriate for individuals with moderate mental health needs and linked them primarily to 1 case manager rather than a team. In the HF4Y program model [20-22], an intensive case management model should be established in the range of 7 to 10 youths per case manager, with 7 being the ideal number to produce the most desired, optimal outcomes for youth. Case managers work with participants to obtain and maintain housing and to navigate

XSL•FO
RenderX

referrals to external services (eg, mental health support and medical services).

Compared with the HF intervention group, no active intervention is introduced to the TAU group. However, participants may continue to access existing supports and housing available in each community, including income support, drop-ins, physical and mental health clinics, emergency shelters, transitional housing, and longer-term housing. As both Ottawa and Toronto are urban centers with agencies that deliver housing services targeted to young people, it is recognized that some individuals in the TAU group may over time, through new or existing programs, access some of the same services being offered to the HF intervention group. It is also likely that the usual care service patterns will differ between cities.

Participant Retention

Participation retention is a major concern, particularly in RCT studies where receiving maximum response rates and compliance with the research protocol is pivotal to their success. In this longitudinal study, enrolling young people experiencing homelessness and housing precarity was a particularly difficult task because of their involvement in a variety of competing activities, such as school and meeting their basic needs. In addition, barriers such as unstable housing and frequent transitions have made it difficult for youth to maintain a consistent mode of communication over time. The COVID-19 pandemic in February 2020 compounded these challenges, as it disrupted the efforts made to establish and maintain contact with youth.

Existing literature suggests strategies to minimize participant attrition, which broadly include baseline tracking procedures such as collecting detailed information on the participant's location and follow-up procedures, including sending reminders to conduct follow-up interviews [51-53]. Consistent with the literature, this study uses an array of techniques to maintain contact with hard-to-reach participants, which include building rapport, supplementing traditional tracking methods (eg, phone, email, social media, and known associates) with new technologies, and offering financial incentives. More importantly, as data collection is still underway, a key factor is cultivating an appreciation of the contribution of the respondents as experts. Such a "participant-centered" approach [54] ensures that participants are aware of the impact of their participation in the outcomes and success of the study, thereby increasing the likelihood that they will continue to be engaged in the study. Although the existing body of research suggests varying rates of retention depending on the types of strategies used, ranging from 65% to 85% [53], this study aims to keep approximately 75% of the participants engaged in the study over 4 years.

Outcome Areas and Measures

Building on the existing body of research including the At Home/Chez Soi national study, primary outcomes were selected to reflect the unique characteristics of youth experiencing homelessness and to measure the effectiveness of the HF4Y program interventions that are consistent with the program's core principles and the detailed service delivery model [20,21,55]. In evaluating complex interventions, there are a range of factors that likely have an impact on housing stabilization, including sufficient and stable income, health and well-being, involvement with the justice system, involvement in education and employment, and social inclusion [56,57]. The core primary outcomes are thus selected to assess the effectiveness of HF4Y interventions on housing stability (as defined by a joint function of the number of days housed and the number of moves), health and well-being (mental and physical health status), and access to complementary supports, with secondary outcomes consisting of participation in education and employment and social functioning, as listed in Table 1 [55]. Multimedia Appendix 1 provides a comprehensive description of the measures.

In Ottawa and Toronto, interviews and surveys designed to collect quantitative data were administered at baseline, and each follow-up takes place at specific time points (3-6 months) over 4 years. At entry into the study (baseline), youth participants were interviewed using a range of questions aimed at collecting demographic data, physical health conditions, access to care, housing retention (using residential timeline follow-back), and employment (using vocational timeline follow-back; refer to Multimedia Appendix 1 for a detailed description of the interview measures). Following the interview, the participants were administered a battery of survey measures for physical and mental health and well-being, social inclusion, self-esteem and self-efficacy, resilience, hope, quality of life, and a measure reflecting complementary skills that impact the various domains (Table 1). In-person and phone-based follow-up quantitative interviews are being conducted at 3- or 6-month intervals depending on the instrument used. Since the onset of the COVID-19 pandemic, interviews and surveys with youth participants have been conducted remotely via Zoom (Zoom Video Communications) or phone. The number and timing of interview sessions were decided based on two factors: (1) the intention to evaluate longer-term outcomes and trajectories of change for each participant and (2) the recognition that participants may miss appointments owing to the nature of their situation and issues. This may be even more pronounced in the TAU group that has no interaction with the intervention, and, therefore, a potentially weaker incentive to attend appointments as scheduled.

The collection of primary data is mostly achieved through interviews conducted via Zoom or phone, with a mixture of both paper- and computer-based survey methods. Each interview appointment takes approximately 30 to 60 minutes to complete, and the participants are compensated for their time. Computer-based surveys administered through the *Qualtrics* survey platform are entered into a secure central database using wireless technology. Hard-copy data are stored securely following double-lock procedures at each site, and electronic backups are stored on cloud-based, secure, institutional network–based storage. Several strategies are being used to ensure optimal data quality: (1) using validated and reliable tools for susceptible youth populations; (2) using a cross-site protocol for data management, data entry, quality checking, and cleaning; (3) practicing common data-checking routines at each site through monthly multisite data quality committee meetings; (4) training interviewers for face-to-face and web conferencing

XSL•FO
RenderX

interaction with participants; and (5) fielding interviewer questions centrally and making decisions where necessary across both RCT sites.

Following a sequential mixed methods approach [38], a subset of 20 youths per group at each RCT site was randomly selected (10 participants from the HF intervention group and 10 from the TAU group) to participate in a narrative interview, once at 6 months and later at 18 months. Demographic data of participants successfully recruited into the qualitative study were then assessed to ensure balance in demographic variables including age, gender identity, and ethnoracial background.

The purpose of this qualitative research inquiry is (1) to supplement the quantitative data collected with respect to the effectiveness of the HF4Y program and (2) to help identify areas that need improvement for future scaling of the HF4Y program. This qualitative approach is also intended to allow us to understand the lived and living experiences of study participants in their own words through life story (or "narrative") interviews. For the large majority of youth participants, homelessness is not the product of a single event, but it is seen as a journey in which individual agency and life decisions take center stage. The qualitative interviews follow a semistructured format and include questions that are mapped onto the quantitative outcome domains. The follow-up interviews help understand how youths' lives have changed during the RCT and what things may have contributed to those changes. These interviews specifically inquire about the types of services within and outside the HF4Y program that participants are currently receiving. They also explore the types of services participants require but are not currently receiving as well as their perspectives on the helpfulness or limitations of the services they are accessing.

Analytical Procedures

HF intervention and TAU groups will be compared within each RCT site; although if it is determined that no significant differences exist between the 2 sites in terms of sociodemographic characteristics and outcome measures collected at baseline, the TAU and intervention groups will be combined accordingly across sites to increase the power of the study. There will be an interim analysis using 2-year quantitative data, with the final analyses based on the 4-year data. It is expected that certain participants might not adhere to the protocol or could discontinue their involvement owing to health issues or fatigue arising from repeated assessments. As deviations from the protocol are inevitable and likely to occur in real-time practice [58-60], there exist a number of approaches that can preserve the integrity of the randomization process including an intention-to-treat analysis, which considers all participants initially randomized in the study.

In addition, certain participants may be more likely not to respond to surveys, or certain questions might be more likely to have missing responses. With respect to missing data, 3 common mechanisms can be observed: missing completely at random, missing at random, and missing not at random [61,62]. For data missing completely at random, single imputation methods can be used to address the missing values, albeit with a tendency to provide conservative estimates of the treatment effect; for example, missing values can be replaced with the last observed values or the mean values. For data missing at random and missing not at random, multiple imputation can be used, which produces a more accurate and less biased estimate of the treatment effect [63].

For continuous outcome measures, differences between the intervention and control groups will be examined by using mixed-effects modeling for repeated measures. For binary outcomes, logistic models will be used, and negative binomial modeling will be used for all count outcome measures to account for any possible overdispersion in the data. Sociodemographic characteristics collected at baseline will be entered into the models as covariates, and the interaction between time and intervention will be considered to capture the interaction effects. All quantitative analyses will be conducted in SPSS (IBM Corp) and R studio (Posit) software packages with power set at 80% (α=.05 and β=.20) to detect an effect size of 0.5 between the TAU and intervention groups for the primary outcome domains.

Qualitative data will be assessed through thematic analyses to identify common themes related to outcomes and to analyze the underlying intervention process, consistent with the approaches suggested by Miles et al [64] and Saldaña [65]. The qualitative data provide a rich source of the narratives regarding young people's experiences with homelessness, housing instability, and interaction with the HF4Y program itself. Interviews will be transcribed and imported into NVivo (QSR International) software for analysis. Rather than focusing on preexisting theoretical constructs using an a priori method, an emergent, bottom-up approach will be used for coding [64]. The process of coding will shift back and forth from the key narratives provided by the participants to the researcher's interpretation of the meaning of those narratives, which will be documented through the researcher's analytic memos. Recurring patterns gleaned from the codes will be grouped as themes and will be thematically classified under broader themes. The final set of themes will be summarized and presented in a table, where representative quotes from transcripts will be paired with themes as textual evidence.

In addition to the quantitative and qualitative analyses, each agency is responsible for completing monthly reports that provide important metrics for all participating youth, including demographic information and key indicators such as the number of youth housed during the month and the number of youth who exit a program. Furthermore, program fidelity evaluations are conducted within each HF4Y program. These evaluations assess how well the intervention aligns with the HF4Y model and identify any areas that may require adjustments or additional support.

Data Access

Quantitative data are entered directly into laptops configured specifically for the project and are stored using a contracted service provider who will manage data storage for the study on an off-site, centralized server with high levels of physical network security. No data are stored on the hard drive, and after entry, the hard copies are kept in secure storage at each site. Access to the data is limited to authorized users only, using a multilevel permission protocol.

XSL•FO
RenderX

Results

The HF4Y study has been registered with the International Standard Randomized Controlled Trial Number (ISRCTN10505930). Human participant research ethics approval has been obtained from the Office of Research Ethics at York University. Recruitment was conducted between February 2018 and March 2020. Data collection is expected to be completed at both sites by March 2024, and preliminary analysis of data collected between baseline and 24 months is underway. The preliminary findings of the study will be published through public-facing reports at 24 months, and these results will be generated from deidentified and aggregate-level data (final results will be reported at 48 months). These reports will be made publicly available for the broader network of community partners and all levels of government (federal, provincial, and municipal), and they will be hosted virtually for a larger readership. Furthermore, several peer-reviewed, scholarly publications will be published based on the study's findings in top-tier journal outlets with an open-access option. During the course of the study, research vignettes and blog posts will highlight the ongoing progress of the research project and discuss the lessons learned, and this will be followed by a number of webinars and presentations at major national and international conferences. In addition, as part of the MtS project and in the context of what we have learned from implementation science [66-70], a robust training and technical assistance capacity has been developed to enable the spread and scaling of the HF4Y program. In particular, an iterative interaction between research and practice enhances service design and contributes to the continuous quality improvement of training and technical assistance.

Discussion

Strengths and Limitations

As the first pilot RCT to test the effectiveness of the HF4Y intervention in Canada, this study's strength lies in its approach to engaging participants and community partners in the study design while using a sequential, mixed methods design during the quantitative phase, followed by a qualitative phase. However, this study has some limitations. A larger sample size would make the study's findings more robust in terms of aggregate-level analyses. The current sample size could potentially limit the generalizability of our results. Participant dropouts, missed intervals, and noncompliance between the HF intervention and TAU groups could also affect the outcomes. Furthermore, RCT studies have limitations including issues related to low sample sizes, external validity, and missing data, which are applicable to this study.

Public Health Implications

The findings of this study will help build an evidence base on the impact of HF4Y through a rigorous program of developmental and outcomes evaluations. The findings will have potential public health implications for youth experiencing homelessness or housing precarity, as housing stability is central to preventing homelessness and addressing the range of physical and mental health issues resulting from housing instability [55]. Consistent with the emerging evidence at the international level [24,26], we anticipate an increase in housing stability and a reduction in homelessness, followed by longer periods of housing retention in the HF4Y intervention groups compared with the TAU group. This could lead to enhanced physical and mental well-being, improved social functioning, and increased community integration while allowing participants to meaningfully engage in education and employment opportunities. In addition, improved housing quality and increased housing stability are likely to lead to a reduction in the use of hospitals and emergency services as well as improved clinical outcomes, such as psychiatric symptoms and substance use, and reduced involvement in the criminal justice system.

Conclusions

Although there is emerging evidence on the efficacy of HF4Y globally [24-26], there is limited knowledge about its effectiveness specifically in Canada. This knowledge gap is significant because the HF4Y interventions and programs in Canada must adhere closely to the model's core values and principles to be recognized as true HF4Y interventions. This study will contribute to our understanding of how to effectively deliver and scale up the HF4Y intervention, with the aim of continually improving the HF4Y model and promoting better outcomes for youth.

The HF4Y pilot study will provide an evidence base for transforming policy and program interventions to address youth homelessness. This requires a shift away from solely managing the crisis and toward prioritizing prevention, which entails supporting those who are experiencing or at risk of homelessness to regain stable housing. By empowering individuals to sustain their housing, the HF4Y demonstration project actively seeks to engage youth in education and cultivate their sense of inclusion in the community, thereby creating a foundation for long-term health and well-being.

Acknowledgments

Funding for this study is provided by the Government of Canada through the Youth Employment and Skills Strategy Program of the Department of Employment and Social Development, Canada. The funding is being implemented through a partnership between A Way Home Canada, the Canadian Observatory on Homelessness, and local partner agencies.

Abstract

Background: Low- and middle-income countries are facing the emerging burden of chronic noncommunicable diseases (NCDs). Apart from loss of human lives and premature deaths, NCDs result in huge costs for treatment to individuals and the health system. Although NCDs develop in later life, the risk factors begin at an early age. The key to the control of the global epidemic of NCDs is primary prevention based on comprehensive community-based programs.

Objective: This study aims to develop, implement, and evaluate the effect of a participatory health promotion initiative utilizing the existing mechanisms of Village Health Nutrition and Sanitation Committees (VHNSCs), women's self-help groups (SHGs), and schools on modifiable risk factors for NCDs among young people aged 10-30 years.

Methods: The proposed type II hybrid effectiveness implementation cluster randomized field trial will be conducted in the catchment area of 4 primary health centers (PHCs) in Wardha district, India, comprising 100 villages with a population of 144,000. Each PHC will be randomly allocated to one of the 3 intervention arms or the control arm. The 3-intervention arm PHCs will utilize a unique strategy with either VHNSC or SHG members or school students as change agents for health action against common modifiable NCD risk factors. This study will be implemented in 3 phases from January 2022 to December 2024. First, the preparatory phase for baseline assessments includes anthropometry, behavioral and biochemical risk factors for NCDs, and participatory development of the health promotion intervention modules. Second, the implementation phase will focus on capacity building of the change agents and implementation of the participatory health promotion initiative. The implementation will include organization of community-based events, 6-monthly participatory assessment of change, and preparation of a sustainability and exit plan toward the end of this phase. Third, the evaluation phase will consist of studying the effectiveness of each intervention strategy in the reduction of risk factor prevalence at the population level.

Results: We will assess 12,000 (3000 in each arm) randomly selected individuals for behavioral risk factors and 1600 (400 in each arm) individuals for biochemical risk factors during baseline as well as endline assessments. Difference in differences,

XSL•FO
RenderX

ANOVA or multivariate analysis of covariance, and regression analysis will be performed to assess the effectiveness of the interventions. Qualitative methods such as focus group discussions and stories of change will be documented and analyzed using thematic framework analysis. The implementation outcomes will be reported using the PRISM (Practical Robust Implementation and Sustainability Model) RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) framework. The results are expected to be published by mid-2025.

Conclusions: This study will show the magnitude of risk factors for NCDs, its determinants, feasibility, effectiveness of community-based interventions, and health promotion models for NCD prevention.

Introduction

Background

Low- and middle-income countries such as India are facing the emerging burden of chronic noncommunicable diseases (NCDs) while still struggling with the unfinished agenda of improving maternal and child health, nutrition, and infectious disease spread [1]. The burden of cardiovascular diseases, chronic respiratory diseases, diabetes, cancer, and mental disorders is predicted to increase significantly in the next 25 years [1]. NCDs are estimated to account for about 75% of all deaths in India by 2030 [1]. Cancer deaths are projected to double from 2004 to 2030, and cardiovascular disease deaths are predicted to increase from 2.7 million in 2004 to 4 million in 2030 [1]. Apart from high costs to the health system, NCDs result in high out-of-pocket expenditure. The overall economic burden of NCDs in India is estimated to amount to approximately 5%-10% of the gross domestic productivity, thus imposing huge social and economic costs, impeding not only health improvements but also economic progress and social development of the country [2]. Evidence suggests that NCDs disproportionately impact people at younger ages and are increasingly afflicting the poorer segments of the society [2,3].

The National Family Health Survey has shown that throughout India, over 10% of the population aged 15 years and older have elevated blood sugar levels and over 20% of the population have elevated blood pressure levels [4,5]. Various studies [6-9] have highlighted the need of early interventions for the primary and secondary prevention of NCD-related risk factors. For instance, a study in Central India reported that the prevalence of hypertension was 5.75% among adolescents, which highlights the need for blood pressure and nutritional monitoring among adolescents [6]. Overweight or obesity has been reported in 4.3% of schoolchildren in Wardha, with a dietary deficiency in 57% of the adolescent girls [7]. Metabolic syndrome (clustering of abdominal obesity, hypertension, disturbed glucose metabolism, and dyslipidemia) has been reported in 9.3% of the rural adult population in India [8]. A recent review from low- and middle-income countries highlights the role of community-based interventions through health-promotion initiatives in reducing the risk factors related to NCDs. Such interventions significantly reduce the risks ranging from lifestyle and diet modifications, smoking, alcohol, etc [9].

The key to the control of the global epidemic of NCDs is primary prevention based on comprehensive community-based population-wide programs. There is a common agreement that community empowerment is crucial for the success of such programs, and partnerships among different stakeholders are required to provide effective pathways for the design and delivery of NCD prevention and control programs. Although India counts on different national programs to control NCDs, the gaps in implementing these programs and a clear strategy of what works and how to implement it at the local level is lacking. Notably, health promotion is a common component in all these programs [2,9,10]. Indian states such as Tamil Nadu and Kerala have piloted efforts around NCD prevention and control through various health promotion activities [11]. Although some community-based interventions have been conducted in India, there is a great variation in terms of the components of the interventions and the target population. However, to have a population-level impact and to reach communities in the periphery, the health promotion component of the NCD programs needs to be adapted to the local context [2,9].

Few studies [12-17] focusing on lifestyle intervention programs at the community level have shown considerable benefits in terms of promoting health education through healthy diets, increasing physical activity, and screening for diabetes prevention and control [12]. A community-based study in Gujarat targeting adults for the prevention and control of diabetes, consisting of health education sessions provided by trained community health workers, led to improved knowledge of diabetes and cardiovascular diseases and a reduction in the overall blood pressure in the studied population [13]. A community-based program in India for NCD prevention and control in Ballabgarh district was evaluated by Krishnan et al [14]. Volunteers and schoolteachers were trained in addition to communication campaigns, camps, and reorientation of health services at the community level. The intervention led to better management of NCDs at health facilities [14].

XSL•FO
RenderX

Several school-based health education programs in India have successfully reduced the rates of both tobacco experimentation and offer of tobacco by peers [15,16]. School-based educational programs can significantly influence children's behavior in inculcating healthy lifestyle practices. A school-based intervention called MARG (medical education for children or adolescents for realistic prevention of obesity and diabetes and for healthy aging) showed a significant increase in the intake of healthy foods, decrease in the intake of fried and fatty energy-dense foods, and increase in the physical activity and time spent on outdoor games along with improvements in glycemic parameters and lipid profiles [17]. The MYTRI (Mobilizing Youth for Tobacco-Related Initiatives in India; 2002-2007) project consisted of randomized controlled intervention trials that established the effectiveness of school health interventions in reducing tobacco use among Indian adolescents by reducing current tobacco use and their future intentions to use tobacco and by enhancing their health advocacy skills [16].

Several studies [18-22] have also emphasized the potential of self-help groups (SHGs) in improving health-related outcomes at the population level, especially in terms of knowledge, attitude, and practice of healthy behaviors for NCDs as well as other health-related conditions. VHNSCs were constituted under the National Rural Health Mission in India to enable community participation in health-related activities, formulate village health action plans, and implement and monitor the same in the villages. The VHNSC is responsible for the health of the villagers, and they are mandated to undertake preventive, promotive, and curative health activities at the village level [23].

In this study, we aim to develop, implement, and evaluate the effects of a participatory health promotion initiative utilizing the existing mechanisms of VHNSC, women's SHGs, and schools on behavioral as well as biochemical modifiable risk factors for NCDs (obesity or overweight, tobacco use, stress, unhealthy diet, physical inactivity, harmful use of alcohol, high blood pressure, high blood sugar, and increased blood cholesterol) among young people in the age group of 10-30 years.

Rationale of This Study

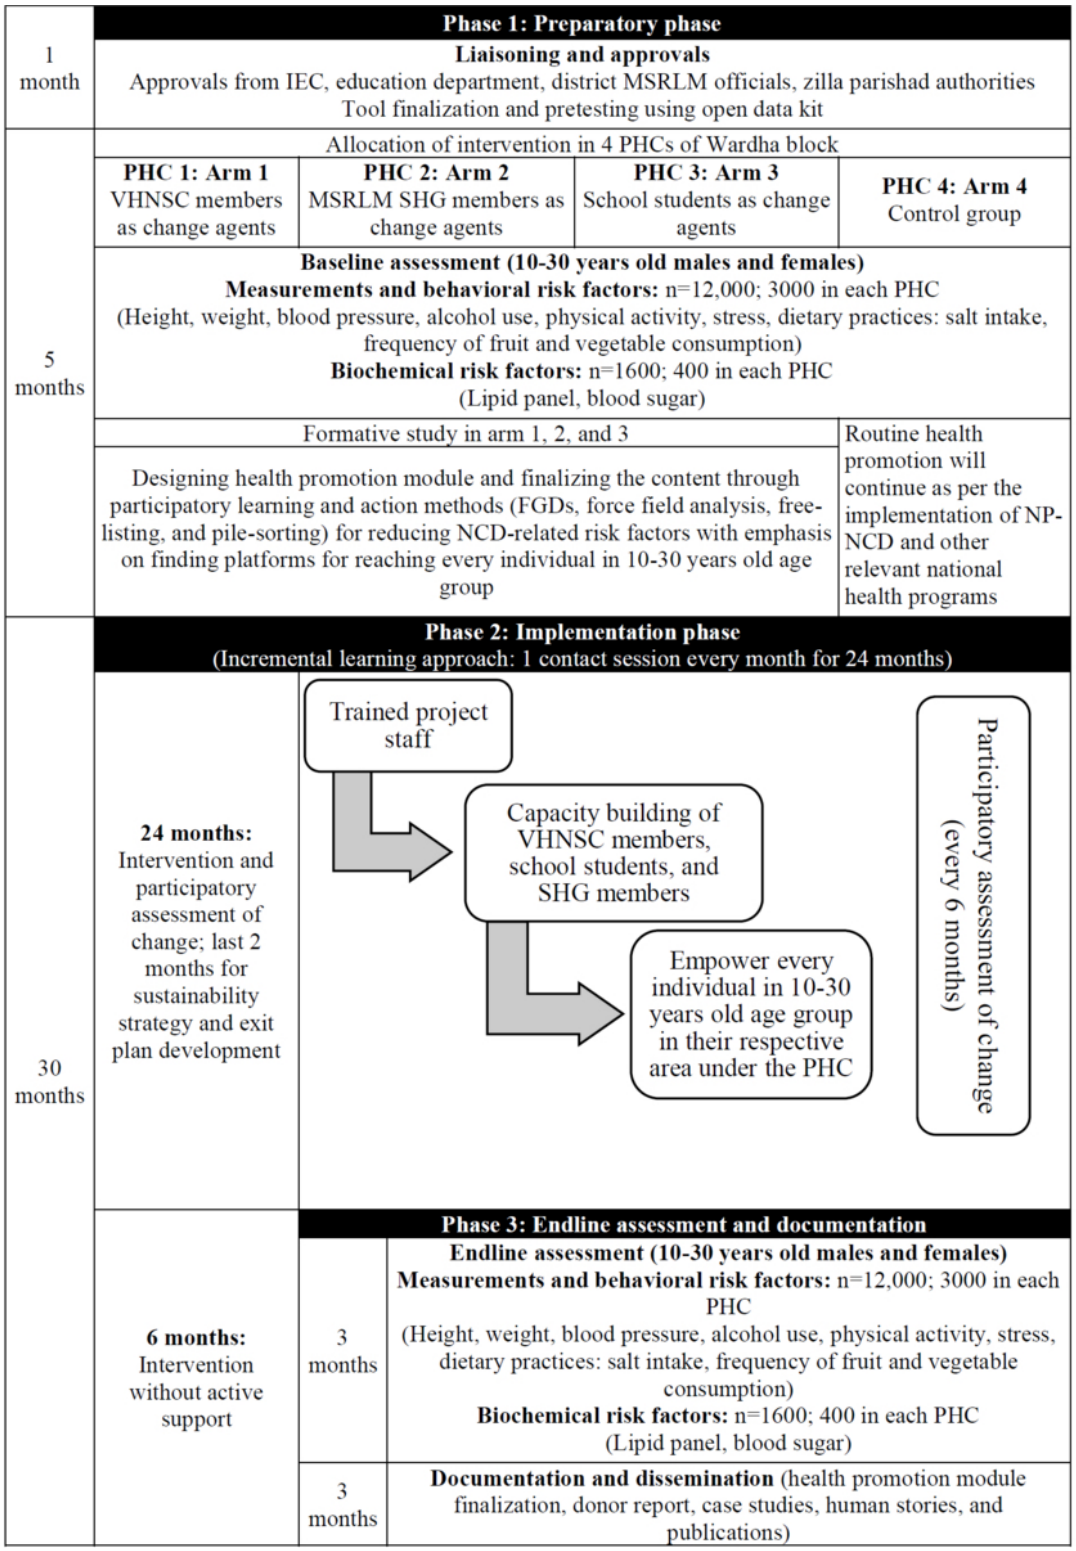
Randomized clinical trials have documented that lifestyle changes can prevent NCDs [24]. However, there is limited evidence, particularly in India, whether such strategies are applicable at the community level, that is, in a real-life setting. The emphasis of our proposed study is to strengthen the primary prevention of NCDs, which is often neglected under the current national health programs. Our proposed study will utilize a health promotion approach as indicated in the Ottawa Charter for Health Promotion [25] and will make efforts to empower and enable young people aged 10-30 years to exercise control and take care of their own health. Our study will focus on young people aged 10-30 years, as this age group is not covered under the National Programme for Prevention & Control of Non-Communicable Diseases (NP-NCD), and it is during this phase of life that NCD-related risk factors begin, which become habits during later years and thus become difficult to change and lead to chronic diseases. Apart from focusing on the commonly emphasized risk factors of tobacco, alcohol, and physical activity, this study will include locally feasible and acceptable strategies to reduce stress, which often is not accounted for in NCD prevention. This study will be implemented in collaboration with the district health system, utilizing the existing mechanisms of Village Health Nutrition and Sanitation Committee (VHNSC), women's SHGs, and schools by using the principles of participatory development and therefore much more likely to be acceptable to the community and sustainable eventually. The NP-NCD currently emphasizes early diagnosis and prompt treatment and at times tends to overlook the primary prevention. Our study, which is the first of its kind in central India for health promotion against NCD risk factors among young people aged 10-30 years, will help strengthen the primary prevention component under the NP-NCD. The proposed study has the potential of producing a community-based health promotion model for the prevention of NCDs through the life cycle approach, and thus, has every chance of leading directly to improvements in population health.

Methods

Study Design

The proposed study will be a type II hybrid effectiveness implementation cluster randomized field trial that will be implemented in a rural area of Wardha district of Maharashtra, India, which also is a part of the field practice area of the Department of Community Medicine, Mahatma Gandhi Institute of Medical Sciences, India. This study will be performed in the catchment areas of 4 primary health centers (PHCs) of Wardha block, namely, Anji, Kharangana, Talegaon, and Waifad. As per the census of 2011, there are around 100 villages in this study area with a population of approximately 144,000 people. However, the census towns (as per census 2011) in the study area will be excluded [26]. This study will be performed from January 2022 to December 2024.

Randomization



The proposed study will have 4 arms: 3 intervention arms and 1 control arm. The unit of randomization would be PHCs and each of the 4 PHCs will be randomly allocated using a simple randomization technique through the lottery method to 1 of the 3 intervention arms or to the control arm. The primary strategy in this study would be health promotion by creating change agents. The 3 intervention arms would differ in the source of change agents. The 3 interventions in this proposed study would be with (1) school students as change agents, (2) VHNSC members as change agents, and (3) women's SHG members as change agents.

Study Implementation Plan

This study will be implemented in collaboration with the district health system. As per randomization of the study arms, the existing mechanisms of VHNSC, women's SHGs, and schools would be utilized for study implementation by using the principles of participatory development in a phased manner as depicted in Figure 1 and as described below.

XSL•FO
RenderX

Figure 1. Study flowchart showing the phases and respective activities. FGD: focus group discussion; IEC: institutional ethics committee; MSRLM: Maharashtra State Rural Livelihood Mission; NCD: noncommunicable disease; NP-NCD: National Programme for Prevention & Control of Non-Communicable Diseases; PHC: primary health center; SHG: self-help group; VHNSC: Village Health Nutrition and Sanitation Committee.

Phase 1: Preparatory Phase (6 Months)

The preparatory phase will include liaising and seeking administrative approvals, staff recruitment, baseline data collection, and a formative study for developing the health promotion module.

Liaising and Seeking Administrative Approvals (First Month)

The preparatory phase will include seeking approval from the institutional ethics committee and concerned district authorities from health, education, zilla parishad, and livelihood mission departments. Piloting of data collection tools and planning for baseline data collection will be performed.

XSL•FO
RenderX

Baseline Data Collection (Second Month to Fourth Month)

A baseline assessment of the prevalence of NCD-related modifiable risk factors, that is, obesity, addiction, stress, and dietary practices, including salt consumption, physical activity, and hypertension or prehypertension will be conducted using the STEPS approach developed by the World Health Organization (WHO) [27]. The study questionnaires will include sociodemographic details, NCD risk factor survey, stress questionnaire, anthropometry, and blood pressure measurements. The details of these tools are given in a later section. Sample size was estimated separately for behavioral and biochemical risk factors by using G*power software (version 3.1; Institute for Experimental Psychology) for behavioral as well as biochemical risk factors.

Sample Size for Behavioral Risk Factors

We hypothesize that our interventions would reduce the modifiable behavioral risk factors for NCDs by 25% over a period of 3 years. With an assumption of the lowest prevalence of NCD-related risk factors at 13% [6-8,28,29] to detect the aforesaid difference, with 95% CIs, power of 80%, intracluster correlation coefficient of 2, an approximate sample of 12,000 participants, that is, 3000 in each arm, was calculated. Sample size was estimated using the lowest risk factor prevalence, as it gives the maximum possible sample size. We will utilize stratified random sampling (stratified by gender) to select the study participants. The sampling frame will be prepared from the already existing health and demographic surveillance system, which is established by the Department of Community Medicine, Mahatma Gandhi Institute of Medical Sciences, in 5 PHCs (including the study PHCs) covering around 113 villages and a population of about 120,000 people. The health and demographic surveillance system is updated every 6-12 months, and data from the most recent round will be used for the abovementioned purpose.

Sample Size for Biochemical Risk Factors

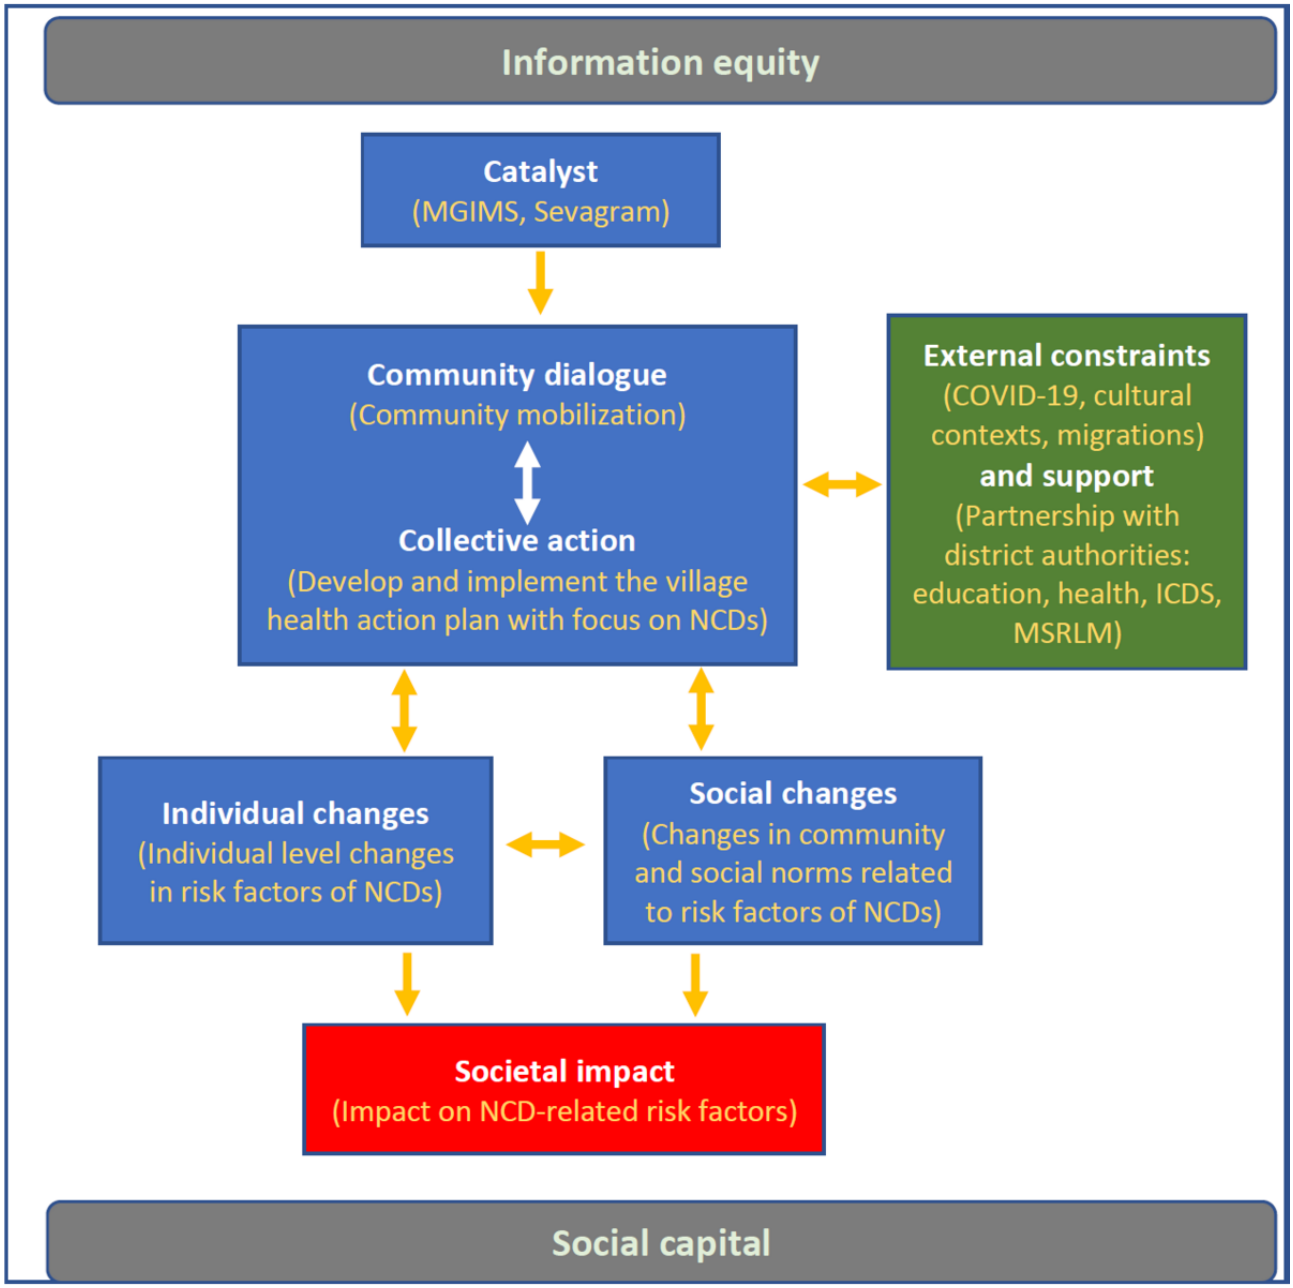
An approximate sample of 1600 participants, that is, 400 in each arm, has been estimated. This sample size will help to detect an effect size of 10% mean difference from baseline with 90% power, 95% CIs, assuming 10% sample wastage. These 1600 participants would be a randomly selected subset of the 12,000 respondents (as specified for assessing the change in behavioral risk factors). The random sampling will be performed using the "sample_n" function of "dplyr" package in R software (version 4.1.2; R Foundation for Statistical Computing).

Inclusion and Exclusion Criteria

All individuals in the age group of 10-30 years, as selected through the sampling procedure described earlier who or whose parents or guardians give written informed consent, will be included in this study for evaluation of the intervention. Those experiencing severe illness or chronic diseases will be excluded from the study since their behavioral and biochemical risk factors may be influenced by their diseased status.

Formative Study for Developing the Health Promotion Module (Second to Sixth Month)

Formative research using qualitative methods and participatory learning and action techniques will be performed, which will help us in understanding the current practices pertaining to NCD-related risk factors and help us identify the possible opportunities and mechanisms to implement the intervention. Focus group discussions, force-field analysis, free-listing, and pile-sorting will be performed to understand the community perceptions on NCD-related risk factors, their prevention, and control. Based on the findings of the formative study, the health promotion module will be developed. These modules will be central to the participatory health promotive interventions to be implemented in the next phase. The health promotion module will have incorporated monthly session plans that will be implemented through monthly contact sessions in an incremental learning approach. The health promotion module will also emphasize deciding strategies for reaching every young person in the age group of 10-30 years and its delivery mechanisms. The strength of this strategy will be that the concerned stakeholders will be able to identify and implement initiatives that are acceptable and feasible to them (eg, stress mediation strategies, local strategies for increasing consumption of locally available and easy to access nutritious food, promotion of physical activity).



Phase 2: Intervention Phase (30 Months)

Design

The intervention phase will include the implementation of the participatory health promotion initiative based on the integrated model of communication for social change (Figure 2) [30]. Of the total duration of 30 months, 24 months will be active intervention through the study and 6 months will be the intervention without active support to assess the sustainability of the intervention. VHNSCs, although mandated to undertake preventive, promotive, and curative activities at the village level since many years, now need further capacity building to undertake such activities. The capacity of the existing VHNSCs will be used to implement the village health plan against NCDs in coordination with various community-based organizations such as SHGs, farmer groups, and adolescent groups. As discussed earlier, the health promotion module will be implemented in the community through VHNSCs, school students, and SHG members as change agents. The population in all the 4 arms will continue to receive routine care through the existing government programs for NCDs. However, no additional activities will be conducted in the control arm in this study.

XSL•FO
RenderX

Adaptation of the integrated model of communication for social change in this study (adapted from Figueroa et al [30], which is published under Creative Commons Attribution 4.0 International License [31]). ICDS: Integrated Child Development Services; MGIMS: Mahatma Gandhi Institute of Medical Sciences; MSRLM: Maharashtra State Rural Livelihood Mission; NCD: noncommunicable disease.

Formation of Vitalizing Community for Health Promotion Against Modifiable Risk Factor NCD (V-CaN) Clubs

The key implementation strategies through these change agents in the intervention arms will be the formation of the Vitalizing Community for Health Promotion Against Modifiable Risk Factors of NCD (V-CaN) clubs for developing and implementing an NCD-specific health action plan for their own villages, undertaking various community-based events for health promotion, celebration of V-CaN days for spreading awareness, and creation of a social norm. The formation of these V-CaN clubs will be facilitated by the study team, and the change agents in their respective arms will be encouraged to form V-CaN clubs in their village with representation from all concerned stakeholders from that village to help disseminate and promote the learnings of the participatory health promotion module.

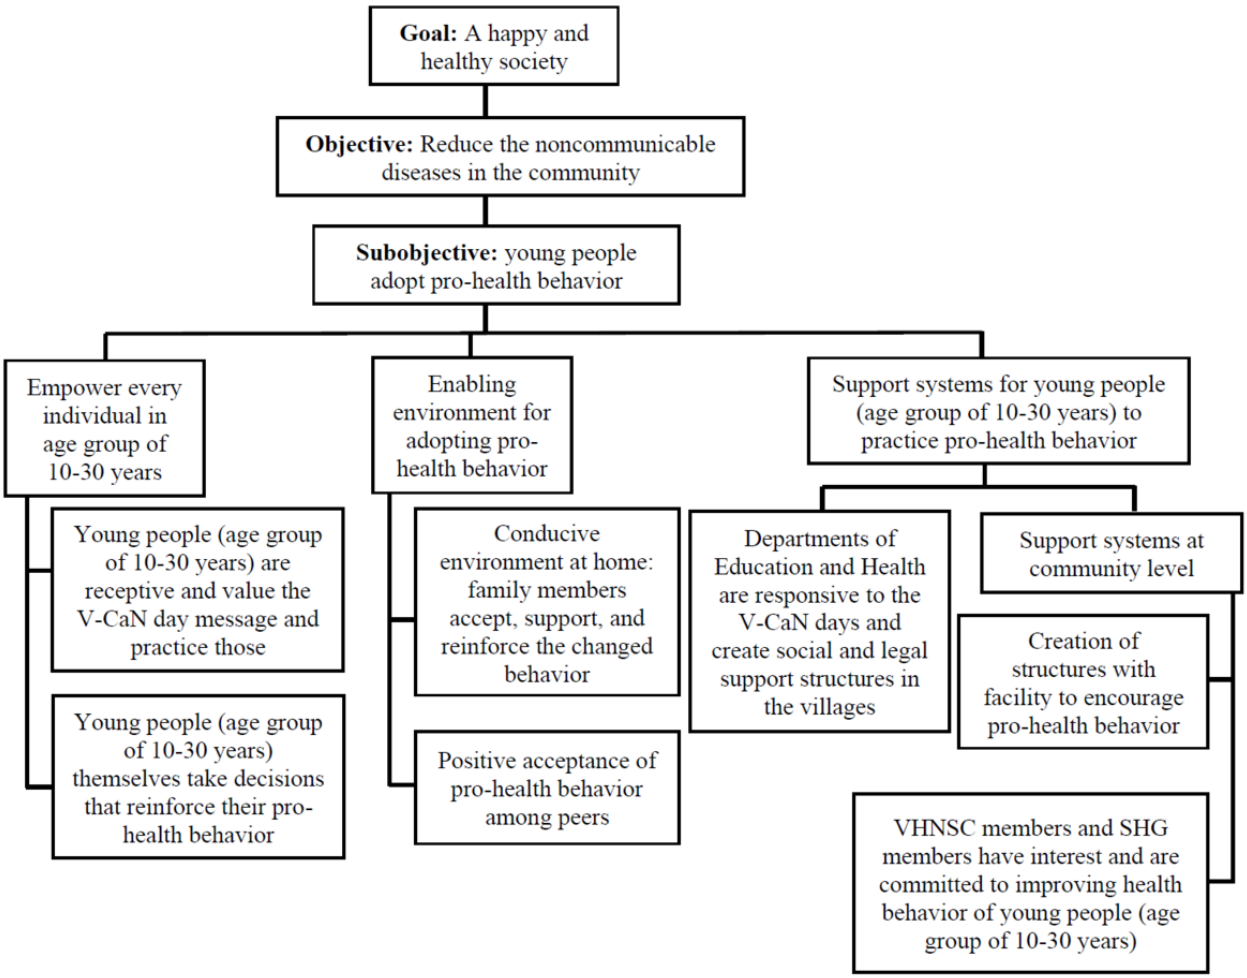
These V-CaN clubs will focus on preparing NCD-specific health action for themselves. The V-CaN clubs will also give emphasis on relieving stress through locally acceptable and feasible stress meditation strategies. A monthly meeting of these V-CaN clubs will be conducted to review monthly activities and ensure prompt health actions. As specified earlier, there will be no additional activities (V-CaN club formation) in the control arm; however, the population in the control arm will continue to receive routine care through the existing government program, that is, NP-NCD.

NCD-Specific Health Action Plan

The V-CaN club members will be expected to make a health plan against NCDs to take the learning from the monthly sessions forward. The health plan will focus on reaching every person in the age group of 10-30 years in their area. It will also

XSL•FO
RenderX

include activities that they will undertake during the next 2 years for bringing about behavior change in young people. The plan will focus on identifying and implementing initiatives that are acceptable and feasible to the local community for motivating the community to indulge in pro-health behavior as described above.



Organizing V-CaN Days

A V-CaN day (Melawa) will be organized in all the intervention villages and schools once in every 6 months with the objective to facilitate the behavior change process in the participants to (1) give up tobacco and alcohol consumption habits, if any, (2) eat a proper balanced diet, and (3) indulge in physical activity every week. The activities on the V-CaN day will be arranged in collaboration with village level health functionaries, namely, VHNSCs, ASHA (Accredited Social Health Activist), and AWW (Anganwadi worker). The effort will be to emphasize the harmful effects of the NCD risk factors by using modes such as exhibitions, role plays, demonstrations, and participatory games. Efforts will be taken to maximize the participation in these V-CaN day celebrations.

Sustainability Strategy and Exit Plan

An exit plan will be prepared in consultation with the V-CaN clubs regarding how to sustain the initiative after the implementation phase of the study. Each V-CaN club will be facilitated to prepare a plan for mobilizing resources for continuing the activities of V-CaN club. In the last 6 months of the implementation phase of the study, the activities will continue without any active support from the study staff. The sustenance of activities for the next 6 months will be monitored and documented through the study and will be a proxy indicator of the sustainability of the intervention. Factors affecting sustainability will be studied through doer (villages or schools that are able to sustain) and non–doer analyses (villages or schools that are not able to sustain). We have developed a theory of change (Figure 3) and a results framework (Table 1) for the study that will be used for monitoring and evaluation (process, output, and effect) of the study and documenting the change.

Figure 3. Theory of change for this study. SHG: self-help group; V-CaN: Vitalizing Community for Health Promotion Against Modifiable Risk Factors of Noncommunicable Diseases; VHNSC: Village Health Nutrition and Sanitation Committee.

Table 1. Results framework for the proposed Vitalizing Community for Health Promotion Against Modifiable Risk Factors of Noncommunicable Diseases (V-CaN) study.

Questions	Answers	Key assumptions
What is the problem you are trying to solve?	• Enabling every young person to adopt a pro-health behavior	• Quality and longevity of the intervention
Who is your key audience?	• All young people aged 10-30 years	• Young people are receptive and value the V-CaN[a] day messages and practice them
What is your entry point for reaching your key audience?	• VHNSC[b] members, school students, MSRLM[c] SHG[d] members	• Health and education departments are responsive to V-CaN days and give due priority to them • VHNSC members, school students, and MSRLM SHG members have interest and are committed to improving the health behavior of young people
What steps are needed to bring about the change?	• Receiving administrative approvals • Necessary supplies and logistics • Training of trainers (supervisors) • Training and capacity building of VHNSC members, school students, and MSRLM SHG members • Reaching all young people aged 10-30 years through identified approaches	• VHNSC members, school students, and MSRLM SHG members are able to tide over the social norms or restrictions and conduct or participate in V-CaN day activities
What is the measurable effect of your work?	Impact • Obesity or overweight • Prehypertension • Hypertension • Pro-health behavior of all young people Effect • Decreased prevalence of prehypertension or hypertension • Decreased prevalence of overweight or obesity • Increased frequency and consumption of fruits and vegetables • Increased level of physical activity • Decreased stress levels • Decreased tobacco use • Decreased alcohol use • Decreased salt intake Output • V-CaN days held (number conducted or number planned) • V-CaN clubs formed • Proportion of young persons (10-30 years) reached	• Master trainers have interest and are committed to improving the health behavior of young people • Good quality in-system trainings are planned and conducted • Master trainers are able to transfer the skills to VHNSC members, school students, and MSRLM SHG members
What are the wider benefits of your work?	• Decreased prevalence of noncommunicable diseases	• Young people have the necessary family and social support to engage in pro-health behavior
What is the long-term change you see as your goal?	• A healthy and happy society	• Stakeholders are young children and their parents, panchayat raj institution members, VHNSC members, school students, and MSRLM SHG members

Participatory Assessment of Change

Concurrent evaluations using the participatory method of web (spider) diagram will be performed every 6 months to assess behavior change among the young people.

Phase 3: Endline Assessment and Documentation (6 months)

Endline surveys and assessments for the effectiveness of health intervention measures will be performed in both the intervention and control groups. Case studies and human stories of change will be documented.

Data Collection and Statistical Analysis Plan

Data Collection Tools

The data collection instrument will be designed based on the WHO-STEPwise tool for NCD risk factor surveillance during baseline as well as endline assessments [27]. The WHO-STEPwise approach to the surveillance of NCD risk factors uses a standard survey instrument and a methodology that can be adapted to different country resource settings. It will be suitably modified to meet the objectives of this study and will be pilot tested. Data will be collected on Android-based tablets by using a survey solution platform developed by the World Bank through individual surveys. Anthropometry, physical measurements, and biochemical assessments will also be conducted in young people in the age group of 10-30 years. The data collection tools will consist of (1) baseline demographic information about individuals in households (age, gender, education, occupation, socioeconomic status, etc); (2) health behaviors consisting of tobacco use in smoked and smokeless form, alcohol consumption, dietary pattern (consumption of fruits, vegetables, salt, etc), and physical activity; (3) stress measurements of the study participants by using the perceived stress scale-10 that has already been used and validated in India [32,33]; (4) physical measurements, which will include measurements of height, weight, and blood pressure; and (5) biochemical assessments, which will include fasting blood sugar and lipid profile.

Operational definitions of health behaviors and procedures for physical measurements and biochemical assessments will be as per the standard procedures in the WHO-STEPwise tool for the NCD risk factor surveillance. Height and weight will be measured as described in the WHO STEPwise surveillance module. For blood pressure measurements, all the readings will be recorded by trained personnel to reduce the interobserver variation. Training in all relevant techniques will be given, including care for avoiding expectation error and digit preference. The forearm will be kept at the level of the heart. The sphygmomanometer will also be kept at the level of the heart. Two readings of blood pressure will be taken: one at the beginning of the assessment and the second at midway in the assessment. If the first 2 readings differ by more than 5 mm Hg, an additional reading will be taken and the average of the 3 readings will be noted. For blood sugar and lipid profile, 5 mL of fasting venous blood sample will be collected and transferred to the central laboratory of the institute for further processing and reporting [34]. As specified in the methodology earlier, all the measurements would be performed on 12,000 participants, except for biochemical assessments, which will be performed for a random subset of 1600 participants from among the larger cohort of 12,000 participants. However, a separate random sampling will be performed as specified earlier for the endline assessment as well.

Statistical Analysis Plan

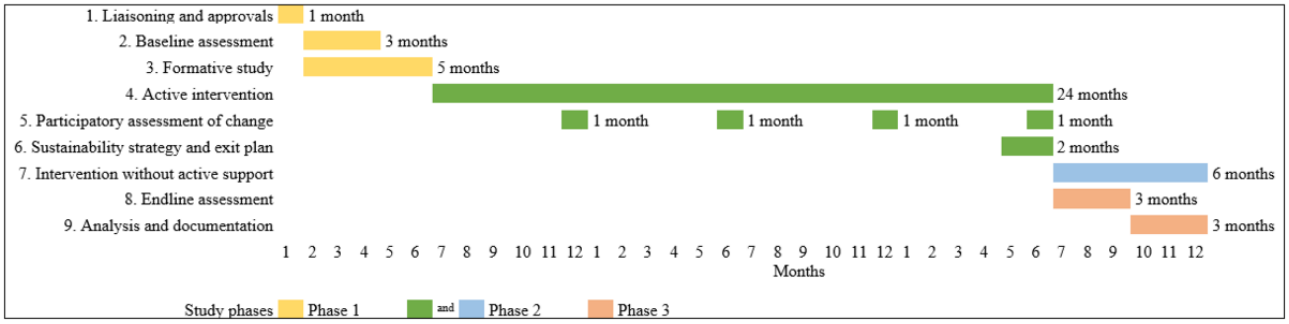
The primary outcome variable for this study would be the prevalence of various modifiable NCD risk factors as compared to baseline. Descriptive analysis will be performed using proportions with 95% CIs. For the quantitative information, difference in differences analysis using *Z*-test for differences between proportions of independent samples and ANOVA or multivariate analysis of covariance will be used to find out the effectiveness of the intervention between the intervention and the control groups. Here, the 3 interventions will be evaluated independently to demonstrate the feasibility and efficacy of each of the 3 intervention modalities. In addition, multivariate regression will be performed for finding the determinants of the risk factors, and exploratory factor analysis will be performed to explain the observed variances between intervention and control groups. For the qualitative data, thematic content analysis will be performed.

Quality Assurance

A 3-member project steering committee will be formed for technical guidance and overall quality assurance of the study. The committee will consist of a senior public health professional, a member of the district administration, and a health communications expert. Standard operating procedures will be developed for measurements of blood pressure, height, and weight. Standard and calibrated ISO-marked nonmercury automated sphygmomanometers will used throughout the study to minimize the instrumental error. Height and weight will be measured using standard calibrated electronic weighing scales and stadiometer. Similarly, standard operating procedures will be developed for blood collection and transport of samples for fasting blood sugar and lipid profile estimation. Blood sugar and lipid profile estimation will be performed in the National Accreditation Board for Testing and Calibration Laboratories–accredited central laboratory of the institute. Approximately 5% backcheck of the filled forms will be performed by study assistants for ensuring the quality of data collection. Supportive supervision checklists will be prepared for concurrent quality monitoring for monthly meetings of V-CaN clubs and V-CaN days.

Ethics Approval

This study has been registered with Clinical Trials Registration India prospectively on October 28, 2020. Ethics approval has been obtained from the institutional ethics committee, Mahatma Gandhi Institute of Medical Sciences, before the start of the trial vide letter MGIMS/IEC/COMMED/79/2020. A written informed consent will be taken from all adults before enrolling in this study. For schoolchildren and adolescents, written consent will be taken from their parents and verbal assent from the participants. Treatment of study participants diagnosed with hypertension during screening will be ensured at the respective PHC. If needed, a referral to the appropriate higher center will



XSL•FO
RenderX

be given to the study participants. Study participants will be interviewed and examined in private; women or adolescent girls will be examined in the presence of another female. The information in the study records will be kept strictly confidential. The identity of the study participants will be kept confidential by assigning them a unique identification number. Anonymized data would be used for scientific publications. Data quality will be checked before analysis.

Results

This study will be performed over a course of 3 years, as described in Figure 4, and the results are expected to be ready to be published or disseminated by mid-2025. Our findings will be disseminated through scientific publications in peer-reviewed journals, academic seminars, national and international conferences, and administrative stakeholders at the district, state, and national levels. Special dissemination strategies will be conducted at community and school levels through local-level gatherings and meetings.

Figure 4. Timelines for the proposed study.

Discussion

Our study is one of its kind trying to focus on reducing the exposure to risk factors related to NCDs in young people in the age group of 10-30 years. The findings of this study will provide us with evidence based on exposure prevention and lifestyle modification at a stage when exposures become habits and subsequently the lifestyle.

Expected Outcomes

This study will help to find out the magnitude of the problem of risk factors for NCDs in rural areas, its determinants, and the feasibility and effectiveness of a community-based trial. This study will also provide insights into the positive influences and barriers for behavioral change communication. The findings of this study will help us to develop a community-based health promotion model for the prevention of NCDs through the life cycle approach. Thus, the proposed research has every chance of leading directly to improvements in population health. We will use the PRISM (Practical Robust Implementation and Sustainability Model) RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) framework to assess the implementation outcomes as outlined in Tables 2 and 3 so as to facilitate its translation into policy and practice [35,36].

XSL•FO
RenderX

Table 2. Description of the PRISM (Practical Robust Implementation and Sustainability Model) contextual domains and elements incorporated in the study.

PRISM[a] domains	Elements of PRISM domains
Program (intervention)	
Organizational perspective	• Readiness of the institute, government administration, and investigators • Coordination and collaboration between MGIMS[b] and district authorities of health, MSRLM[c], and education departments as well as interdepartmental collaboration • Strong evidence base of behavioral risk factors targeted in the study • Estimated high burden of NCDs[d] in future • Usability and adaptability of the community mobilization process • Mechanism for addressing barriers of study staff
Individual (beneficiary) perspective	• Community-centered interventions • Community empowerment to adopt healthy behavior • Addressing barriers of beneficiaries in participation and adoption of behavior change during V-CaN[e] days/monthly V-CaN meetings • Feedback of results to be shared
Recipients	
Organizational characteristics	• Schools, VHNSCs[f], MSRLM SHGs[g]—implementation climate across the 3 intervention arms • Developing and implementing village health action plans through V-CaN clubs • Trainings given under the study • Keeping the group motivated as a whole to work toward healthy behavior • Existing community norms • Time management for study-related activities along with primary objectives of the organization • Decision-making
Individual (beneficiary) characteristics	• Keeping the group members motivated to work toward healthy behavior • Knowledge and beliefs of individuals • Competing interests of individuals
Implementation and sustainability infrastructure	• Universally existing infrastructure of schools, VHNSCs, and SHG networks • Dedicated study team for study duration and V-CaN clubs for future sustainability • Participatory approach for preparing health promotion modules and planning of interventions • Scope of flexibility/creativity as per the village health action plan prepared under the study • Exclusively dedicated time duration for studying sustainability • 6 monthly participatory assessments of change and program evaluation at the end of the study
External environment	• Existing national program for NCDs (NP-NCD[h]) • Competing health agenda and priorities • Migrations • Behavioral/cultural acceptability for pro-health behavior • Community resource mobilization

Table 3. Description of the RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) critical outcome indicators to be assessed.

RE-AIM[a] dimensions	RE-AIM indicators
Reach	• Characteristics of participants, that is, students, SHG[b] members, VHNSCs[c] (eg, age, gender, education) and comparison of characteristics across the 3 arms • Participation rates (as proportion of all eligible/approached) • Dropout rates
Effectiveness	
Primary	• Change in the prevalence of risk factors related to NCDs[d] • Feasibility of each intervention for reduction of risk factor prevalence
Secondary	• Characteristics of individuals who comply with the behavior change versus noncompliers • Change in the prevalence of obese/overweight individuals, patients with hypertension or prehypertension, patients with diabetes or prediabetes • Change in the mean blood pressure/blood sugar/serum cholesterol levels of population
Adoption	• Proportion of V-CaN[e] club monthly meetings held/V-CaN days celebrated out of committee • Reasons for missed V-CaN club meetings/V-CaN day celebrations (comparison across the 3 arms)
Implementation	• Fidelity of intervention sessions (trainings, V-CaN meetings, V-CaN days) • Content delivery and satisfaction of beneficiaries • Best practices, innovations, and improvisation in the 3 arms
Maintenance	• Sustainability and exit plan • Proportion of villages delivering the interventions during the last 6 months of the study period without active support of the study team • Enabling and inhibiting factors for maintenance/discontinuation and adaptation

[a]RE-AIM: Reach, Effectiveness, Adoption, Implementation, Maintenance.

[b]SHG: self-help group.

[c]VHNSC: Village Health Nutrition and Sanitation Committee.

[d]NCD: noncommunicable disease.

[e]V-CaN: Vitalizing Community for Health Promotion Against Modifiable Risk Factors of Noncommunicable Diseases.

Future Plans Based on Expected Outcomes

This study will be a value addition to strengthen the primary prevention component under the NP-NCD and Rashtriya Kishor Swasthya Karyakram, as it is going to be implemented in collaboration with the district health system, utilizing the existing mechanisms of VHNSC, community-based organizations, and frontline health workers. If proven effective, the possibility to implement the health promotion modules in the control PHC will also be explored at the end of the study. Further advocacy with the administration will be performed for scaling up of the intervention.

Strengths and Limitations of This Study

This cluster randomized study will provide rich evidence regarding prevention of common modifiable risk factors against NCDs. Moreover, outcome evaluation is performed in a very large sample, thereby minimizing the possibility of random errors in the results. Simple random sampling will ensure minimal selection bias. The inbuilt concept of community mobilization and preparation of an exit plan may also lead to sustenance of the program, thereby ensuring the perceived benefits to reach the people even beyond the study duration. External generalizability of this study will be limited only for rural areas with similar profiles and not for urban or tribal areas.

Acknowledgments

This study has been approved and will be funded by the Indian Council of Medical Research, New Delhi, vide letter 5/4/8-23/CD/AVR/202 l-NCD-ll.

Data Availability

After the completion of the proposed study, the findings will be published in a peer-reviewed journal. The data from this study may be available with the authors and will be accessible on request from the corresponding author.

Abstract

Background: Hypertension and diabetes are among the most common noncommunicable diseases in Zimbabwe. These 2 conditions are largely prevented and controlled by lifestyle modifications, such as healthy eating habits, physical activity, and avoiding the use of tobacco and alcohol.

Objective: This study aims to evaluate the effects of a community health worker (CHW)–led health literacy intervention on lifestyle modification among patients with diabetes and hypertension in the City of Harare, Zimbabwe, in terms of (1) adherence to recommended lifestyle changes, (2) blood pressure and blood glucose levels, and (3) medication adherence.

Methods: This is a 6-month–long cluster randomized controlled trial, which will be conducted in primary health care clinics in the city of Harare. A total of 14 clinics will be randomly allocated into either the intervention or control group. A total of 680 (49 participants per clinic) adult patients with hypertension and diabetes will be enrolled for the trial. Participants in the intervention arm will receive a simple health literacy intervention on lifestyle modification, which will be delivered by trained CHWs, while those in the control arm will receive usual care. The intervention consists of 4 face-to-face interactive educational sessions and monthly support visits by trained CHWs and will be carried out over a period of 6 months. The primary study outcomes will be blood pressure and blood glucose levels and levels of adherence to the recommended lifestyle modifications. Other outcomes will include adherence to medication. Data management and analysis will be done using Epi Info software, and the data will be analyzed using the intention-to-treat principle.

Results: Recruitment of study participants commenced on June 1, 2023, and was completed on July 30, 2023. Baseline data are being collected after participants' recruitment, and the final data collection will be completed by January 31, 2024.

Conclusions: There is an information dearth regarding the effectiveness of CHW-led interventions for the management and control of hypertension in Zimbabwe. Our study offers an opportunity to show the effectiveness of CHWs in addressing the gaps in the management of hypertension and diabetes. The findings from our study will provide crucial evidence on the effectiveness and feasibility of a simple intervention delivered by CHWs in resource-constrained areas.

Introduction

Hypertension and diabetes are among the leading causes of morbidity, disability, and premature death worldwide. In 2019, diabetes was the direct cause of 1.5 million deaths worldwide, and 48% of all deaths due to diabetes occurred before the age of 70 years [1-3]. An estimated 1.28 billion adults aged 30-79 years worldwide have hypertension, with an estimated 46% being unaware of their condition. The prevalence of both hypertension and diabetes has been increasing more rapidly in low- and middle-income countries, compared to high-income countries. This is a cause for concern in these countries, considering their already high burden of communicable diseases [1,3].

Studies have shown links between hypertension and diabetes [4-6]. For instance, hypertension is more common in patients with diabetes, and similarly, diabetes is also more common in patients with hypertension than in the general population [4]. Previous studies have reported that hypertension occurs in 50% to 80% of patients with type 2 diabetes [5]. These two conditions are predominantly lifestyle related, as they are highly associated with risk factors like obesity, stress, excessive salt intake, physical inactivity, excessive alcohol intake, and smoking [3,6,7]. Therefore, prevention, control, and management of these two conditions involve lifestyle modifications. The recommended lifestyle changes include weight reduction, healthy eating, reducing alcohol consumption, regular physical exercise, and quitting smoking [8-10].

Lifestyle modification poses a challenge for patients with hypertension and diabetes, and several studies have demonstrated high noncompliance with the recommended lifestyle modifications worldwide [11]. Although studies have shown that nonadherence to recommended lifestyle modifications is influenced by several factors, inadequate knowledge and lack of support have constantly been highlighted as major contributing factors [12-17]. Therefore, there is a need for educational interventions to assisst patients with hypertension and diabetes in adopting the reccommended lifestyle modifications easily. In most instances, counseling about the reccommended lifestyle modification is done by physicians and nurses as part of their routine clinical care [14]. However, in resource-limited settings, where there is a shortage of health care workers, effectively counseling patients on the reccommended lifestyle modifications poses a challenge [18]. As a result, there is a need to explore other cost-effective strategies to ensure the effective counseling of patients regarding lifestyle modifications. Task-shifting to community health workers (CHWs) has been proven as one such cost-effective and sustainable approach in chronic disease prevention and control, particularly in areas with limited economic and health care resources [15,16,18].

CHWs are voluntary public health workers who are trusted members of the community they serve [17]. They play a crucial role in primary and tertiary prevention of diseases, particularly in low- and medium-income countries. According to the Alma Ata Declaration on Primary Health Care, CHWs are the cornerstone of health promotion, as they facilitate community members' participation in health programs [19]. Overall, CHWs build individual and community capacity to manage chronic conditions by increasing health knowledge and self-sufficiency through a range of activities, such as outreach, community education, informal counseling, social support, and advocacy [20-22]. In Zimbabwe, CHWs primarily provide community-based care, but for many years, their efforts have been focused on home-based care for people living with HIV and tuberculosis, with limited focus on addressing noncommunicable diseases (NCDs) [21]. This shows the need to continuously come up with effective CHW-led interventions for the management of common NCDs.

We have developed a simple CHW health literacy intervention on lifestyle modification, and we have designed a study to evaluate the effects of the intervention among patients with hypertension and diabetes in the city of Harare, Zimbabwe. This paper describes our research design and discusses the rationale of our study. We hypothesize that the intervention will have a positive effect on (1) adherence to recommended lifestyle modifications, (2) adherence to medication, as well as (3) blood glucose and blood pressure levels.

Methods

Study Design

The study is a cluster randomized controlled trial, which will be conducted in the city of Harare in Zimbabwe from June 2023 to January 2024. The design, implementation, and reporting of the study are based on the recommendations from CONSORT (Consolidated Standards of Reporting Trials) statement on cluster randomized controlled trials [23]. The cluster randomized controlled trial will have a 6-month follow-up period and will consist of 1 intervention arm and 1 control arm.

Study Setting

The study will be conducted in 14 primary health care clinics in the city of Harare; these clinics were purposefully selected from a total of 39 health facilities (12 polyclinics, 6 family health services clinics, 15 satellite clinics, and 2 infectious diseases hospitals) in the city. The 14 facilities that have been selected for the study are the ones that offer comprehensive services, including curative services, chronic pain care, maternal and child health services, HIV prevention services, and community health services. These clinics are in the high-density suburbs of the city, with each clinic serving a population of 80,000-100,000 people, the majority of whom are socioeconomically disadvantaged. The 14 health facilities will

XSL•FO
RenderX

be randomly allocated into either the intervention or the control arm. Thus, each study arm will comprise 7 health facilities.

Interventions

The intervention arm will receive the CHW-led health literacy intervention, while the control arm will receive usual care.

CHW-Led Health Literacy Intervention for Lifestyle Modifications

The intervention was designed by the principal investigator (PI), and its development entailed two processes, as follows: (1) conducting a scoping review of the literature on CHW-based interventions for hypertension and diabetes and (2) validating the content through consultations with 10 experts (ie, 3 health promotion officers, 2 nutritionists, 2 medical doctors, 1 Diabetes Association of Zimbabwe official, 1 pharmacist, and 1 nurse). The intervention is based on the constructs of the Health Belief Model [24], and thus, it aims to (1) convey the consequences of the patient's poor adherence to recommended lifestyle modifications, (2) communicate to the patient the list of recommended lifestyle modifications and highlight the benefits, (3) provide assistance in identifying and reducing barriers to adopt the recommended lifestyle modifications, and (4) develop cues to action for the patient.

This intervention consists of face-to-face educational sessions and support visits to patients and will be delivered by trained CHWs. A total of 4 educational sessions will be conducted at either the patient's home or the primary care clinic, through which the patient is routinely monitored. The first session will be held at the clinic on the day of recruitment. The second and the third sessions will be held at either the clinic or the patient's home, as preferred by the patient. The fourth session will be a home visit, where the CHW will visit the patient in their home to provide support and follow-up. After the fourth educational session, the CHWs will continue to make monthly home visits to the patient.

In terms of content, in the first session, the CHW will educate the patient on the recommended lifestyle modifications and the consequences of nonadherence. In the second session, focus will be on the patient's barriers to adopting recommended lifestyle modifications and ways to overcome them. At the end of this session, patients are expected to write down their own plan for lifestyle modifications on a card, which they will then place in a visible location in their home. This will serve as a cue to action. The second session will be highly interactive, compared to the first session. The third and fourth sessions will be supportive and evaluation sessions during which the CHW assesses whether the patient has been following the action plan established in the second session. In the fourth session, which will be conducted at home, available family members will be involved to support the patient, and this will serve as another cue to action for the patient and will also help to build the patient's self-efficacy. Any deviations from the plan will be discussed and ways to correct will be explored. The monthly home visits conducted after the fourth educational session will serve as support visits, where the CHW will continue to reinforce the importance of adhering to lifestyle modifications.

In terms of timing, the first session will be conducted on the day of recruitment, and the second session will be scheduled a week after the first session. The third session will be conducted 2 weeks after the second session, and the fourth session will also be conducted 2 weeks after the third session. A month after the fourth session, the patients will receive monthly home visits at a date and time convenient for them. Each educational session will last 45-60 minutes, while the monthly support visits will last 10-15 minutes.

To ensure that the intervention adheres to the protocol and maintains study fidelity, the CHWs who will deliver educational sessions will undergo a 1-day training; this training will be conducted by the PI, 1 nurse, and 1 health promotion officer from the city of Harare. The CHWs will be given notes on the recommended lifestyle modifications, to which they will refer when conducting educational sessions. All the CHWs participating in the study have been working as CHWs for periods ranging from 5 to 30 years, and upon their initial recruitment as CHWs, they underwent an 8-week training program. They will also receive refresher trainings as needed, in accordance with the guidelines for CHWs in Zimbabwe [21,25].

Usual Care

The usual care for patients with diabetes and hypertension in the city of Harare involves patients coming to the clinic for monthly reviews and medication collection. Patients also receive counseling on medication adherence and recommended lifestyle modifications, particularly on the day when they are diagnosed and start their medication. Although there is no formalized CHW intervention, CHWs are involved in the continuum of care when patients fail to report for their monthly reviews for 3 consecutive months. Additionally, patients may seek consultation with CHWs in their communities, as needed. Table 1 summarizes the interventions that will be implemented in this study.

Table 1. Summary of study interventions.

Component	Control arm (usual care)	Intervention arm (community health worker–led health literacy intervention)
Main components	Health education session on the importance of adhering to medication and lifestyle modifications on the day medication is initiated by a nurse or doctor and monthly drug pickups at local health facilities	Usual care and 4 interactive educational sessions and monthly home visits by community health workers
Theoretical background of educational sessions	None	Health Belief Model [24]
Role of community health workers	Follow-up when the patient misses clinic appointments for 3 consecutive months	Continuous support in the management and control of diabetes and hypertension

XSL•FO
RenderX

Randomization

All 14 targeted health facilities will be randomly allocated to either the intervention or the control arm. Each arm will consist of 7 clinics. The randomization process will be conducted by an official from the city of Harare, from the City Health Department, who will not be part of the study staff. The randomization process will be done using the simple randomization technique, based on computer-generated random numbers. To reduce bias and improve study fidelity, group allocation will be concealed to the data collectors until the completion of baseline data collection.

Inclusion and Exclusion Criteria

All adults aged 18 years and older, with a confirmed diagnosis of hypertension and diabetes, residing within the targeted health facility's catchment area, and capable of providing written informed consent will be eligible for enrollment.

Exclusion criteria will include the following: (1) individuals having hypertension- and diabetes-related complications that cannot be managed in a primary care setting, (2) individuals who are pregnant or planning to become pregnant during the course of the trial, (3) individuals who will not be able to stay within the catchment area of the clinic where they are enrolled for the duration of the trial, and (4) individuals who will not be able to give consent for any reason, such as severe mental health disorders.

Recruitment of Participants

Participants will be recruited by trained research assistants every day of the 1-week recruitment period. The recruitment process will be done concurrently at control and intervention sites. Baseline data will be collected on the day of the recruitment, and research assistants will not be aware of group allocations during the recruitment and the baseline data collection periods.

Outcome Measures

The outcome evaluation for this study will be based on data collected both at baseline and during the postintervention follow-up (after 6 months). Data collection tools will be identical for data collection at both periods and include information on patient's demographics, disease history, lifestyle behaviors, medication use, primary use of health care services, and hospitalizations. Height, weight, waist circumference, glycosylated blood glucose levels, and blood pressure will also be measured.

The primary study outcomes will be blood pressure and blood glucose levels as well as levels of adherence to recommended lifestyle modifications. Other outcomes will include changes in medication adherence and additional health-related outcomes, such as frequency of hospitalization or the occurrence of complications.

Assessment of Primary and Secondary Outcomes

A consolidated interviewer-administered questioner comprising of all measures (as detailed in Multimedia Appendix 1) will be used to collect data. The interviewer-administered questionnaire consists of 5 sections, as follows: section A (sociodemographic characteristics), section B (details of the patient's condition), section C (blood pressure, BMI, and glycosylated hemoglobin [HBA_{1c}] measurements), section D (adherence to lifestyle modifications), and section E (adherence to medication).

Lifestyle Modifications

Patients' levels of adherence to recommended lifestyle modifications will be assessed using self-reported questions adapted from the Hypertension Self-Care Activity Level Effects Scale (H-SCALE) questionnaire. The H-SCALE is a validated self-reported questionnaire for assessing self-care practices for hypertension prevention and control [26]. The questionnaire assesses 5 key recommended lifestyle modifications (ie, low-salt diet, physical activity, smoking cessation, weight management, and abstinence from alcohol) as well as adherence to medication. Table 2 shows how each recommended lifestyle modification will be assessed based on the H-SCALE.

XSL•FO
RenderX

Table 2. Assessment of lifestyle modifications using an interviewer-administered questionnaire adapted from the Hypertension Self-Care Activity Level Effects Scale (H-SCALE).

Recommended lifestyle modification	The WHO[a] recommendation	Assessment method
Weight reduction and management	Maintain normal body weight (BMI 18.5-24.9 kg/m^2)	First, the patient's BMI will be assessed based on the patient's height and weight. All patients with a BMI above 24.9 will be considered as overweight. Second, 10 questions will be used to assess activities undertaken to manage weight through dietary practices, such as reducing portion size, making food substitutions, and exercising to lose weight. Participants who say yes to 5 or more questions will be nonadherent to recommended weight management practices.
Reducing dietary salt intake	Reduce dietary salt intake to less than 2400 mg of sodium per day or less than 6000 mg sodium chloride per day.	A total of 6 questions will be used to assess practices related avoiding salt while cooking and avoiding foods high in salt content. Patients who answer yes to 3 or more questions will be considered as nonadherent to a low salt diet.
Reducing dietary fat intake	Avoid foods high in cholesterol and fat content	A total of 2 questions will be used to assess practices related to avoiding foods high in cholesterol and fat content. Patients who answer yes to any 1 question will be considered as nonadherent to a low fat or cholesterol diet.
Increasing fruit and vegetable consumption	Consume 5 servings (equivalent of 5 tablespoons) of vegetables and 3 servings (equivalent of to at least 3 fruits) of fruits every day.	A total of 2 questions will be asked to assess adherence to fruits and vegetables. Patients who answer yes to any 1 question will be considered as adherent to a high fruit and vegetable diet.
Smoking	Avoid smoking	Smoking status will be assessed by 1 question. All patients who answer yes to the question will be considered nonadherent to nonsmoking recommendations
Moderation in alcohol consumption	Limit alcohol consumption to no more than 2 drinks (eg, 24 oz of beer, 10 oz of wine, or 3 oz of 80-proof whiskey) per day in men and no more than 1 drink per day in women and lighter-weight persons.	Alcohol intake will be assessed using 2 questions. Participants who answer yes to any 1 of the questions will be considered nonadherent to the alcohol recommendation moderation.
Physical activity	Engage in regular aerobic exercises, such as brisk walking for at least 30 minutes per day, for at least 5 days a week.	Physical activity will be assessed by 1 question. Participants who answer yes to the question will be considered as being adherent to the physical activity recommendation.

[a]WHO: World Health Organization.

Hypertension and Diabetes Control

Patient's hypertension and diabetes control will be assessed by blood pressure and HbA_{1c} measurements, respectively. Blood pressure of 140/90 mm Hg or higher will be considered uncontrolled hypertension, while an HbA_{1c} level above 8% (53 mmol/mol) will be considered uncontrolled diabetes [27].

Adherence to Medication

Patients' adherence to medication will be assessed using a widely used and validated tool, the 8-item Morisky Medication Adherence Scale (MMAS-8) [28-31]. The MMAS-8 consists of 8 questions that assess patients' adherence to medication. Patients who score 8 points on the MMAS-8 will be considered to have high adherence, and patients who score 7 and 6 will be considered to have medium adherence; those scoring less than 6 points will be classified as having low adherence.

Other Health Outcomes

Other health outcomes, such as hospitalization and the occurrence of diabetes and hypertension complications, will be assessed from the patients' clinic records.

Sample Size

Based on the recommendations for sample size calculation for cluster randomized controlled trials with a fixed number of clusters [32], a total of 680 participants will be required for the trial. Therefore, the study will comprise 14 clusters, with 49 participants per cluster. The sample size was calculated using the following parameters, obtained from the review of literature: 80% study power, 0.5 effect size, 1 SD, 0.05 coefficient of variation, and 20% lost to follow-up adjustment.

Data Collection and Management

Recruitment of participants started in June 2023. Baseline data were collected during the recruitment of participants. Follow-up data will be collected after 6 months, in January 2024. Data will be collected using the research assistants' smartphones. The questionnaire will be uploaded onto the phones and the REDCap platform will be used for storing and managing the data. The computer system that will be used for storing the data will be password protected so that the data will only be accessible to authorized individuals. Patients will be assigned unique identifying numbers at the beginning of the study and the same number will be used in the follow-up data collection period. Data will be managed according to the International Conference on Harmonisation Guidelines for Good Clinical Practices [33].

XSL•FO
RenderX

To minimize errors, range checks and skip patterns within data entry screens will be used. Data will be backed up on a password-protected external hard drive as well as on Google Drive.

Data Analysis

Data analysis will be performed using the Epi Info (Centers for Disease Control and Prevention) software. The primary analysis will be conducted under the intention-to-treat principle. For individual outcomes, proportions will be compared using the chi-square test, and continuous measures will be compared using 2-tailed *t* tests. Stratified analysis will be conducted to control for confounding and assess the effect modification by demographic variables and medication adherence. The effects of the intervention will be tested by ANOVA, which will allow adjustment for baseline differences between groups. Two-sided *P* values and 95% CIs will be used to determine statistical significance of results.

Ethical Considerations

Permission to carry out the study in the city of Harare clinics was obtained from the City Health Services Director. Ethical clearance was obtained from the University of Zimbabwe's institutional review board, the Joint Research and Ethics Committee (JREC/339/2022). Written informed consent will be obtained from all study participants. Confidentiality of the study participants will be maintained at all stages of the study.

All participants will be treated fairly, and they will not be intentionally subjected to any harm. During the study, all participants who present with any other health education needs that do not result in contamination of the study will be assisted. Those with complications or any other needs beyond the scope of the research team will be referred to appropriate HCWs. The knowledge that will be generated from this study will be disseminated to all pertinent stakeholders using various strategies, such as publications and feedback meetings.

Results

Recruitment of study participants commenced on June 1, 2023, and was completed on July 30, 2023. Baseline data are being collected after participant recruitment, and the final data collection will be completed by January 31, 2024.

Discussion

Expected Findings

Hypertension and diabetes are global health challenges that have placed significant burdens on health care systems in all nations [34]. The burden of chronic NCDs is rapidly increasing worldwide. Nevertheless, many countries, particularly low- and medium-income countries, do not have adequate health care resources to effectively deal with these prevalent health problems. Therefore, there is a dire need for effective interventions to tackle these challenges. These interventions rely on adequate human resources. However, in resource-limited countries like Zimbabwe, there is a shortage of health workers, and they are already overburdened with the management of infectious diseases, such as HIV or AIDS, tuberculosis, and diarrheal diseases. Therefore, task-shifting the counseling responsibilities for patients with chronic NCDs is one of the options that should be considered. The findings from our study will thus add to the body of knowledge needed for the development of interventions to address NCDs in resource-limited settings.

Evidence-based national and international guidelines on managing hypertension and diabetes are well-established, cost-effective approaches, suitable for adoption in resource-constrained settings, but they have not been adequately investigated [8]. Our study offers an opportunity to show the effectiveness of CHWs in addressing the gaps in the management of hypertension and diabetes. The use of CHWs to address the shortage of professional health care workers in the management of hypertension, diabetes, and other chronic NCDs has been widely recommended [35]. Evidence from several low- and medium-income countries indicates that this is a feasible and cost-effective strategy [36-38]. However, there is an information dearth regarding such evidence, specifically for the Zimbabwean setting, and particularly, in the urban setup. To the best of our knowledge, our study will be the first to assess the effectiveness of CHWs in improving the much-needed lifestyle modification among patients with hypertension and diabetes in the city of Harare. The findings from our study will provide evidence on the feasibility and effectiveness of a simple intervention delivered by the CHWs in resource-constrained areas. Overall, our study is vital to the achievement of Sustainable Development Goal target 3.4, which aims to reduce premature mortality from NCDs by one-third [39].

Strengths and Limitations

The strengths of our study include CHWs who are already integrated in the Zimbabwean primary health care system. The CHWs have prior experience in disseminating health education on various health topics, particularly prevention of diarrheal diseases and malaria, which are prevalent in the country. Additionally, the CHWs are routinely involved in follow-ups with patients who have hypertension and diabetes, ensuring they do not miss monthly checkups. Therefore, if successful, our intervention will modify and strengthen community-based management of hypertension and diabetes. Unlike most of the CHW-based interventions being implemented in other low- and middle-income countries, our intervention is based on a tested and tried health behavior model, the Health Belief Model [24]. Therefore, we envisage that the intended behavior change in the adoption of recommended lifestyles will be successful. Moreover, our intervention will be innovatively addressing some of the most challenging barriers to the management of chronic NCDs, such as human resources. Hence, if successful, this intervention can be potentially scaled up to the entire nation.

Nonetheless, there are weaknesses in our study, mainly emanating from the cluster randomized controlled trial design. First, our study does not involve blinding of study participants. Lack of blinding is one of the weaknesses inherent in cluster randomized controlled trials that include behavioral interventions. However, to reduce bias associated with lack of blinding, there will be partial blinding of data collectors during the collection of baseline data. The data collectors will not know

XSL•FO
RenderX

the arm to which each clinic will belong. In addition, there is a possibility of information sharing among participants in the intervention and control group, since the suburbs in Harare are within close proximities. To limit the sharing of information, participants in the intervention group will receive a detailed explanation of the study's importance from the PI. There is also a possibility of social desirability bias in assessing lifestyle modifications. Participants may report what they perceive as the desired behavior rather than their actual behavior. However, the study will assess overall changes in blood glucose and hypertension levels as well as BMI, which are more objective outcome measures.

Conclusions

Our trial aims to evaluate the effects of a CHW-led health literacy intervention for lifestyle modifications among patients with diabetes and hypertension in Harare, Zimbabwe. Findings from our study will provide reliable evidence on the effectiveness of a simple community-based intervention in the management and control of the two most common NCDs in Zimbabwe. In summary, our study will contribute to the much-needed body of knowledge on the effectiveness of using CHWs in the management of chronic NCDs in resource-limited countries.

Acknowledgments

We would like to thank the city of Harare's City Health Director for granting permission to carry out the study in the city of Harare's health facilities. We would also like to thank our colleagues from the Family Medicine, Global and Public Health unit, for their peer review of the initial study proposal. We are grateful to all the participants who will be enrolled in this study.

Abstract

Background: Systemic lupus erythematosus is a chronic, multisystem, inflammatory disease of autoimmune etiology occurring predominantly in women. A major hurdle to the diagnosis, treatment, and therapeutic advancement of this disease is its heterogeneous nature, which presents as a wide range of symptoms such as fatigue, fever, musculoskeletal involvement, neuropsychiatric disorders, and cardiovascular involvement with varying severity. The current therapeutic approach to this disease includes the administration of immunomodulatory drugs that may produce unfavorable secondary effects.

Objective: This study explores the known relationship between the autonomic nervous system and inflammatory pathways to improve patient outcomes by treating autonomic nervous system dysregulation in patients via noninvasive vagus nerve stimulation. In this study, data including biomarkers, physiological signals, patient outcomes, and patient quality of life are being collected and analyzed. After completion of the clinical trial, a computer model will be developed to identify the biomarkers and physiological signals related to lupus activity in order to understand how they change with different noninvasive vagus nerve stimulation frequency parameters. Finally, we propose building a decision support system with integrated noninvasive wearable technologies for continuous cardiovascular and peripheral physiological sensing for adaptive, patient-specific optimization of the noninvasive vagus nerve stimulation frequency parameters in real time.

Methods: The protocol was designed to evaluate the efficacy and safety of transauricular vagus nerve stimulation in patients with systemic lupus erythematosus. This multicenter, national, randomized, double-blind, parallel-group, placebo-controlled study will recruit a minimum of 18 patients diagnosed with this disease. Evaluation and treatment of patients will be conducted in an outpatient clinic and will include 12 visits. Visit 1 consists of a screening session. Subsequent visits up to visit 6 involve mixing treatment and evaluation sessions. Finally, the remaining visits correspond with early and late posttreatment follow-ups.

Results: On November 2022, data collection was initiated. Of the 10 participants scheduled for their initial appointment, 8 met the inclusion criteria, and 6 successfully completed the entire protocol. Patient enrollment and data collection are currently underway and are expected to be completed in December 2023.

XSL•FO
RenderX

Conclusions: The results of this study will advance patient-tailored vagus nerve stimulation therapies, providing an adjunctive treatment solution for systemic lupus erythematosus that will foster adoption of technology and, thus, expand the population with systemic lupus erythematosus who can benefit from improved autonomic dysregulation, translating into reduced costs and better quality of life.

Introduction

Background

The origin of autoimmune disease is a disruption of immune tolerance of self-antigens thought to occur in genetically susceptible individuals after exposure to environmental triggers. Possible environmental factors that predispose to autoimmunity include exposure to infectious agents, ultraviolet light, dietary components, chemicals, xenobiotics, toxins, and stress, as well as reduced exposure to factors that protect from the development of autoimmune diseases. Autoimmune diseases can be systemic or can affect specific organs or body systems including the endocrine system, gastrointestinal system, liver, neurological system, and musculoskeletal system and connective tissue [1].

Systemic lupus erythematosus (SLE) is a chronic systemic autoimmune disorder that commonly affects the skin, joints, kidneys, and nervous system. Abnormal activation and processing of cell death signals by the immune system trigger the release of nuclear debris from apoptotic and necrotic cells and stimulate the production of antinuclear antibodies (for example, anti-Ro and anti-DNA), with subsequent inflammation, organ damage, and pathology [2].

Many patients with SLE experience flares of disease activity interspersed with quiescent periods. The current understanding of the factors driving the different phenotypes and its pathogenesis in SLE is limited and directly affects treatment. The current therapeutic approach to SLE most commonly includes the administration of antimalarials, immunosuppressants, and biological agents. These treatments have allowed great progress to be made, and, currently, SLE-related mortality is 10% within 10 years, compared with the 1960s, when the mortality was 50% within 3 years, according to an analysis of a multisite, international SLE cohort [3]. However, these current medication options for SLE produce secondary effects, such as ocular toxicity, renal damage, risks of infections, hematological toxicities, gastrointestinal events, ovarian toxicities, and in particular, comorbidities associated with the long-term adverse effects of glucocorticoids in the musculoskeletal, cardiovascular, peripheral vascular, ocular, and metabolic domains [4].

A major hurdle to the treatment of autoimmune diseases is their heterogeneous nature. SLE is referred to as “the great imitator” because patients can experience a wide range of symptoms with varying severity [5] that appear to belong to other diseases. The heterogeneity of SLE presents challenges not only with diagnosis but also with treatment and therapeutic advancements. Broadly, manifestations of SLE include fatigue, fever, weight changes, lupus nephritis, and complications involving the following systems: musculoskeletal, gastrointestinal, pulmonary, cardiovascular, cutaneous, neuropsychiatric, hematological, and ocular.

The autonomic nervous system (ANS) is mainly composed of 2 primary branches: the sympathetic nervous system (SNS) and parasympathetic nervous system (PNS). The ANS exhibits complex central control and plays a critical role in mediating interactions between the nervous and immune systems and coordinates the interplay among cells, tissues, and organs throughout the body to maintain homeostasis via its widespread innervation of the glands, smooth muscles, and heart [6].

In many inflammatory diseases, dysautonomia manifests as an imbalance in the activity and reactivity of the SNS and PNS [7]. Increased sympathetic nerve outflow has been shown to activate pro-inflammatory cytokines and produce reactive oxygen intermediates, processes strongly implicated in the pathogenesis of SLE [2]. SLE was found to have SNS predominance or PNS dysregulation owing to decreased heart rate variability in patients with SLE. The prevalence of autonomic dysfunction ranges widely from 6% to 93% in patients with SLE [8]. Autonomic imbalance is related to an increased risk of developing cardiovascular disease—a major cause of morbidity and mortality in patients with SLE. Therefore, therapeutic strategies aimed at rebalancing the ANS may provide improved outcomes in patients with SLE.

Prior Work

Vagus nerve stimulation (VNS) stimulates the tenth cranial nerve, the longest nerve of the organism that links the central nervous system and body by innervating major organs, such as the heart, lungs, and gastrointestinal tract. The vagus nerve is a major component of the PNS that enables bidirectional communication between the brain and different organs of the body by transmitting and exchanging sensory and motor information. The vagus nerve has been shown to play a crucial role in regulating inflammation [9] by activating the cholinergic anti-inflammatory pathway, which reduces pro-inflammatory cytokine production, inhibits pro-inflammatory activity of immune cells, and promotes the release of anti-inflammatory molecules [10]. This process is mediated by the release of acetylcholine, which binds to alpha-7 nicotinic acetylcholine

XSL•FO
RenderX

receptors on immune cells, such as macrophages and T-cells, and inhibits their pro-inflammatory activity [9]. This vagus nerve–mediated pathway has been shown to have potential therapeutic applications for a range of inflammatory disorders, including rheumatoid arthritis, inflammatory bowel disease, and sepsis [11-13].

Although invasive VNS has shown positive results for the treatment of multiple diseases [11-14], VNS device implantation is associated with multiple complications, such as hoarseness, bradycardia, coughing, shortness of breath, tingling, syncope, paresthesia, muscle pain, asystole, delayed arrhythmias, sleep apnea, and surgical trauma [15-17]. To avoid implant‐related complications, noninvasive VNS (nVNS) devices that stimulate the vagus nerve through transcutaneous stimulation were developed. nVNS has shown positive therapeutic results with no significant adverse events reported for a large collection of diseases [18-28].

Varying the waveform parameters of nVNS can dramatically change the therapeutic outcome. High-frequency nVNS has been shown to stimulate different vagal fibers than those stimulated by low‐frequency nVNS, resulting in different therapeutic effects [26,28-32]. The pulse width may have a different effect on patients; a short pulse width may produce significantly less overall activation in the human brain than long pulse widths. The stimulation intensity also plays an important role and can be delivered at the subsensory, sensory, or maximal tolerance levels. Other nVNS parameters, such as the output current and signal ON and OFF times, have unknown therapeutic effects. In addition to variations in the therapeutic response, the physiological response to a given nVNS configuration can suffer from significant inter and intrapatient variability. As a result, the optimal nVNS parameters for patients with SLE are unknown. To optimize the nVNS parameters for SLE treatment, computational models can be used to study complex physiological interactions of the vagus nerve and to predict therapeutic outcomes to different nVNS configurations. Computational models have been developed for invasive VNS [33-38] and nVNS [39-41]. However, these systems have yet to be put into the context of SLE [10].

Hypotheses and Aims

The discrepancy that exists in the use of nVNS parameters requires investigation to enable the appropriate administration of nVNS to patients with autoimmune diseases, such as SLE, for the improvement of ANS dysregulation. Therefore, the hypotheses of this study are as follows:

1. ANS dysregulation can be improved through the application of personalized nVNS.
2. At postintervention, the treatment groups (active and sham nVNS) will have different outcomes and scores.
3. Improved ANS function in patients with SLE can lead to better patient outcomes and increased quality of life.

Based on this premise, the aims of this clinical trial are as follows:

1. Collect data related to biomarkers, physiological signals, patient outcomes, and patient quality of life.
2. From the collected data, propose a computational model that can (1) identify the biomarkers and physiological signals related to SLE activity, (2) understand how the identified biomarkers and physiological signals change with different nVNS frequency parameters, and (3) include a decision support system with integrated noninvasive wearable technologies for continuous cardiovascular and peripheral physiological sensing for adaptive, patient-specific optimization of the nVNS frequency parameters in real time.
3. Validate the findings of Aranow et al [28], who found that the use of nVNS reduced pain and fatigue in patients with SLE.

Methods

Participants and Recruitment

Patients are recruited from the autoimmune disease outpatient clinics of the Hospital Clínic de Barcelona and Hospital Universitari Mútua Terrassa for a multicenter, national, randomized, double-blind, parallel-group, placebo-controlled, outpatient study. To compare our results with those of Aranow et al [28], a minimum of 18 adult patients (6 per study arm) is required. There is growing evidence that sex affects the pathophysiology, incidence, prevalence, development, and response to therapy in many diseases. In SLE, 90% of all diagnoses are in women [42], who are most commonly affected by clinical flares between the ages of 15 years and 44 years, or during childbearing years. Due to this disproportionality between sexes, this study aims to have a women:men ratio of 9:1, in keeping with SLE prevalence between sexes. The inclusion and exclusion criteria are summarized in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

1. Age ≥18 years
2. Diagnosis of systemic lupus erythematosus (SLE; defined by the American College of Rheumatology or Systemic Lupus International Collaborating Clinics [SLICC] criteria)
3. Musculoskeletal pain ≥4 on a nonanchored, 10-cm visual analog scale (VAS)
4. British Isles Lupus Assessment Group (BILAG) C on the musculoskeletal domain of the BILAG 2004
5. If on corticosteroids, stable dose of ≤10 mg/day (prednisone or equivalent) for at least 28 days before baseline
6. If on background immunosuppressive treatment, stable dose for at least 28 days before baseline
7. Able and willing to give written informed consent and comply with the requirements of the study protocol

Exclusion criteria

1. Treatment with rituximab within 1 year of baseline
2. Treatment with cyclophosphamide within 2 months of baseline
3. Expectation to increase steroid or immunosuppressive treatment
4. Antiphospholipid syndrome
5. Fibromyalgia (as defined by a score >13 on the fibromyalgia symptom scale)
6. Chronic fatigue syndrome
7. Treatment with an anticholinergic or sympathomimetic medication, including over-the-counter medications
8. Implantable electronic devices, such as pacemakers, defibrillators, hearing aids, cochlear implants, or deep brain stimulators
9. Joint replacement within 60 days prior to study enrollment or planned within the course of the study
10. Any planned surgical procedure requiring general anesthesia within the course of the study
11. Intra-articular cortisone injections within 28 days of the start of study
12. Chronic inflammatory disorders apart from SLE affecting the joints
13. Investigational drug or treatment during the 28 days or 7 half-lives of the investigational drug prior to the start of study drug dosing (day 0), whichever is the greater length of time
14. Active infection including hepatitis B, hepatitis C, or HIV at baseline due to high prevalence of neuropathy
15. Any condition that, in the opinion of the investigator, would jeopardize the participant's safety following exposure to a study intervention
16. Pregnancy or lactation
17. Hemoglobin <9.0 gm/dL (according to the most recent complete blood count)
18. Comorbid disease that may require administration of corticosteroid
19. Inability to comply with study and follow-up procedures
20. Known cardiac arrhythmia, severe cardiac disease, or neurodegenerative disease
21. Peripheral or autonomic nervous system involvement, including SLE-related neuropathies, toxic polyneuropathies, metabolic neuropathies (including diabetes)
22. Previous experience with vagus nerve stimulation devices

Screening

The screening period is set at 4 weeks and begins when the patient signs the informed consent form, which includes a full description of the study and procedures involved, patients' rights and responsibilities, and alternative treatments that are available if the patient does not decide to participate in the study. During the screening period, the investigators must confirm that the patient meets all inclusion criteria and no exclusion criteria for the study (see the Participants and Recruitment section). Eligible patients are randomized at week 0.

Patients who are registered for this trial may have one or more active symptoms of lupus but the investigators believe that their condition is stable enough to participate. This trial design permits patients to continue their regular immune suppressive therapies at stable doses, but they are not allowed to receive additional corticosteroids during the short duration of the protocol, even if they receive a sham intervention.

Intervention

At the second visit (week 0, baseline), after all assessments are completed and baseline laboratory samples are obtained according to the schedule of activities (see the Follow-Up

XSL•FO
RenderX

section), patients are randomly assigned (1:1:1) to active (1 Hz or 30 Hz) or sham (placebo) nVNS. The rationale underlying the choice of 1 Hz and 30 Hz (minimum and maximum values of the nVNS treatment device) is based on the discrepancies found in the literature regarding the choice of a frequency value, as well as previous findings indicating that high and low frequencies of nVNS treatment stimulate different vagal fibers. The effect of VNS in epilepsy and depression is thought to be mediated through the activation of vagal afferent fibers via high-frequency (20-30 Hz) stimulation, whereas the activation of the cholinergic anti-inflammatory pathway has been found to be mediated through vagal efferent fibers involving low‐frequency (1-10 Hz) stimulation [29]. A study by Borovikova et al [30] found that VNS at 1 Hz frequency for 20 minutes was effective for the preferential recruitment of efferent parasympathetic fibers. Other reports have also shown that low-frequency (5 Hz) VNS is able to activate vagal efferent fibers [31]. In various studies of nVNS in inflammatory diseases, the amplitude was generally set individually to a constant tingling, nonpainful sensation. In these same studies, interestingly, 25 Hz [19,21,24,26] was the most frequently studied frequency, while other frequencies used were 100 Hz [23], 30 Hz [22], 5 kHz [32], and 1 Hz [12,25]. Only 2 studies have explored the low-frequency range to stimulate the vagal efferent fibers and thus, the cholinergic anti-inflammatory pathway. Straube et al [26] compared 25 Hz with 1 Hz in the treatment of chronic migraines and found a significantly larger reduction in headache days in the 1 Hz group.

Patients are blinded to the treatment allocation and are requested to refrain from discussing the details of their treatment with other patients, physicians, and clinic staff. The clinical coordinators are also blinded to the treatment allocation, and the responsible engineer instructs the patients on the proper use of the device. The study personnel have been designated to address the patient's questions and concerns as well as to record any side effects related to the use of the device.

Active or sham nVNS is administered for 5 minutes during 5 consecutive days in a similar schedule to the treatment followed by Aranow et al [28] (5 minutes during 4 consecutive days). Clinical assessments and laboratory samples are obtained at scheduled visits according to the schedule of activities. During the treatment period, in addition to randomized treatment, patients also continue their usual medication regimen for SLE, including background standard-of-care therapy (see the Participants and Recruitment section for more details).

nVNS is administered using a Parasym device (Parasym Ltd). The Parasym device is compliant with the relevant standards contained in the Medical Device Directive 93/42/EEC. The Parasym Device is CE marked and available for purchase by individuals of the European Union.

According to the available literature, adverse effects are scarce. Although a low incidence of skin irritation has been reported from using the Parasym device, no serious adverse events have been reported in the literature. In a systematic review, Redgrave et al [43] analyzed data from 1322 participants (across 51 studies) who received nVNS. This review found that only 2.6% of participants discontinued use due to side effects, and the most common side effect reported was skin irritation at the stimulation site that typically ceased shortly after use. The low rate of cardiac arrhythmias (0.3%) is noteworthy because cardiac arrhythmias are recognized as early and late complications of invasive VNS.

Follow-Up

Patients who complete the treatment period of the study will then attend weekly follow-up evaluations for 1 month. Subsequently, if the values of the measured biomarkers and scales of activity do not return to baseline levels ($P<.05$), additional follow-up evaluations will be performed at months 2 and 3. Patients who discontinue study treatment early will have the same posttreatment follow-up visits, unless the patient withdraws informed consent.

Primary and Secondary Outcomes

The primary outcome of this study will be the evaluation of the causal relationship among the waveform frequency of nVNS, physiological signals, and therapeutic effect of the treatment. Therefore, we will analyze clinical and physiological changes in patients with SLE after nVNS using different waveform frequency parameters between the exploratory study at the first visit (baseline) and 30 days after the first nVNS treatment session. The secondary outcome of this study will be a comparison between our results and those of Aranow et al [28]. Both outcomes fall under the overall objective of the Modelling and Control of Non-invasive Vagus Nerve Stimulation for Autoimmune Diseases (VaNeSA) project, aimed at developing a VNS platform with an integrated VNS decision support system, including an nVNS device and portable physiological sensors that will optimize nVNS waveform parameters to maximize the therapeutic effect and minimize unwanted side effects.

The therapeutic effect and side effects will be measured using clinical, neurophysiological, and analytical tests divided into 3 sections: serum biomarkers (Textbox 2), clinical activity indices (Textbox 3), and ANS assessment (Textbox 4).

Furthermore, the addition of continuous cardiovascular and peripheral physiological sensing offers a convenient tool for this investigation owing to the intimate relationship of the vagus nerve with the heart and peripheral physiology and the ubiquity of noninvasive wearable technologies. This will allow the capture of real-time information regarding the state of the patient and their response to nVNS, which will facilitate real-time predictions of physiological responses to nVNS. Physiological signals are evaluated using a Fitbit Charge 5 activity band (Textbox 5).

Textbox 4. Autonomic nervous system evaluation.

1. Cardiovagal evaluation: continuous electrocardiogram heart rate changes during deep breathing, Valsalva maneuver, and postural changes
2. Sympathetic evaluation: beat-to-beat blood pressure changes to Valsalva maneuver and postural changes
3. Heart rate variability (HRV): continuous electrocardiogram recorded at rest for 5 minutes for HRV analysis
4. Composite autonomic symptom scale 31 (COMPASS-31)

Textbox 5. Physiological signals measured with a Fitbit Charge 5.

1. Heart rate: heart rate and heart rate variability value every 5 minutes
2. Physical activity: steps, distance, and elevation every 5 minutes
3. Sleep: daily sleep duration and sleep quality

Schedule of Activities

In total, between 10 and 12 visits are scheduled. The activities of each of these visits are detailed in Table 1. In the first visit (V1), the screening session, each patient is provided with a Fitbit Charge 5 activity band and assessed for 90 minutes. The next treatment visits (V2-V6) will last between 15 minutes and 30 minutes. We will then conduct 2 telephone follow-ups (V8 and V9) of up to 15 minutes each. Subsequently, early (V7) and late (V10) posttreatment follow-ups will be conducted for 30 minutes. Finally, if the measured biomarker values and activity scales do not return to baseline levels ($P<.05$), a very late posttreatment follow-up of 1 or 2 visits (V11 and V12), each lasting 30 minutes, will be performed.

Statistical Analysis

The Wilcoxon rank sum test will be used to compare the change in endpoints from baseline to day 7 and from baseline to day 21 in participants receiving active and sham nVNS. Spearman rank-order correlation will be used to assess the potential associations between endpoints. False discovery rate control will be used to mitigate the problem of a false positive rate error. Statistical analysis will be performed using the SciPy Python-based library.

Ethics Approval

This study is being conducted in compliance with the Declaration of Helsinki (Fortaleza, Brazil, October 2013). The study is being carried out in accordance with the protocol and with the relevant legal requirements, Law 14/2007 of July 3, on Biomedical Research. The study was approved by the Clinical Research Ethics Committee of the Hospital Clínic of Barcelona (protocol identifier: HB/2021/1286; approved March 14, 2022). Informed consent is obtained from all participants invited to participate in the study prior to the baseline visit. Data will be processed in accordance with ethical principles that guarantee the anonymity of the participants.

Results

The study is supported by the Spanish Ministry of Science and Innovation through grant PID2020-117171RA-I00 funded by MCIN/AEI/10.13039/501100011033 in July 2021. The data collection began on November 19, 2022. The clinical study staff have been engaged in activities including enrollment and data collection. As of March 1, 2023, a total of 10 participants had been admitted for their first appointment, 8 had met the inclusion criteria, and 6 had completed the treatment. Recruitment and data analysis are expected to be completed in December 2023.

Discussion

Overview

This study belongs to a collection of studies pertaining to the VaNeSA project. The overall goal of the VaNeSA project is to develop an nVNS platform with nVNS, an integrated nVNS decision support system, and physiological wearable sensors that will optimize nVNS waveform parameters to maximize the therapeutic nVNS effect while minimizing unwanted side effects.

This clinical trial is the first conducted in the VaNeSA project that will analyze the physiological signals, biomarkers, and clinical outcomes to determine the most effective measures to monitor, optimize, and personalize nVNS in patients with SLE. The ultimate aim of this study is to confirm that the application of personalized nVNS will improve ANS dysregulation, a possible driver of autoimmune disease, leading to better patient outcomes and quality of life. After this study, computational models to describe and predict the impact of nVNS on the ANS and clinical outcomes for patients with SLE will be created, implemented, and validated. The goal of developing computational models is the objective not only of this study but also of the framework project (VaNeSA project) in which there will be more clinical experimentation with other related diseases and other sets of nVNS parameters. The results obtained in this clinical trial will serve to determine the most appropriate approach for obtaining these models, but the idea is to condition the physiological responses of the treatment to the therapy administered so that we can develop a first prototype to induce the application of specific stimulation parameters to each patient. Although the creation of computational models depends on the overall quality of the final results, the initial plan is to use modelling algorithms using artificial intelligence techniques. We plan to implement a decision tree–based methodology since it seems to be one of the best alternatives, as their conditional

XSL•FO
RenderX

control statements decompose complex data into more manageable parts. The validated computer models, a decision support system, and wearable physiological sensors will be integrated into an nVNS platform allowing for the optimization and personalization of nVNS therapy in real time. Finally, the nVNS platform will be tested and validated.

Limitations and Strengths

This randomized, double-blinded, placebo-controlled clinical trial is one of the first studies delving into the impact of nVNS on clinical outcomes for patients with SLE. The design is a parallel study used to ensure optimal blinding and adjust to the time constraints of the study. However, this study design is weaker than that of a crossover design. The nVNS sessions are being performed by the hospital staff, potentially limiting the willingness of patients to enroll in the study due to the frequency of required hospital visits but ensuring correct treatment delivery and safety (sham treatment, stimulation intensity, localization, and duration). Evidence from this trial will have a limited effect on the knowledge of the optimization of the nVNS parameters because only the frequency domain is evaluated while the remaining characteristic parameters of the nVNS will remain unknown. The small sample size may also pose a limitation in terms of sample representation and statistical power. Finally, in comparison with prior research, our study involves a comprehensive number of biomarkers and activity indices, including ANS and PNS evaluations, that will provide extensive baseline characterization and explore dose-response characteristics of nVNS, allowing nVNS to be contextualized for clinical use.

Conclusions

This study addresses the potential use of nVNS as an adjunctive treatment for SLE. The goal of the study is to provide information on the use of nVNS in SLE and move toward a patient-tailored therapeutic solution that can encourage the adoption of VNS technologies and thus expand the SLE population that can benefit from improved autonomic dysregulation, resulting in reduced costs and improved patient outcomes and quality of life.

Acknowledgments

This work was supported by the Spanish Ministry of Science and Innovation through grant PID2020-117171RA-I00 funded by MCIN/AEI/10.13039/501100011033.

Data Availability

Deidentified participant data will be shared upon reasonable request after completion of the trial and publication of the study results. Data will be available for use if the request is approved by the appropriate institutional review board and the Trial Steering Committee and a signed data access agreement is in place.

Conflicts of Interest

None declared.

Abstract

Background: During the hospitalization period, it is possible to observe considerable changes in the vital parameters of patients, which may require emergency interventions or intensive treatment. The alteration of signs and symptoms that lead to physiological instability that can worsen the clinical picture with progression to shock, respiratory failure, or cardiorespiratory arrest is currently defined as clinical deterioration. Identifying signs of clinical deterioration at an early stage can lead to substantial decreases in mortality rates, the need for emergency interventions, and unscheduled treatments in intensive care units. Identifying and appropriately referring patients who show signs of clinical deterioration can be facilitated by applying early warning systems that provide rapid responses. The nursing team is usually the first to identify clinical changes in patients. Although the literature demonstrates that early recognition of clinical deterioration is the key to early intervention and leads to better outcomes, we only sometimes pursue the most appropriate intervention.

Objective: This study aims to implement and evaluate an evidence-based professional training program designed for nurses and coordinated by a nurse using the "just-in-time" methodology and the National Early Warning Score 2 (NEWS2) to assess the risk of early clinical deterioration and appropriate referral in inpatient units of a public university hospital in southeastern Brazil.

Methods: This intervention protocol is structured according to the recommendations of the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) Declaration 2013. The type of training to be offered, "Just-in-Time Training," consists of a teaching modality that facilitates the delivery of a time-based and work-based education, with greater emphasis on providing on-the-job learning as needed. A qualitative stage will also be conducted through focus groups and interviews with nurses to verify the factors that influence the professional practice related to the early evaluation of the clinic. A script of previously tested questions will guide and standardize the different groups. The data will define the intervention's elements: the strategy, the type of training, the location, the teaching methodology, and the teaching material.

Results: The study has received authorization from the ethics committee, and participants will be recruited in July 2023. Data collection should be completed in October of the same year. The results obtained at the end of this research will be shared with the participating nursing team through the presentation of reports. In addition, the research results will be submitted to scientific journals and presented at international scientific conferences.

Conclusions: This study will support nurses and possibly other clinicians to improve their approach to early recognition of clinical deterioration in patients.

nursing; hospitalization; clinical deterioration; patient safety; early warning score; education

Introduction

A patient's clinical deterioration originates from physiological changes detected by monitoring vital signs, which can indicate early or potentially critical patients who need special monitoring in the wards [1,2]. Such changes can indicate a greater probability of cardiorespiratory arrest and lead to unplanned hospitalizations in intensive care units and death [3]. If there is a delay in the identification of these patients, it will result in delayed intervention and, therefore, in the increase of hospital mortality. The early identification of alterations in vital signs can facilitate greater efficiency in the care provided to the patient because the reduction in morbidity leads to a reduction in the length of hospital stays and lower expenditure on health, which can guarantee a better quality of care [1,4].

The nursing team is usually the first to identify clinical changes in patients. The nursing team comprises a diverse group of health care professionals collaborating to deliver patient care. This team typically includes registered nurses, licensed practical nurses or licensed vocational nurses, certified nursing assistants, nurse practitioners, nurse managers or supervisors, clinical nurse specialists, and additional support staff. These professionals possess specialized skills and training, allowing them to provide comprehensive care, administer treatments, monitor patient conditions, and fulfill administrative responsibilities. The composition of the nursing team may vary based on health care settings and specific patient needs.

The evaluation of vital signs is a routine activity of the nursing team in the hospital and is of extreme importance as it tracks the evolution of the clinical picture and the individual's health and can predict clinical deterioration. Intrinsically, nursing is linked to patient surveillance and monitoring changes that may indicate warning signs, and these factors are interlinked with survival outcomes in cases of in-hospital cardiorespiratory arrest. Therefore, the nursing team can predict these events early to increase patient safety and prevent this clinical deterioration [5].

Early recognition of clinical deterioration is the key to early intervention and can lead to better patient outcomes [5]. Early warning systems are designed to detect changes and activate rapid response teams to minimize complications resulting from the degradation of the patient's clinical condition before reaching a critical state of complex regression, which can be fatal [6]. Various systems have been described in the literature that use simple physiological parameters and routine assessments performed daily by nurses to manage the risk of degradation of the patient's clinical status by adapting the level of care they need [7]. These systems are used to identify and respond efficiently to the needs of patients in an acute situation or phase [8].

Considering the PICOT (Population, Intervention, Comparison, Outcome, and Time) approach [9], this training was designed with nurses working in a hospital setting as the population of interest, the implementation of a professional training program for early clinical deterioration risk assessment as the intervention, the standard practice without the professional training program (ie, pretraining and posttraining) as the comparison, the improved identification and appropriate referral of patients showing signs of clinical deterioration as the outcome, and before and after the implementation of the professional training program as the timeframe. Therefore, the following research question guided the development of this training: "In nurses working in a hospital setting, does the implementation of a professional training program for early clinical deterioration risk assessment (compared to standard practice without the program) improve the identification and appropriate referral of patients showing signs of clinical deterioration?"

Considering this research question and given the options available in the literature of instruments that aim to facilitate the assessment of clinical deterioration, we decided to develop a training project for nurses to assess early clinical deterioration in a university hospital through the use of an alert scale designed for early identification of signs of clinical deterioration in patients. This protocol aims to implement and evaluate an evidence-based professional training program designed for nurses and coordinated by a nurse using the "just-in-time" methodology and the National Early Warning Score 2 (NEWS2) to assess the risk of early clinical deterioration and appropriate referral in inpatient units of a public university hospital in southeastern Brazil.

Methods

This study was structured according to the recommendations of the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) Declaration 2013 (Multimedia Appendix 1) [10].

Trial Design and Settings

A quasi-experimental study of the type before and after, with a single arm, will be conducted with all nurses from inpatient units of a tertiary-level university hospital in the interior of the southeast of São Paulo to implement a training program to assess the risk of early clinical deterioration. This study aims to demonstrate causality between the proposed intervention and the nurses' ability to use the NEWS2 tool to assess the patient's clinical deterioration and provide appropriate referrals. Quasi-experimental designs are often used when assigning participants randomly to different groups is not feasible or ethical. This allows for intragroup comparison of outcomes (ie, comparing the pretraining and posttraining results in the same group). In this study, having only a subset of the staff receiving the training would not be feasible. Although a quasi-experimental design does not offer the same level of control as a randomized controlled trial, it can provide valuable

XSL•FO
RenderX

insights into the effects of the training program because it offers a real-world evaluation of the intervention's impact within the specific setting and considers the practical constraints of implementation.

The trial was registered in the Brazilian Registry of Clinical Trials (ReBEC) with the number RBR-5hq9y3k. For the design of the method, the limits of the Guideline for Reporting Evidence-Based Practice Educational Interventions and Teaching (GREET) [11] were respected.

Eligibility Criteria

All assisting nurses allocated to the university hospital's clinical and surgical hospitalization units in the interior of São Paulo will be included. During the data collection period, nurses who are inactive or on health or maternity leave or vacation will be excluded because they cannot be invited to participate in the training due to labor legislation issues.

Intervention

The type of training to be offered, known as "Just-in-Time Training" (JITT), consists of an education modality that facilitates the delivery of time-relevant and work-based education, with a greater emphasis on teaching provision at work as needed [12]. JITT is a training approach that focuses on providing relevant and specific information to individuals when they need it to perform a task or solve a problem and is designed to provide immediate and targeted support, allowing nurses to acquire knowledge or skills quickly and efficiently. JITT is often used in contexts where time is limited and there is a need for spontaneous and on-demand learning. The effectiveness of the JITT method stems from several factors, such as punctuality, contextualization, and flexibility. By providing nurses with the correct information at a convenient time and place, JITT increases learning efficiency, minimizes continuums, and empowers individuals to quickly acquire the knowledge and skills they need to perform effectively in their specific tasks or problem-solving scenarios [12].

The JITT approach to recognizing and responding to patient deterioration has theoretical and educational relevance in its design. Education takes place in the clinical setting using real meetings with patients to guide the content. This approach is closely aligned with learning through a theory of practice, as the literature recommends [13]. In this perspective, workplaces are viewed as learning environments; optimizing the experiences provided by health workplaces, increasing learning potential, and promoting the involvement of workers can improve workers' ability to respond to future occupational challenges.

The training program developed for nurses was based on the intervention mapping [14] protocol that describes the path from problem identification to problem solution or mitigation. Each of the six stages of intervention mapping comprises several tasks, integrating theory and evidence. Completing tasks in one step creates a product that drives the subsequent step. Completing all steps serves as a model for designing, implementing, and evaluating an intervention based on theoretical, empirical, and practical information.

Needs Assessment: A Theoretical and Experiential Approach

The needs assessment will be gathered by reviewing the literature on nurses' knowledge and use of early deterioration tools. To use the experiential approach, a qualitative step will be conducted through the realization of focus groups and interviews with nurses from inpatient units to verify the factors that influence professional practice related to the early assessment of clinical deterioration. A script of previously established questions will guide and standardize the different groups (Textbox 1). The invitation to nurses will be made through a direct approach by verbal invitation from the researcher herself.

The interviews and focus groups will be based on a pre-established script (Textbox 2). All groups will have their audio recorded for future analysis, with the saturation criterion as a parameter for the decision to stop collection. The data collected in this phase will be evaluated through content analysis.

Textbox 1. Presentation of the project in the focus groups.

- Team presentation: 3 nurses.
- Aims: Invite nurses to participate in a project offering training on early assessment of clinical deterioration.
- Planning: After agreeing and signing the consent form, the nurses will participate in a 30-minute focus group meeting. Six months after the meeting, training will be offered. Those who participate will receive feedback and a certificate.
- Setting: Nursing Department, University Hospital.

XSL•FO
RenderX

Textbox 2. Script to guide focus groups.

- Do you know what early assessment of clinical deterioration in patients is?
- Do you usually perform an early assessment of the clinical deterioration of patients admitted to the wards? If so, how?
- For you, what is the importance of this assessment in your daily work in the ward?
- Do you use data from early clinical deterioration assessment to guide the care plan of patients under your supervision? If so, what data? How?
- Do you think it is feasible to carry out an early assessment of the clinical deterioration of patients admitted to the wards?
- In your opinion, what factors can favor the early assessment of clinical deterioration of patients admitted to the wards?
- In your opinion, what factors can hinder the early assessment of clinical deterioration of patients admitted to the wards?
- How would you like to receive this training? Reflect and give your opinion on the best strategy, the type of training, location, teaching methodology to be used and teaching material.

Establishment of Training Objectives

Following the needs assessment stage, we will establish the training objective. The most appropriate content and training strategies for the target population and context should be identified at this stage. The data obtained will allow us to define the elements of the intervention, including the strategy, type of training, location, teaching methodology, and teaching material.

Intervention Strategy Proposal

In this stage, the content to be addressed, the methods design, and the strategies and means of communication will be defined.

Pretest

This phase will consist of a pretest of the intervention applied to a population subsample to verify operational aspects of the chosen content, strategy, and means of communication. This step aims to assess the adequacy and feasibility of the proposed intervention.

Preintervention Assessment

In this step, a questionnaire [15] will be used to assess the theoretical content related to each participating nurse's early assessment of clinical deterioration to compare the pretraining and posttraining results. The Brazilian version of the rapid response team (RRT) survey, which aims to explore nurses' knowledge and perceptions of RRTs, was translated and adapted into Brazilian Portuguese and validated (LBdA Lourenço and TM São-João, unpublished data). This instrument has 3 parts: part 1 contains 4 hypothetical case studies; in part 2, respondents must evaluate each factor according to its degree of importance; and in part 3, participants must include their basic information regarding characteristics and work history.

Although this tool has been widely used globally, no studies have been published on its psychometric properties. Assessing the psychometric properties of a measurement tool is relevant for ensuring its validity, reliability, and suitability for data collection in most research contexts. However, there are situations where a psychometric evaluation may be unnecessary, such as for well-established and widely used tools, especially those that do not measure psychosocial constructs (eg, the RRT survey). Once the tool has been extensively used, widely accepted, and has a solid empirical foundation in the literature, conducting a full psychometric assessment may not be necessary [16].

Implementation of the Intervention

The planned intervention will be implemented via the chosen method, and the participants will be informed in advance to allow for planning and effective participation.

Postintervention Assessment

In this step, the Brazilian version of the RRT survey will be reapplied to compare the pretraining and posttraining results and evaluate the effectiveness of the intervention.

Assessment of Suitability, Acceptability, and Quality of the Intervention

The nurses' assessment regarding the suitability, acceptability, and quality of the proposed intervention will be assessed through a self-answered, open-questions questionnaire. This questionnaire will have its content submitted for validation by specialists.

Criteria for Discontinuing or Modifying Allocated Interventions for a Given Trial Participant

Participants will be discontinued for not attending scheduled meetings or ending participation in the study during the intervention or data collection phase.

Strategies to Improve Adherence to Intervention Protocols and Procedures for Monitoring Adherence

An SMS text message will be sent to participants' telephones a day before the scheduled appointment, reminding them to attend the training.

Relevant Interventions That Are Permitted or Prohibited During the Trial

During the intervention, participants must not engage in any other training regarding clinical deterioration.

Outcomes

A form for analyzing the sociodemographic profile will be applied to nurses with the following variables: age, sex, education level, time of training, place, and time of work in the unit.

The effect of evaluating the theoretical content related to the early assessment of clinical deterioration by each participating nurse will be considered to compare the pretraining and posttraining results.

XSL•FO
RenderX

Sample Size and Sampling

The minimum sample size was calculated according to the stages of data collection in the pretest and posttest. To evaluate the responsiveness of part 1 of the RRT survey comparing the scores from the two evaluation periods, a paired student *t* test was used. In this calculation, a significance level of 5% was assumed with a test power of 80% and an effect size of 0.50, which, according to Cohen [17], can be considered an effect size of medium degree. The calculation resulted in a minimum sample of 34 participants. To carry out this sample calculation, G*Power 3.1.9.2 software was used [18,19].

To assess the internal consistency of part 2 of the RRT survey, we referred to the recommendation proposed by the COSMIN (Consensus-Based Standards for the Selection of Health Measurement Instruments) initiative that at least 50 participants are necessary for a sample to be considered adequate when this measurement property is evaluated [20].

To evaluate assertiveness in filling out the NEWS2 before and after the intervention, the same methodology was proposed by the COSMIN initiative that at least 50 participants are necessary [20]. Thus, 50 participants will be included in the study to meet all the proposed objectives.

Recruitment

The human resources records of each eligible participant will be accessed through a list of registered nurses in floor units. Participants who engage in the study will be scheduled for a baseline appointment. On the appointed day, the interviewer will personally invite the participant and both will sign two copies of the research consent form.

Randomization and Allocation Concealment

Considering the nature of a JITT, no randomization will be conceived. All nurses allocated in floor units will be sequentially included according to their availability, schedule, and willingness to participate.

Implementation

The lead investigator will implement intervention strategies.

Blinding

This is not a blind study as both the lead investigator and participants will know they are receiving an intervention.

Data Collection

The experiment will be offered from July to December 2023 and include nurses who work in the clinical and surgical floor units.

Initially, a meeting will be held with the managers of the inpatient units to present the training program. Then, nurses will be recruited through an individual invitation to be offered by the researcher in the work units. After acceptance by the participants, a roster will be set up, together with the managers of the units, to assist in the organization of work rosters so that every position is covered when the nurses leave to participate in the training. Several training sessions will be made available in the morning, afternoon, and evening to carry out the training within the working hours of each nurse and according to what was described in the JITT method. The training sessions are structured to be 1 hour long and include the following steps: training presentation, signing of the informed consent form, application of the pretest, training, application of the posttest, and final evaluation. All nurses will participate in a single session and receive a participation certificate after completing all the steps described. The training will be carried out in a training room within the hospital.

Content analysis will be carried out during the qualitative phase (focal group). The most appropriate contents and strategies for nurses, as defined by them, will be combined to determine the elements of the intervention. Regarding the web-based questionnaire and the RRT survey, both of which are quantitative instruments, any increase in the score from the pretest to posttest will represent an improvement and, consequently, indicate the effectiveness of the intervention.

Data Management

The gathered data will be compiled in a spreadsheet using Excel 2010 (Microsoft Corporation) using double entry. In this spreadsheet, numerical encodings will be created for categorical variables. Quantitative variables will be inserted as collected. To avoid erroneous double entries or differences in the created codes, preset values for categorical variables will be used. The spreadsheet containing the data will be password-protected and solely accessible by the lead investigator.

Data Analysis

The data spreadsheet will be imported into SAS 9.4 software (SAS Institute). The results of the focus groups, as well as the preintervention and postintervention assessment questionnaires, will be submitted for content analysis.

Statistical Analysis

Qualitative variables will be described by calculating frequencies and percentages, and quantitative variables through position measurements and dispersion.

Comparisons between the two time periods concerning the score of the NEWS2 instrument and part 1 of the RRT survey instrument will be carried out using paired Student *t* tests or paired Wilcoxon tests [21], according to the data distribution. The distribution of data will be evaluated using the Shapiro-Wilk test.

The internal consistency of part 2 of the RRT survey instrument will be assessed using Cronbach α coefficient [22]. This coefficient ranges from 0 to 1, where values >.7 indicate that the measurements are reliable [23].

The statistical software SAS and SPSS (version 28; IBM Corp) will be used to carry out the analysis with a significance level of 5%.

Data Monitoring

No monitoring committee was established for this study because we understand it will bring minimal risk to participants, as described in the section Harms below. In addition, the protocol may be terminated early due to these minimal predicted risks.

XSL•FO
RenderX

Harms

For this study, small risks and discomforts to participants are foreseen. Participants may feel uncomfortable during the encounters or while answering any questions about clinical deterioration, and they may need to know the answer.

Auditing

The following audit procedures will be considered: (1) compliance audits, by assessing the extent to which nurses are complying with the prescribed training protocol (ie, reviewing records, documentation, and training logs to verify if nurses have completed the required modules, attended relevant sessions, or fulfilled certification requirements); (2) knowledge assessments, by assessing nurses' understanding of the content; (3) skills evaluations, by observing and assessing nurses' performance of the specific skills or procedures required through direct observation, simulated scenarios, and practical assessments; (4) feedback surveys, to gather feedback from nurses about their training experience; and (5) quality assurance reviews of training materials, resources, and procedures, to ensure they align with evidence-based practices.

Ethical Considerations

The local Research Ethics Committee approved the study (Certificate of Submission for Ethical Review n. 37499220.9.0000.5404). All enrolled participants will sign the informed consent form, according to Resolution 196/96 of the National Health Council, when instructed about anonymity and the freedom to withdraw their consent at any time during the research. It should be noted that the database will not be sent abroad for analysis. The study was also registered in ReBEC (RBR-5hq9y3k).

The lead investigator shall keep research forms for 5 years, at which time they shall be incinerated. A multimodal dissemination strategy will be used to share findings with multiple stakeholders. Strategies will include scientific publications and presentations in the form of an expository and oral class in previously scheduled meetings with hospital managers and the participating nursing team, with the results obtained at the end of the training program implementation.

Results

Data collection will start in July 2023 with results expected in December of the same year. This study aims to describe a protocol for a professional training program developed for nurses so that they can implement early assessment of the risk of clinical deterioration and offer appropriate referrals. The protocol will also influence nursing managers and nurses in elaborating protocols and clinical practice because, as the first team to identify changes in the status of patients, the importance of nursing in detecting clinical deterioration is recognized.

The results obtained at the end of this research will be shared with the participating nursing team through the presentation of reports. In addition, we will submit the research results to scientific journals and present them at international scientific conferences.

Discussion

Innovative Protocol for Nurse Training in Early Detection of Clinical Deterioration

This study will describe a protocol for a professional training program designed for nurses to implement early risk assessment of clinical deterioration. This protocol is unprecedented and of great relevance, as some studies [24,25] have already demonstrated that the implementation of clinical deterioration evaluation directly impacts nurses in three areas of competence: (1) evaluation and care of patients (through the detection of clinical deterioration and development of skills and knowledge); (2) referring patients (through knowledge of the language and lines of communication in the referral process and deciding whether to seek help); and (3) coping experiences. Studies have also demonstrated that most patients who required hospitalization in intensive care units or who experienced cardiopulmonary complications exhibited signs of clinical deterioration hours before the event; more than 80% of these patients could be identified approximately 24 hours before these serious adverse events [26]. In this way, identifying patients who can benefit from intensive care units becomes crucial [26].

The development of this proposal is expected to implement a pioneering early warning system with Unicamp Clinical Hospital to increase the quality of care, improve indicators related to patient safety, and decrease the preventable hospital mortality rate.

Limitations

Some limitations pertaining to the study's design and methodology exist. The limited generalizability is a concern, as the study will be conducted in a specific public university hospital in southeastern Brazil, potentially limiting the applicability of the findings to other health care settings or regions. Potential selection bias is another limitation, as the recruitment process will not be randomized. The data collection period may restrict the gathering of a comprehensive and long-term data set.

The second set of limitations revolves around data collection and analysis. The qualitative stage involving focus groups and interviews with nurses introduces the possibility of self-reporting bias, where participants may provide socially desirable responses, or their recollections may not accurately reflect their actual practices. Finally, it is not possible to control or account for potential confounding factors, such as patient demographics or other interventions that may influence the outcomes.

Despite the acknowledged limitations, this paper provides a valuable contribution by outlining the design of a nurse-led intervention program that other health care professionals can replicate. The structured and systematically mapped intervention presented in this study offers the potential for improved resource allocation and results optimization. By enhancing nurses' ability to detect early signs of clinical deterioration and facilitating prompt and accurate interventions, this program holds promise for improving patient outcomes and increasing the likelihood of positive treatment outcomes.

XSL•FO
RenderX

Some studies have demonstrated the effectiveness of using intervention mapping in nursing in planning and implementing interventions and evaluating results. The research subjects reported that the interventions allowed a better understanding of the studied models [27,28].

Conclusions

This study aims to contribute to advancing nursing practices in the context of clinical deterioration among inpatients. The intervention proposed in this research is grounded in established theoretical principles and is characterized by its cost-effectiveness and ease of implementation. Specifically tailored for adult patients in inpatient units, this program holds the potential to substantially enhance nurses' ability to accurately diagnose and promptly intervene in cases of early clinical deterioration. The paper introduces an evidence-based professional training program designed for nurses and led by a nurse, implementing a risk assessment protocol for early clinical deterioration within the inpatient units.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request. Data and metadata will be made available in the University of Rhode Island Research Data Repository (DigitalCommons@URI) after the completion of the project and for 10 years.

Authors' Contributions

LBdAL idealized the primary concept of this study. The strategy was then conceived and refined by LBdAL and TMS-J. The protocol was written by LBdAL and TMS-J, with final revision by LBdAL, TMS-J, MdJM, and MdFNS.

Conflicts of Interest

None declared.

Abstract

Background: Academic success has been the primary criterion for admission to many nursing programs. However, academic success as an admission criterion may have limited predictive value for success in noncognitive skills. Adding situational judgment tests, such as Casper, to admissions procedures may be one strategy to strengthen decisions and address the limited predictive value of academic admission criteria. In 2021, admissions processes were modified to include Casper based on concerns identified with noncognitive skills.

Objective: This study aims to (1) assess the incremental validity of Casper scores in predicting nursing student performance at years 1, 2, 3, and 4 and on the National Council Licensing Examination (NCLEX) performance; and (2) examine faculty members' perceptions of student performance and influences related to communication, professionalism, empathy, and problem-solving.

Methods: We will use a multistage evaluation mixed methods design with 5 phases. At the end of each year, students will complete questionnaires related to empathy and professionalism and have their performance assessed for communication and problem-solving in psychomotor laboratory sessions. The final phase will assess graduate performance on the NCLEX. Each phase also includes qualitative data collection (ie, focus groups with faculty members). The goal of the focus groups is to help explain the quantitative findings (explanatory phase) as well as inform data collection (eg, focus group questions) in the subsequent phase (exploratory sequence). All students enrolled in the first year of the nursing program in 2021 were asked to participate (n=290). Faculty will be asked to participate in the focus groups at the end of each year of the program. Hierarchical multiple regression will be conducted for each outcome of interest (eg, communication, professionalism, empathy, and problem-solving) to determine the extent to which scores on Casper with admission grades, compared to admission grades alone, predict nursing student performance at years 1-4 of the program and success on the national exam. Thematic analysis of focus group transcripts will be conducted using interpretive description. The quantitative and qualitative data will be integrated after each phase is complete and at the end of the study.

Results: This study was funded in September 2021, and data collection began in March 2022. Year 1 data collection and analysis are complete. Year 2 data collection is complete, and data analysis is in progress.

Conclusions: At the end of the study, we will provide the results of a comprehensive analysis to determine the extent to which the addition of scores on Casper compared to admission grades alone predicts nursing student performance at years 1-4 of the program and on the NCLEX exam.

Introduction

Overview

There is an increased demand for registered nurses (RNs) with the increasingly complex health care system and aging population [1]. The strength of the global nursing workforce depends on the nursing education sector, and as a result, it is essential to invest in nursing education. Since the COVID-19 pandemic, there has been a 30% increase in applications to nursing programs [2]. Nursing education has limited resources to meet this demand [1], and there is increasing competition for seats [3]. The International Council of Nurses is concerned about this increased need for RNs and maintaining a high-quality workforce [2]. In their 2021 Strategic Workforce Plan for Nursing and Midwifery, the World Health Organization (WHO) stated that enough nurses need to be educated to have the "knowledge, competencies, and attitudes" to meet the population and health system's needs [4]. Optimizing admission procedures and admitting applicants that are the best fit for the profession is a way to invest in nursing education, develop the nursing workforce, and support the WHO global strategic direction. This paper describes a research protocol for a multiphase mixed methods study. The purpose of the study is to assess the effectiveness of a situational judgement test, Casper, as part of the admission decisions in the Bachelor of Science in Nursing (BScN Collaborative) program in predicting student performance during the program and on the National Council Licensure Examination (NCLEX).

Background

Admission criteria that accurately predict student success related to the performance of cognitive and noncognitive skills can help admit applicants with the prerequisites to develop nursing competencies. This can also help reduce the loss of invested resources from failure or attrition [3]. Cognitive skills refer to academic achievement and "involve the ability to understand complex ideas, to adapt effectively to the environment, to learn from experience, to engage in various forms of reasoning, to overcome obstacles by taking thought" [5]. Noncognitive skills comprise "personal traits, attitudes, and motivations" [6]. It is important to note that noncognitive skills usually involve mental processes such as decision-making, interpersonal skills, and emotional maturity, but they are more difficult to measure than cognitive skills (Textbox 1) [7].

Textbox 1. Description of key terms. Casper measures collaboration, communication, empathy, equity, ethics, motivation, problem solving, professionalism, resilience, and self-awareness.

Cognitive skills

- Academic achievements
- Ability to understand complex ideas, learn from experience, and reason [5]

Noncognitive skills

- Personal traits, attitudes, and motivation (eg, empathy) [6]
- Involve mental processes (eg, decision-making and interpersonal skills)

Situational judgment tests (SJTs)

- A methodology for assessing decisions in relation to underlying knowledge, skill, traits, and other attributes [8]

Casper

- A web-based SJT (90-110 minutes) that assesses noncognitive skills
- Test-takers respond to scenarios concerning what they would do and why
- Trained raters score the test
- Interrater reliability and intraclass correlations range from 0.84 to 0.94 [9]

Applicants who have appropriate decision-making skills that reflect capabilities related to noncognitive skills may be more suitable for the nursing profession. Noncognitive skills related to areas such as communication, empathy, problem-solving, and professionalism are essential to assume the roles of an RN (eg, advocate, coordinator of care, and educator) and deliver competent care to often complex patients and families across the life span in different settings (eg, acute care and the community).

There is strong evidence that cognitive ability predicts program success, but there is limited evidence related to noncognitive skills. The authors of a 2020 systematic review of 16 cohort studies explored preadmission criteria that predicted student success in undergraduate nursing programs in the United States. These authors reported that it was well established that cognitive predictors such as admission grade point average (GPA) predicted program success. Although not used as admission criteria, age, gender, and ethnicity also predicted success. Other possible predictors included grades on standardized tests, such as the Test of Essential Academic Skills. It is important to note that the definition of success used by most studies varied and was related to academic success, passing the licensure exam, attrition, program completion, and GPA in nursing and science courses. These authors contend that it is difficult to isolate a single variable as the best predictor of student performance, and it would be more reliable to use a combination of variables [1].

XSL•FO
RenderX

No research has considered the predictive validity of noncognitive skills on student performance as well as the value of adding these criteria, that is, the incremental validity, to the nursing admission process. Incremental validity is defined as "the improvement obtained by adding a particular procedure or technique to an existing combination of assessment methods. In other words, incremental validity reflects the value of each measure or piece of information to the process and outcome of assessment" [10].

One possible approach for nursing admissions is using situational judgment tests (SJTs) to measure noncognitive skills, combining these results with cognitive criteria. SJTs are defined as "a methodology for assessing how an individual's underlying knowledge, skills, traits, and other attributes are expressed when making decisions about job-related scenarios" [8]. The use of SJTs has been identified as a valid approach for selecting medical school applicants concerning the performance of nonacademic skills. The authors of a systematic review of 30 studies (10 observational, 17 cohort with follow-up from 1-9 years, and 3 observational with longer follow-up) conducted a meta-analysis of 26 of these studies that reported validity correlations related to SJT and student performance. A pooled correlation was obtained of 0.32 (95% CI 0.26-0.39; $P<.001$) [11]. A total of 15 of the 17 studies that assessed the incremental validity of adding SJT found modest values of 5%-10% of additional variance accounted for (ie, the R^2 of regression models with and without SJTs differed by 5-10 percentage points). This suggests that there is value to adding SJTs, but SJTs alone cannot account for the outcomes assessed. The authors point out that this is a modest relationship but was considered in the context of medical school admissions, where many applicants are strong. Therefore, detecting slight differences is difficult [11].

The authors of a 2020 scoping review reported that no research was identified between 2006 and 2019 concerning using SJT for nursing school admissions [12]. A literature search did not identify any research published after 2019. Research is needed to explore the predictive nature of SJTs to inform nursing admissions decisions. Nursing admission committees need evidence of the incremental validity of admission criteria that can predict student success both academically and in noncognitive skills [13].

The BScN (Collaborative) program at Memorial University of Newfoundland (MUN) is a competitive program composed of 2 admission options: the 4-year option and the accelerated option. Over 600 applicants per year apply for 291 seats at 3 sites. Historically, admission decisions were primarily based on academic performance, but starting in 2021, the admissions process was modified to include Casper, a SJT that assesses noncognitive skills. The Casper score, the applicants' academic average, and references were used in the admissions decisions.

Casper is a web-based test developed by Acuity Insights that takes 90-110 minutes to complete. Test-takers are asked to respond to various scenarios that are designed to measure noncognitive skills concerning what they would do and why. The goal of these scenarios is to ascertain "behavioral tendencies" of individuals who are applying to programs that are person-centered. The test is divided into 2 sections: a video response section and a written response section. Trained raters score the test, and within 2-3 weeks of completion, the Casper score, converted to a *z* score, is sent to the program the applicant applied to. Casper assesses for the following noncognitive skills: collaboration, communication, empathy, equity, ethics, motivation, problem-solving, professionalism, resilience, and self-awareness. As noted above, these noncognitive skills are essential for nursing practice. The interrater reliability of Casper is strong, with intraclass correlations ranging from 0.84 to 0.94 across 55,988 applicants (Textbox 1) [9].

The goal of using Casper in our nursing program was to guide the admission of applicants with the best potential for success in the program and the profession. The need to include the assessment of noncognitive skills during the admissions process was further reinforced by findings of the 2016-2018 Employer Survey Report (prepared by BScN Collaborative Program), which raised concerns about recent graduates' performance in the clinical area with professionalism, empathy, communication, and problem-solving. These concerns were also highlighted in discussion with the College of Registered Nurses of Newfoundland and Labrador, the admissions committee, and faculty members.

This study proposes a mixed methods research (MMR) study to address and add to the knowledge related to predictors of success in a nursing program concerning noncognitive skills and program success. In particular, the predictive nature of Casper will be examined concerning optimizing admission decisions and admitting applicants with the greatest potential of completing the program, meeting the competencies of the nursing profession, and passing the NCLEX.

Purpose

The purpose of this multiphase MMR study is to assess the effectiveness of Casper as part of the admission decisions in the BScN (Collaborative) program in predicting student performance in years 1, 2, 3, and 4 of the program, and on the NCLEX, compared to academic performance alone. Overall academic success will be evaluated, as well as performance in psychomotor skills laboratory sessions and clinical settings. Problem-solving, empathy, and other skills are expectations in both types of settings, and all are expected to improve as students progress through the program.

The overarching MMR research question is, What is the effectiveness of the addition of Casper to admission decisions in predicting student success across the curriculum? The objectives of the quantitative and qualitative analysis and the integration of both are as follows:

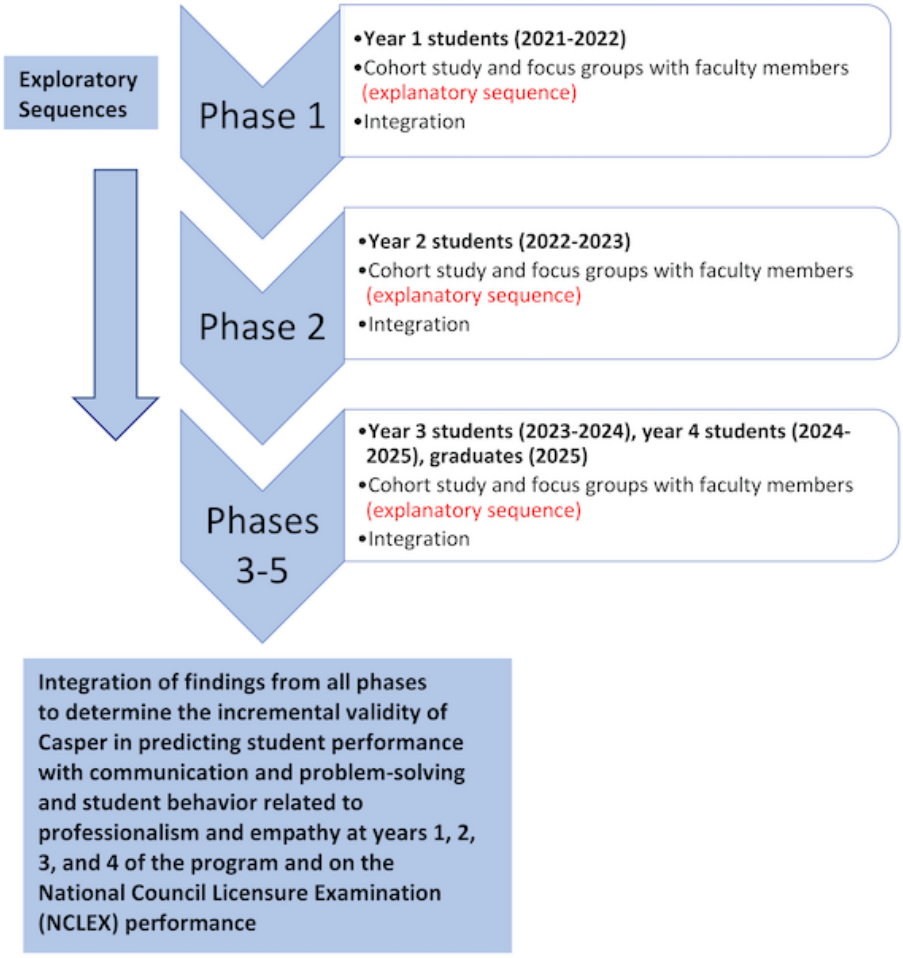
1. To assess the incremental validity of Casper scores in predicting student performance with communication and problem-solving and student behavior related to professionalism and empathy at years 1, 2, 3, and 4 of the program, and on NCLEX performance, compared to academic ranking alone.
2. To examine clinical and laboratory faculty members' perceptions of student performance, challenges, and influences related to professionalism, empathy,

XSL•FO
RenderX

communication, and problem-solving in psychomotor skills laboratory sessions and the clinical area.

Methods

Ethical Considerations



We obtained ethical approval (20222324) from the Newfoundland and Labrador Health Research Ethics Authority in February 2022, and this approval was renewed in January 2023.

Study Design and Setting

This study will use a multistage evaluation MMR study design with 5 phases and 2 embedded sequences (Figure 1). An interpretive description was used to guide the qualitative portion of the study. Both MMR and interpretive description are underpinned by pragmatism, and as such, both objective and subjective knowledge are valued and used to answer the research questions [14,15].

In each study phase, there is an embedded explanatory sequence whereby quantitative data collection (longitudinal cohort study) will be followed by qualitative data collection (focus groups). The goal of the qualitative interviews is to help explain the quantitative findings and gain a more robust understanding of student performance concerning professionalism, empathy, communication, and problem-solving. The other embedded sequence is an exploratory sequence, whereby what is learned in each phase will inform focus group questions in the subsequent phase.

Figure 1. Mixed methods model that illustrates the exploratory and explanatory sequences and points of integration.

Student Recruitment

In March 2022, all first-year students in the 4-year option and accelerated option at all 3 sites were invited to participate. These students were admitted in 2021 and were the first cohort to complete Casper as part of the admission process. Students who chose to participate will be followed through their program to the completion of the NCLEX exam. A faculty member at each site not associated with the study acted as an intermediary and introduced the study using a script. If students were interested, an investigator came to the class to further explain the study, and an information letter was provided to students. At that time, informed consent was obtained from students wanting to enroll, and the first set of questionnaires was completed. Students who chose not to enroll at that time were told that if they decided they would like to enroll, they could contact the research assistant within 1 week. It was explained to students in the consent form that participation (or not) would not affect any courses that they take in the nursing program; there were no known risks to participating in the study; all identifying information would be kept confidential; study data would be

XSL•FO
RenderX

anonymized and safely stored using a secured drive; and only the research team would have access to the data.

A demographic profile was completed for each student (eg, age, gender, Canadian province or country of origin, and previous education). The student's Casper score and admission GPA for those who had completed university courses, or the high school average, were obtained through the Nursing Admissions Office. To access these data, a conditional agreement was reached between the university and the researchers.

Faculty Recruitment

Focus groups with clinical and laboratory faculty will be conducted at the end of each year of the program at a mutually convenient location and time. Recruitment is done by email using purposive convenience sampling. Emails will be sent to clinical and laboratory faculty that taught this group of students in the previous year. During the focus groups, we explore faculty perceptions of student performance, challenges, and influencing factors related to noncognitive skills in the laboratory and clinical settings. Written informed consent is obtained from participants in the focus groups. It is explained in the consent form that all information that identifies participants will be kept confidential, and only the research team has access to the data. As well, it is explained that there may be potential risks, including being uncomfortable sharing experiences in the context with others in the focus group. Every effort is made by the researchers to ensure participant comfort as well as safety during the focus group (eg, the researchers will ask the participants to respect the privacy of fellow participants and treat all information shared with the group as confidential).

Sample Size

To assess incremental validity, the R^2 of regression models, with and without SJTs, are compared to see if the addition of the SJT explains more of the variance found. The sample size of this study was calculated using the findings of a previous study [16] that assessed incremental validity using R^2 analysis. In it, researchers examined the incremental validity of adding SJTs to the use of a clinical problem-solving tool (CPST) for predicting performance in workplace simulation exercises as part of the selection process for postgraduate medical training. The researchers found that a regression model with CPST but not SJT explained 35% of variance (R^2=.35) whereas a model with both CPST and SJT explained 57% of the variance (R^2=.57) seen in the simulation scores. Their sample size of 135 was sufficient to detect this difference. Our target sample size is, therefore, 135, assuming we will see similar differences for the addition of SJT to admission grades (instead of CPST) on different outcomes. Few of the other studies reported in the systematic review by Webster et al [11] assessed outcomes similar to ours, few related to admission to medical schools, and most were conducted on very large (pooled) cohorts of medical students (N>1000) making it difficult to identify the minimum sample size required. No data are available related to nursing students. Assuming an attrition rate of 10%, which is normally seen in our program, 150 students will be recruited.

Quantitative Data Collection

This study has 5 phases, with quantitative data collection occurring in appropriate psychomotor skills courses during each academic year and at the end of each phase (ie, end of each year and after NCLEX completion). Figure 2 depicts the timeline for data collection.

Figure 2. Timeline for data collection (2022-2026).

Outcomes and Measures

The following outcomes, identified as concerns related to graduate performance and entry-level competencies of RNs, will measure nursing student performance: communication, problem-solving, empathy, professionalism, GPA and grades, and NCLEX success.

Communication is being evaluated during psychomotor testing in a nursing skills laboratory session using a tool developed for the study. One specific course was chosen for each year of the program. In these courses, students learn and practice foundational skills (eg, health assessment, basic care, and safe medication administration) and complex psychomotor skills (eg, complex dressings, care of chest tubes, and care of central lines). Nursing skills laboratory session testing is scenario-based

XSL•FO
RenderX

and requires students to demonstrate effective communication skills (eg, verbal skills and documentation). Laboratory faculty who evaluate students during the psychomotor testing, use consistent rubrics for that course, and complete these tools based on the student's performance related to communication. The communication tool assesses whether students introduce themselves, use appropriate language, and complete appropriate documentation. There are additional criteria to assess if the testing involves a real person (eg, the student used appropriate listening skills). The possible range of scores for this assessment tool is 0-14, with higher scores indicating strong communication skills. Face validity was established by having faculty who have extensive experience conducting psychomotor assessments with nursing students review the tool to ensure the content was appropriate and relevant. The interrater reliability score was 100%. Laboratory faculty received training on how to complete the tool (Multimedia Appendix 1).

Problem-solving is being evaluated during psychomotor testing in a nursing skills laboratory session using a tool developed for the study. One specific course has been chosen for each year of the program. Nursing skills laboratory session testing is scenario-based and requires students to demonstrate effective problem-solving skills. Laboratory faculty who evaluate students during the psychomotor testing, using consistent rubrics for that course, will complete this tool based on the student's performance related to problem-solving. The problem-solving tool evaluates whether the student recognizes the problem, attempts to address the problem, and takes appropriate action to address the problem. The possible range of scores for this assessment tool is 0-6, with a higher score indicating strong problem-solving skills. Face validity was established by having faculty who have extensive experience conducting psychomotor assessments with nursing students review the tool to ensure the content was appropriate and relevant. The interrater reliability score was 94%. Laboratory faculty received training on how to complete the tool (Multimedia Appendix 2).

Empathy will be measured with the Jefferson Scale of Empathy (reliable and valid). This 20-item self-report scale takes approximately 10 minutes to complete and measures 3 constructs: "perspective taking," "compassionate care," and "standing in a patient's shoes." Each item is answered using a 7-item Likert scale (1=strongly agree and 7=strongly disagree). The scores can range from 20 to 140, with higher scores indicating stronger empathy [17].

Professionalism will be measured with an adapted Nurses Professional Values Scale-Three (NPVS-3; reliable and valid). This measurement is a 28-item self-report scale. The demographics questions were removed as the questions were either not appropriate for our context or the information would be obtained from the MUN Registrar's Office. Professional nursing values are evaluated using a 5-item Likert scale: not important (A), somewhat important (B), important (C), very important (D), and most important (E). Numeric values were assigned to each letter and added together to get the total score. The scores can range from 28 to 140. A higher score indicates a stronger nurse's professional value orientation [18].

For GPA and grades, GPA (yearly and cumulative) and marks in academic nursing courses will be obtained at the end of the academic year from the registrar's office.

For NCLEX success, data will be obtained from the College of Registered Nurses of Newfoundland and Labrador (CRNNL) regarding NCLEX success in terms of pass or fail. If available, as NCLEX scoring is changing, the overall performance (logit score) and performance on individual test categories (logit score) will be obtained. The CRNNL is the regulatory body and professional association for all RNs and nurse practitioners and the custodian for the National Council of State Boards of Nursing data. An agreement was signed between the researchers, MUN, and CRNNL to access the data.

Predictor Variables

Data will be collected on several predictor variables. Admission grades and Casper scores are the predictor variables of interest (ie, the independent variables to be assessed in terms of predictive and incremental validity). The other variables will be assessed and controlled for as potential confounders.

- Admission grades: the admission GPA will be obtained for students who had some postsecondary education before admission; the admission high school average will be obtained for students admitted directly from high school. These data will be obtained from the registrar's office.
- Admission Casper score: students complete Casper as part of their admissions application. Results will be obtained from the nursing admission office.
- Demographics: age, gender, province, and program of study (ie, 4-year option and accelerated option) and program site, as the BScN (Collaborative) program is offered at 3 sites. These data will be obtained from the nursing admissions office.

Quantitative Data Collection Procedures

At the end of each year of the program, the research assistant or researchers will meet with the students to complete the 2 pen and paper questionnaires: the Jefferson Scale of Empathy and the NPVS-3. The research assistant has been trained in data collection and the use of measurement tools. Students are monitored to ensure they are not talking to each other. As a thank-you for participating, students are given a CAD $10 (US $7.32) coffee card at each phase of data collection. The completed problem-solving and communication tools will be obtained directly from the laboratory instructors.

Completed questionnaires and tools at the sites are placed in a sealed envelope and sent to the MUN Faculty of Nursing Research Unit by courier. If there is a delay in sending the completed questionnaires by courier, the questionnaires are stored in a locked filing cabinet in one of the researcher's offices. Data will be obtained from the Registrar's Office, Nursing Admissions Office, and CRNNL at the appropriate times, using procedures established with each source.

Qualitative Data Collection

Qualitative data collection will occur at the end of each academic year. Figure 2 depicts the timeline for data collection. Both primary investigators (PIs) have expertise in qualitative

XSL•FO
RenderX

research and experience in focus group facilitation. The PIs will conduct the focus groups at the MUN Faculty of Nursing and will provide instruction, guidance, and support for focus group facilitators at the other 2 sites. Focus group interviews with clinical and laboratory faculty will be recorded and transcribed verbatim. An interview guide is used (Textbox 2). Interpretive description will be used to guide data collection, and consistent with this approach, initial focus group questions were guided by the research purpose and objectives [17]. Subsequent interview guides will be developed based on the unfolding data analysis [19,20]. With interpretive description, the researcher goes beyond description and asks what it means, what I can do with these findings, and why it is important [15]. Quirkos (version 2.5.2; Quirkos), a qualitative software package, will be used to categorize the data to identify themes.

Textbox 2. Phase 1 faculty focus group questions.

Faculty focus group questions
1. Tell me about your experiences with students this past year in the clinical setting concerning communication, professionalism, empathy, and problem-solving.
2. Tell me about your experiences with students this past year in the laboratory setting concerning communication, professionalism, empathy, and problem-solving.
3. Did you experience any challenges related to communication, professionalism, empathy, and problem-solving?
4. What do you think influenced their performance in relation to communication, professionalism, empathy, and problem-solving?

Statistical and Analytic Plan

Descriptive statistics (eg, means and proportions), as appropriate for the data, will be used to describe the characteristics of the participants, including their GPAs and their scores on the different outcome measures. Stata (version 17; StataCorp) will be used to analyze the data. The data will be checked for the amount of missing data; if they are missing completely at random, and if warranted, multiple imputation will be used. Different analyses will be conducted to address each research objective, as described below.

For objective 1 (phases 1-5), hierarchical multiple linear regression will be conducted to determine if Casper is a significant predictor of each outcome (predictive validity) and if a model with both Casper and admission grade explains more of the variance for the outcome than a model without Casper (incremental validity). Each model assessed will contain both the Casper score and the admission average and include potential predictors and confounders (eg, GPA for the year, age, gender, province, program of study, and program site). Modeling will be conducted separately for students who entered directly from high school (admission grade=high school average) and those who had some postsecondary education before admission (admission grade=GPA for the postsecondary courses). The modeling will be repeated at the end of each year (years 1-4) for each of the yearly outcomes (ie, dependent variables): communication, problem-solving, empathy, professionalism, and GPA. The measures used will be the scores for that year.

For the first model that is tested, all the predictor variables will be entered into the model. The predictor variable with the highest *P* value ($P>.05$) will be dropped, and the model without this variable will be tested. The second model will be compared to the previous model using the likelihood ratio (LR) test. If the LR test is not significant ($P>.05$), the variable is not a predictor and needs to be assessed for confounding before being removed from the model. To assess confounding, the coefficient for the main exposure of interest is assessed to see if it changes when the potential confounder is taken out of the model. If it did, that variable would be considered a confounding variable and would be kept in the model. If the coefficient did not change, the variable is not a confounder and will be removed from the model. This process will be repeated, comparing it with the previous model, until all of the variables are tested and the final model has been established. To determine the incremental validity, the R^2 (ie, the percentage of variance explained by the model) for the final model and the R^2 for that model without the Casper score will be compared.

A similar analysis will be conducted in 2025 using logistic regression to determine if Casper is a significant predictor of NCLEX success (predictive validity) and if a model with both Casper and admission grade explains more of the variance for NCLEX success than a model without Casper (incremental validity).

For objective 2 (phases 1-5), under the direction of the methodological approach of interpretive description, the analytical framework, the three Cs (coding, categorizing, and concepts) will be used to conduct a thematic analysis of the data. The following 6 steps are used in this iterative process: initial coding, revisiting initial coding, developing categories, revising the initial list of categories based on additional review of the data, reviewing categories and subcategories, and developing themes (ie, concepts) [21]. The PIs will independently code the focus group data and reach consensus on the themes [19]. We will use verification strategies to incrementally build rigor throughout the qualitative phase of the project [19,22]. These strategies include methodological coherence (eg, ensuring the fit between methods of data collection and analysis with the research design) and concurrently collecting and analyzing data (eg, ensuring that future focus group questions are based on the analysis and findings of previous focus groups) [19,22]. Both PIs and other focus group facilitators are known to faculty participants. Another verification strategy, researcher responsiveness, offers the opportunity for the PIs to reflexively consider their influence on the research [19,22]. For example, debriefing after each focus group to explore how we questioned, probed, and, overall,

XSL•FO
RenderX

facilitated the group to meet the goals of the research. These verification strategies will enhance the trustworthiness and credibility of the data [19,22,23].

The integration will occur after each phase is complete and at the end of the study.

- Explanatory sequences (end of phases 1-5): integration with this design aims to use the qualitative results to explain the quantitative data [14]. Each data set will be analyzed separately (ie, questionnaires completed by students, problem-solving and communication tools completed by faculty, and focus groups with faculty), and then the "fit of the data integration" will be analyzed. This refers to the coherence of the qualitative and quantitative findings; completing this analysis will result in a more comprehensive understanding of the findings. Three possible outcomes will be assessed. (1) Confirmation occurs when the findings from both data sets confirm the results of the other: the 2 data sources provide similar conclusions, and therefore, the results have more credibility. (2) Expansion occurs when the findings from the 2 data sets diverge and expand insights related to the findings. And (3) discordance occurs if the findings of qualitative and quantitative data sets are inconsistent or disagree [24].
- Exploratory sequences (end of phases 1-3): the goal of integration in an exploratory sequence is to build from one database to another [14]. In this study, what is learned in each phase will inform qualitative data collection for the focus group in the subsequent phase.

Results

This study was funded in September 2021. In March 2022, a total of 144 first-year students enrolled in the research, who will be followed throughout the nursing program to the completion of the NCLEX exam in 2026. A total of 3 focus groups with clinical and laboratory faculty were conducted in May 2022. Data analysis of year 1 data is complete, and data analysis of year 2 data has begun. STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for cross-sectional research and COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines for qualitative research will be followed when results are presented [25,26]. The knowledge translation includes reports, presentations, and publications. Year 1 and a portion of year 2 data were presented at the International Council of Nurses Congress in July 2023.

Discussion

The results of this study may provide evidence to support the use of the SJT, Casper, to guide nursing admissions to optimize the selection of applicants who have the greatest potential of completing the nursing program and meeting the competencies of the nursing profession. Specifically, the results will show if Casper helps predict the performance of the 4 noncognitive skills that were measured (ie, communication, problem-solving, empathy, and professionalism) and success on the NCLEX. Identifying and selecting applicants who perform well in these areas will mean that individuals are selected who are a good fit for nursing and therefore may be more likely to remain in the program and be licensed to practice as an RN. This will, in turn, potentially improve the quality of the nursing workforce and patient care.

These findings will have implications for nursing education and administration concerning admissions procedures and whether the use, or continued use, of SJTs is warranted based on the available evidence. As well, the results of this study will hold implications for nurse researchers to further evaluate the use of SJTs such as CASPER. Consideration should be given to conducting a multisite study across several university schools of nursing and comparing student cohorts on outcomes measured by Casper (eg, communication and problem-solving) before and after the implementation of Casper.

There are several notable strengths. This is the first study to report on the predictive ability of situational judgment testing as part of nursing admission criteria. The recruitment of students at 3 nursing schools ensured that participants were representative of the target population. Also, using a multiphase MMR approach and integrating or merging quantitative and qualitative data allows for a more comprehensive answer to the research questions [14]. Concerning this study, using MMR provides a greater understanding across the years of student performance. It also increased understanding of the challenges and influences related to professionalism, empathy, communication, and problem-solving. Using focus groups as the data collection method in the qualitative phase allows for the development of rich, thick descriptions and, thus, ultimately, enhanced understanding of the concepts explored [27]. Finally, using regression in the analysis allows for control of confounding variables, compared to just correlations between Casper and admission grades with the outcomes.

There may be some possible limitations to this study. The first is the attrition of participants throughout the study. We anticipate that there will be some attrition from the study with student failure and withdrawal from the study or program throughout the 5-year study timeline. The COVID-19 pandemic has greatly influenced this cohort, and this may be found to be a contributing factor to attrition and student performance. The second limitation concerns variables that are measured with self-report (eg, professionalism and empathy). Although the tools used are valid and reliable, there is a potential for social desirability bias with these measures. Additionally, while focus groups for data collection are considered a strength, there is the possibility of power imbalances within the group, thus limiting the breadth and depth of the data [27,28]. This will be mitigated by facilitators, who will establish guidelines at the beginning of the focus group and provide opportunities for all participants to participate in the discussion, including the exploration of new ideas as they emerge. The final limitation concerns potential differences in the student experience across the 3 program sites. Although the same curriculum is offered to students at the 3 program sites, there may be some variability in school culture, clinical experiences, and curriculum delivery that could impact the outcomes that are measured. The program site will be controlled for in the regression analysis. These potential limitations will be taken into consideration when interpreting the results.

XSL•FO
RenderX

The addition of a SJT such as Casper may be a strategy that could support admissions committees as they endeavor to admit students that have both the cognitive and noncognitive skills to be successful in a nursing program. SJTs have been widely used for medical education, but there is limited literature on their usefulness for nursing programs. This multistage evaluation mixed methods study will add to the literature about the predictive ability and incremental validity of the SJT Casper. The findings of this study will have implications for nursing education and research.

Acknowledgments

The authors would like to acknowledge funding from Acuity Insights (Alo Grant) and the support of our research assistant, Joanne Smith-Young. We would also like to acknowledge the support from the College of Registered Nurses of Newfoundland and Labrador, the Memorial University of Newfoundland Faculty of Nursing, the Centre for Nursing Studies, and the Western Regional School of Nursing.

Data Availability

The data sets generated and/or analyzed during this study are not publicly available due to participant confidentiality but are available from the corresponding author on reasonable request.

Authors' Contributions

KS prepared the first and second drafts. DM provided feedback on the first and second drafts and refined the third draft. RC provided feedback and read and approved the final version of the protocol. All authors participated in the revisions of the manuscript.

Abstract

Background: Mild cognitive impairment (MCI) is a syndrome preceding more severe impairment characterized by dementia. MCI affects an estimated 15% to 20% of people older than 65 years. Nonpharmacological interventions including exercise are recommended as part of overall MCI management based on the positive effects of exercise on cognitive performance. Interval training involves brief intermittent bouts of exercise interspersed with short recovery periods. This type of exercise promotes cognitive improvement and can be performed in individuals with MCI. Synaptic plasticity can be assessed in vivo by the neurophysiological response to repetitive transcranial magnetic stimulation (rTMS). A method to assess synaptic plasticity uses an intermittent theta burst stimulation (iTBS), which is a patterned form of rTMS. Individuals with MCI have decreased responses to iTBS, reflecting reduced synaptic plasticity. It is unknown whether interval training causes changes in synaptic plasticity in individuals living with MCI.

Objective: This research will determine whether interval training performed using a cycle ergometer enhances synaptic plasticity in individuals with MCI. The three aims are to (1) quantify synaptic plasticity after interval training performed at a self-determined intensity in individuals with MCI; (2) determine whether changes in synaptic plasticity correlate with changes in serum brain-derived neurotrophic factor, osteocalcin, and cognition; and (3) assess participant compliance to the exercise schedule.

Methods: 24 individuals diagnosed with MCI will be recruited for assignment to 1 of the 2 equally sized groups: exercise and no exercise. The exercise group will perform exercise 3 times per week for 4 weeks. Synaptic plasticity will be measured before and following the 4-week intervention. At these time points, synaptic plasticity will be measured as the response to single-pulse TMS, reflected as the percent change in the average amplitude of 20 motor-evoked potentials before and after an iTBS rTMS protocol, which is used to induce synaptic plasticity. In addition, individuals will complete a battery of cognitive assessments and provide a blood sample from the antecubital vein to determine serum brain-derived neurotrophic factor and osteocalcin.

Results: The study began in September 2023.

Conclusions: The proposed research is the first to assess whether synaptic plasticity is enhanced after exercise training in individuals with MCI. If exercise does indeed modify synaptic plasticity, this will create a new avenue by which we can study and manipulate neural plasticity in these individuals.

Introduction

Memory impairment has long been seen as a common consequence of aging, but it could be seen as mild cognitive impairment (MCI), a precursor of dementias such as Alzheimer disease. MCI is characterized by evidence of cognitive decline without a substantial disruption to completing everyday tasks [1,2]. Currently, 15% to 20% of people aged 65 or older are living with MCI [3]. About 10%-15% of individuals with MCI progress to dementia [3], exacerbating the concern for reduced social and functional capacities of such a large number of people and their increased rate of mortality [1,2].

Risk factors for MCI include older age, sedentary lifestyle, low number of years of education, and factors such as hypertension and obesity, various cardiovascular diseases, and neuropsychiatric conditions including depression and anxiety [1]. MCI is recognized as an intermediate phase between a healthy brain state and dementia; however, not all individuals diagnosed with MCI are certain to progress to dementia, and some may even revert to normal life [4]. The progression to dementia is often preceded by subtle difficulties in performing everyday activities [5] and can include diagnoses of subjective cognitive impairment [6], mild behavioral impairment [7,8], and psychiatric disturbances including anxiety [9,10], depression [11-13], and posttraumatic stress disorder [14,15]. Amidst ongoing challenges in developing disease-modifying drugs, nonpharmacological interventions including exercise are recommended as part of the overall MCI management [16] based on the positive effects of exercise on cognitive performance [17-23].

Exercise promotes cognitive improvement [24-32], and individuals living with MCI can participate in various forms of exercise [33,34]. Evidence also supports the notion that exercise interventions have a positive influence on different facets of cognitive function in MCI such as global cognitive functioning [30], immediate recall [22,26-28], delayed recall [26], and executive function [31,32]. However, not all studies report improvements in cognitive performance following exercise training [35-37]. Further, physical exercise may present challenges related to mobility and movement that limit the accessibility of the intervention to all individuals. Nonetheless, physical exercise is an affordable and alternative approach to alleviate symptoms of cognitive decline [17-22,38,39].

Interval training can involve intermittent bouts of exercise performed at either a prescribed or self-determined intensity, interspersed with short recovery periods [40,41]. The latter enables participants to determine their own pace that they deem appropriate and tolerable. They are typically encouraged to identify a pace that is physically challenging and to rate their effort level or perceived exertion. This type of training can be performed by participants with a wide age range who are both healthy and have conditions such as type 2 diabetes [42-44], coronary artery disease [45,46], and obesity [47]. Evidence that aerobic-based interval training can improve cognitive function [24-32] suggests that cognitive improvement could be induced by aerobic interval exercise via upregulation of pathways that promote synaptic plasticity.

Synaptic plasticity involves activity-induced changes in specific patterns of neural activity that alter the strength or efficacy of synaptic transmission, playing a considerable role in the acquisition of information and learning of new behaviors [48]. Synaptic plasticity is modeled by long-term potentiation (LTP) and long-term depression (LTD). LTP increases synaptic transmission as a consequence of high-frequency stimulation of excitatory synapses or the correlation of presynaptic activity and postsynaptic depolarization [48]. In contrast, LTD decreases the strength and efficacy of synaptic transmission [49]. A significant association has been found between LTP, LTD, and age-related cognitive decline. Animal models have shown that reductions in cognition due to age correlate with reductions in the LTP originating in the hippocampus [49].

In humans, synaptic plasticity, and more specifically, LTP-like effects can be assessed in vivo by delivery of transcranial magnetic stimulation (TMS) in protocols called intermittent theta burst stimulation (iTBS) and 5-Hz repetitive TMS (5-Hz rTMS). Both forms delivered over the motor cortex induce LTP-like effects as measured by short-term increases in the efficacy of the corticospinal pathway from cortex to muscle [50,51]. These effects are analogous to animal models of LTP since they are mediated by glutamate and require glutamate binding at *N*-methyl-D-aspartate (NMDA) receptors [51]. In humans, the decline in neuronal excitability and synaptic function seen with aging contributes to memory loss as well as sensory and motor deficits [52]. Thus, in humans, iTBS and 5-Hz rTMS are noninvasive tools to assess whether aging and MCI populations demonstrate synaptic plasticity and whether interventions such as exercise can enhance the magnitude of synaptic plasticity. Compared to age-matched controls, individuals with MCI demonstrate blunted synaptic plasticity as indicated by a reduced response to 5-Hz rTMS [53] and iTBS [54]. These effects are reflected as decreases in motor evoked potentials (MEP) when compared to healthy controls. Healthy controls demonstrate MEP facilitation, as expected, observed by an increase in MEP amplitude during the delivery of a 5-Hz train. In contrast, 5 Hz–induced MEP facilitation is not seen in individuals with MCI, suggesting deficits of glutamate pathways responsible for synaptic potentiation [53]. The delivery of iTBS has yielded similar results in patients with MCI, demonstrating a lack of MEP facilitation [54].

Brain-derived neurotrophic factor (BDNF) is a key regulator of processes crucial for cognition, particularly learning and memory [55-57]. The presynaptic release of BDNF influences

XSL•FO
RenderX

the activation, trafficking, and expression of NMDA receptors as a result of enhanced calcium influx. This calcium influx is thought to allow for the release of BDNF at the postsynaptic terminal. Postsynaptic BDNF release is essential for presynaptic vesicle cycling, which increases synaptic plasticity, ultimately leading to improvements in cognitive functioning [58]. BDNF expression is correlated with cognitive function [57] and is consistently elevated following exercise in healthy older adults, suggesting that the rise in BDNF levels with long-term exercise may reduce mental deterioration in patients with MCI [55].

Exercise increases the secretion of hormones and other factors into the blood from organs such as skeletal muscle, bone, and liver [59-70]. Some of these are known to increase brain BDNF either directly or indirectly. A bone-derived hormone called osteocalcin (OCN), which plays a role in bone mineralization and glucose metabolism, increases following exercise [71-75] and increases BDNF transcription and the number of BDNF vesicles transported to the synapse [76,77]. OCN is carboxylated at 3 different residues and is found in the blood in both carboxylated and partially or fully decarboxylated forms. Acute exercise increases the partially or fully decarboxylated forms of OCN in serum [72-75].

The proposed research will determine whether interval training performed at a self-determined intensity will enhance synaptic plasticity in individuals with MCI. The three aims are to (1) quantify synaptic plasticity after interval training performed at a self-determined intensity in individuals with MCI; (2) determine whether changes in synaptic plasticity correlate with changes in serum BDNF, OCN, and with cognition; and (3) assess compliance to the exercise schedule.

Methods

Screening

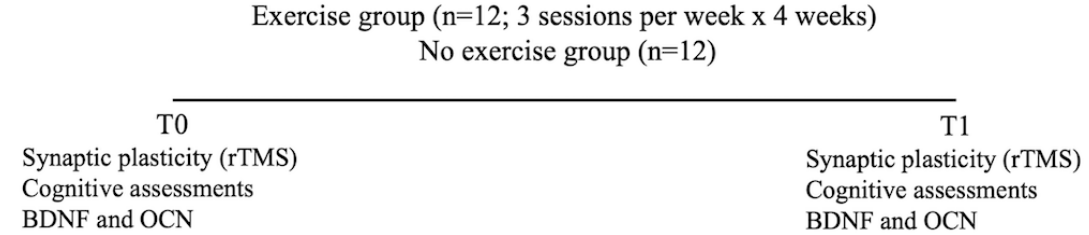
To determine the eligibility of those who have reached out to the study team via advertisements, individuals will be contacted to schedule a phone interview. During the phone interview, individuals will be provided with the details of the study, and eligibility for TMS will be assessed via a TMS screening questionnaire. Individuals will also be asked whether they have been diagnosed by a health care professional or physician with "Mild Cognitive Impairment" or "Mild Neurocognitive Disorder?" If the individual answers "Yes," then they will be asked to provide a written medical note to confirm a diagnosis of MCI at the first scheduled session. In addition, the individual's eligibility to complete the exercise protocol will be assessed using the Canadian Society for Exercise Physiology Get Active Questionnaire (GAQ). If the individual has contraindications to the GAQ, the participant will be asked to contact their family doctor and acquire a medical note clearing them for participation. The parameters of the study, including the procedures and collection measures, will be explained verbally to the participant. If the participant agrees to participate in the study and has no contraindications to the GAQ and TMS screening questionnaire, a time will be arranged for the individual to undergo the experiment. Participants will provide informed written consent on the day of data collection prior to any testing, as well as verbal reaffirmation before each procedure. Researchers will determine the capacity to consent for all participants at the commencement of the study, using a modified University of California, San Diego Brief Assessment of Capacity to Consent questionnaire.

Ethical Considerations

Approval to conduct this study was granted by the Hamilton Integrated Research Ethics Board (ID # 14938) in partnership with Hamilton Health Sciences and conformed to the Declaration of Helsinki. In addition, this study has been registered and approved as a registered clinical trial on clincialtrials.gov (NCT05663918) in December 2022, a World Health Organization (WHO) accredited trial registry.

Power

This pilot study will recruit 24 participants aged 55-80 years old diagnosed with MCI. To determine this sample size, the following features were included in an a priori calculation using G*Power (Heinrich-Heine-Universität Düsseldorf), α=.05, Power (1-β)=0.9, and the effect size was calculated using Trebbastoni et al's findings [53].



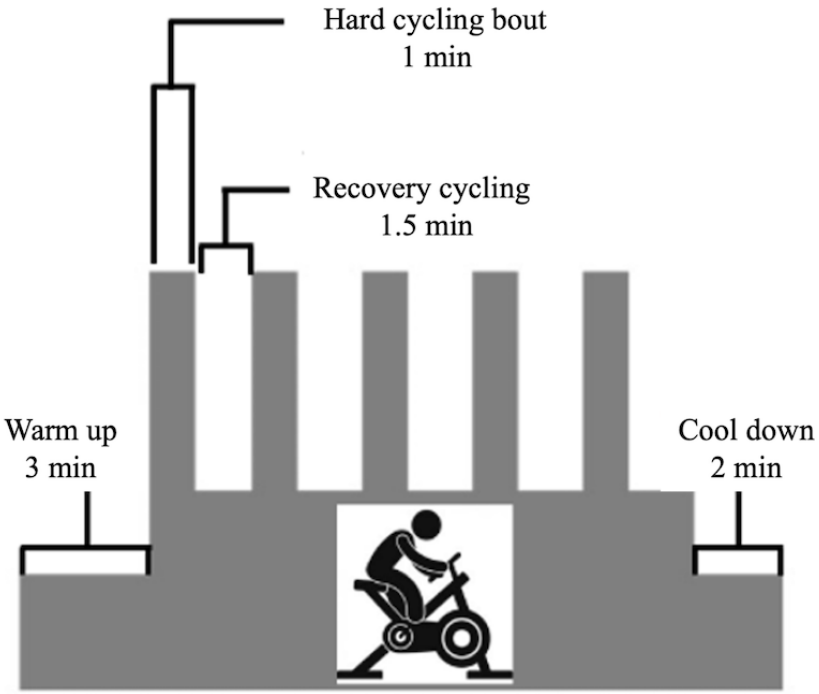
Experimental Design

Individuals will be recruited for assignment to 1 of the 2 equally sized groups: exercise or no exercise. The exercise group will perform the exercise intervention. The no exercise group will serve as the control.

Experimental Protocol

The dependent measures of synaptic plasticity, cognition, and venous blood BDNF and OCN, will be measured before and after the 4-week intervention (Figure 1).

Figure 1. Dependent measures will be obtained in all participants 2-3 days before (T0) and following the exercise intervention (T1). Synaptic plasticity assessed using transcranial magnetic stimulation, cognitive function assessed by neuropsychological battery, and blood draws for serum BDNF and osteocalcin will be performed before and immediately following the intervention. BDNF: brain-derived neurotrophic factor; OCN: osteocalcin; rTMS: repetitive transcranial magnetic stimulation.

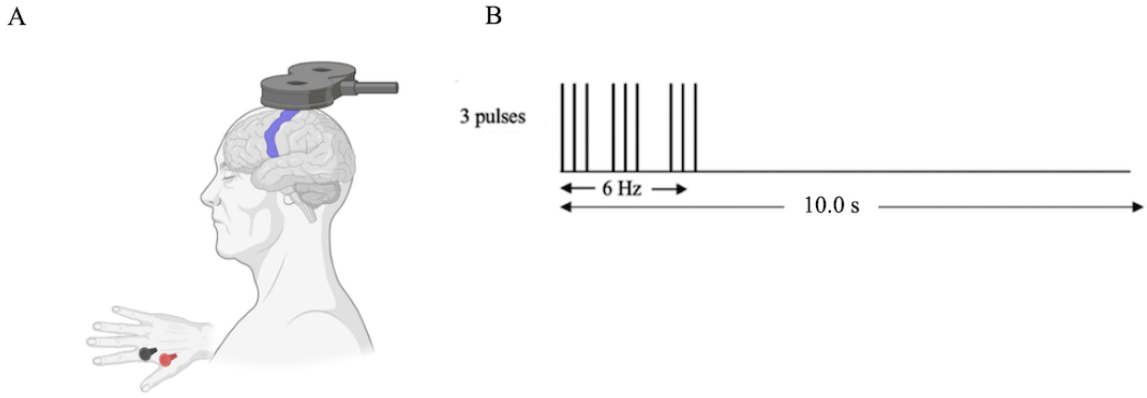


XSL•FO
RenderX

Exercise Intervention

The exercise group will participate in 3 sessions per week of interval training performed at a self-determined intensity, using a cycle ergometer, for 4 weeks (12 sessions), in line with our previous experience in participant retention [41]. Ratings of perceived exertion (RPE) will be measured using Borg's 6-20 scale [78]. Participants will be asked to exercise on a stationary bike at an intensity whereby their RPE is deemed "challenging" to them. The perceived effort and RPE rating will likely be different for participants depending on their initial fitness and exercise tolerance. The important aspect is for an individual to feel that the exercise is challenging. The cycling protocol includes 5 one-minute bouts of maximum effort, interspersed with 1.5 minutes of recovery, which will involve cycling at a light intensity (Figure 2). Participants will also perform a 3-minute warm-up and a 2-minute cool-down for a total exercise duration of 17.5 minutes, as we have described [41,74,79]. RPE will be measured by asking the participant to provide their rating at the end of the last interval.

Figure 2. Self-determined intensity interval training protocol on cycle ergometer to be delivered to exercise group.



Dependent Measures

Synaptic Plasticity

Surface electrodes (9 mm AgCl) will be used to record activity from the first dorsal interosseous (FDI) muscle of the right hand. The active electrode will be placed over the muscle belly. To reduce signal noise, dry ground will be placed on the styloid process at the right wrist. Electromyography (EMG) signals will be magnified ×1000 and bandpass filtered between 20 and 2.5 kHz (Intronix Technologies Corporation Model 2024F). An analog-digital converter will be used to digitize data at 5 kHz (Power1401; Cambridge Electronics Design), prior to being analyzed using commercial software (Signal version 7.01; Cambridge Electronics Design). Repetitive TMS will be performed using a 70-mm inner diameter figure-of-8 coil with a Magstim Super Rapid^2 Plus Stimulator (Magstim). Biphasic magnetic pulses will be delivered over the primary motor area of the dominant hemisphere to find the optimal position for eliciting a MEP in the contralateral FDI muscle [80,81]. The hot spot of the right FDI muscle is defined as the location on the left motor cortex that, when stimulated with rTMS, consistently leads to the largest MEP in the muscle (Figure 3A). This point will be found and registered using Brainsight Neuronavigation and rTMS (Rogue Research).

XSL•FO
RenderX

Figure 3. (A) Transcranial magnetic stimulation will be delivered over the primary motor area of the dominant hemisphere to find the optimal position for eliciting a motor evoked potential in the contralateral first dorsal interosseous muscle. (B) Intermittent theta burst stimulation parameters.

Participants will complete 3 maximal isometric contractions of the right FDI against an immovable structure. The duration of each contraction will be 5 seconds with a 30-second rest interval between trials. The largest EMG activity obtained from any of the 3 trials will be defined as the maximum voluntary contraction (MVC) of the FDI muscle for an individual. The level of EMG activity corresponding to 10% MVC will be displayed on an oscilloscope as a horizontal target line. Participants will be required to match the horizontal target line and maintain 10% MVC by contracting their right FDI during the acquisition of active motor threshold (AMT).

AMT will be defined as the lowest intensity required to evoke a MEP≥200 µV in 5 out of 10 consecutive trials while participants maintain approximately 10% MVC with their FDI [80,81]. This value will be determined using TMS_MTAT_2.0 freeware [82]. The stimulus intensity will be set to 37% maximum stimulator output, and 20 TMS pulses will be distributed over M1, specifically the FDI hot spot, with the stimulus intensity being adjusted after each subsequent pulse as advised by the MTAT software based on the presence or absence of an MEP on the previous trial [83]. Resting motor threshold (RMT) will be defined as the lowest intensity required to evoke a MEP≥50 µV in 5 out of 10 consecutive trials while participants maintaining the FDI at rest [80,81]. This value will be determined using TMS_MTAT_2.0 freeware.

To assess synaptic plasticity, an iTBS protocol (Figure 3B) will be delivered using biphasic pulses in bursts of 3 pulses delivered in 6 Hz trains that will last 2 seconds, followed by 8 seconds with no pulse delivered [50,84,85]. iTBS will be repeated for a total of 612 pulses at 80% of AMT [86]. To assess synaptic plasticity 20 MEPs will be delivered at 120% of RMT. The average of 20 MEPs will be recorded from FDI before and immediately following iTBS.

Cognitive Function

Cognitive functions will be assessed using the National Alzheimer's Coordinating Center Uniform Data Set Neuropsychological Battery, Version 3, comprised of the Montreal Cognitive Assessment, Semantic and Verbal Fluency, Trail-making Tests, Digit Span, Benson Complex Figure Test, and the Multilingual Naming Task.

Brain Derived Neurotropic Factor and Osteocalcin

Blood will be collected after ≥10-hour fast from an antecubital vein at T0 and T1 in red top BD Vacutainer collection tubes (Becton, Dickinson and Company, Franklin Lakes, NJ, USA). Red top tubes will be left to clot at room temperature for 45 minutes and subsequently centrifuged at 3488×g for 10 minutes at 4°C. Serum will be aliquoted into vials and stored at –80°C. Enzyme-linked immunosorbent assay (ELISA) assays will be carried out for the determination of serum BDNF (R&D Systems, Inc, Minneapolis, MN, USA) and total OCN (Human Osteocalcin ELISA kit KAQ1381). After incubation with 5 mg/ml hydroxylapatite (Invitrogen-Thermo Fisher Scientific, Carlsbad, CA, USA) to remove carboxylated OCN [87], serum uncarboxylated OCN will be measured by ELISA. Carboxylated OCN will be determined by subtracting uncarboxylated OCN from the total OCN [74].

Participant Experience

A Likert-type scale (0-4) will be given to participants to rate their enjoyment of the self-determined intensity interval training intervention (exercise group) and the overall research experience during the last visit (exercise and no exercise group).

Compliance

We will quantify the number of participants who demonstrate compliance with the exercise schedule. An individual is deemed 100% compliant if they attend all exercise sessions (3 times per week × 4 weeks=12 sessions). Attendance lower than this will be quantified as a percentage of the total number of sessions (out of 12).

Data Exclusion

Peak-to-peak amplitudes of the MEPs will be collected by the experimenter. Trials will be examined visually, and any trials presenting with EMG activity prior to TMS stimulus artifact will be discarded from the analysis. The remaining EMG data will be analyzed using Signal Software (Cambridge Electronic Design).

Statistical Analysis Plan

To investigate the difference in the magnitude of synaptic plasticity between groups, an unpaired *t* test will compare the percentage change in synaptic plasticity (from T0 to T1) between

XSL•FO
RenderX

the 2 groups (exercise and no exercise). Similarly, the effect of exercise on serum BDNF and OCN levels will be assessed using an unpaired *t* test comparing the change in levels from T0 to T1. Significance will be set to =.05.

Results

As of September 2023, we are currently screening participants for eligibility to participate in the research. We anticipate to complete data collection and analysis by August 2025.

Discussion

Overview

This pilot project is the first to assess changes in synaptic plasticity following a 4-week, self-determined, interval exercise training in individuals with MCI. Individuals will be assigned to 1 of the 2 groups (exercise or no exercise). The exercise group will participate in 12 sessions of exercise across 4 weeks (3 sessions per week). The no exercise group will not participate in the exercise regime, instead, they will be asked to return 4 weeks after their initial visit. Measures of synaptic plasticity, cognition, BDNF, and OCN will be assessed at baseline and 4 weeks later.

Previous research has demonstrated the positive benefits of exercise in individuals diagnosed with MCI. The 12 weeks of resistance training in individuals with MCI improved attention and working memory, and elicited changes in EEG activity [30]. In addition, 2 days of aerobic exercise in MCI subjects improved memory recall [26]. The 12 weeks of aerobic exercise in subjects with MCI improved cognition as reflected by changes in the Mini Mental State Exam [34]. These findings provide evidence that aerobic exercise is capable of modifying cognition in individuals with MCI. It remains unknown whether these improvements in cognition are a result of increases in synaptic plasticity following aerobic exercise.

Our study aims to determine whether synaptic plasticity is modified following 4 weeks of self-determined interval exercise training. Further, we will determine whether any changes in synaptic plasticity correlate with changes in cognition, BDNF, or OCN levels. We anticipate that the exercise group will demonstrate an increase in synaptic plasticity after 4 weeks of exercise compared to the no exercise group. If synaptic plasticity increases in the exercise group, this will be interpreted as a mechanism by which exercise improves cognition in MCI. Further, we hypothesize a positive relationship between a change in synaptic plasticity and measures of serum BDNF and OCN.

A limitation of this study is the use of self-determined interval training, whereby participants determine their own level of exertion. Individuals living with MCI will have varying physical and cognitive abilities which may limit their capacity to perform exercise at an imposed intensity. However, previous research has shown that only individuals who increase their fitness over the exercise period exhibit increased serum BDNF levels [88]. We hope that our approach of tailoring the exercise to the individual will increase the feasibility and retention of the study, thus creating a realistic and effective exercise regimen for individuals with MCI. A second limitation is that we do not consider biological sex or gender in the randomization due to the small sample size. If the study is successful in providing data to support compliance and the exercise regime, it will inform a larger-scale study of exercise training in MCI with biological sex and gender included.

Conclusions

The data obtained from this research study will provide valuable insights into the compliance of a self-determined intensity interval exercise in the MCI population. Exercise provides an affordable and accessible opportunity to promote changes in cognition. This study will determine whether exercise alters synaptic plasticity in a population with impaired cognition.

Abstract

Background: Approximately one-third of patient appointments in Danish health care result in failures, leading to patient risk and sizable resource *waste*. Existing interventions to alleviate no-shows often target the patients. The underlying reason behind these interventions is a view that attendance or nonattendance is solely the patient's problem. However, these interventions often prove to be ineffective and can perpetuate social biases and health inequalities, leaving behind patients who are more vulnerable or disadvantaged (in terms of social, economical, and linguistic factors, etc). A more holistic understanding of no-shows is needed to optimize processes, reduce waste, and support patients who are vulnerable.

Objective: This study aims to gain a deep and more comprehensive understanding of the causes, mechanisms, and recurring patterns and elements contributing to nonattendance at Danish hospitals in the Region of Southern Denmark. It emphasizes the patient perspective and analyzes the relational and organizational processes surrounding no-shows in health care. In addition, the study aims to identify effective communicative strategies and organizational processes that can support the development and implementation of successful interventions.

Methods: The study uses mixed quantitative-qualitative methods, encompassing 4 analytical projects focusing on nonattendance patterns, patient knowledge and behavior, the management of hospital appointments, and in situ communication. To address the complexity of no-shows in health care, the study incorporates various data sources. The quantitative data sources include the electronic patient records, Danish central registries, Danish National Patient Registry, and Register of Medicinal Product Statistics. Baseline characteristics of patients at different levels are compared using chi-square tests and Kruskal-Wallis tests. The qualitative studies involve observational data, individual semistructured interviews with patients and practitioners, and video recordings of patient consultations.

Results: This paper presents the protocol of the study, which was funded by the Novo Nordisk Foundation in July 2022. Recruitment started in February 2023. It is anticipated that the quantitative data analysis will be completed by the end of September 2023, with the qualitative investigation starting in October 2023. The first study findings are anticipated to be available by the end of 2024.

RenderX

Conclusions: The existing studies of nonattendance in Danish health care are inadequate in addressing relational and organizational factors leading to hospital no-shows. Interventions have had limited effect, highlighting the Danish health care system's failure to accommodate patients who are vulnerable. Effective interventions require a qualitative approach and robust ethnographic data to supplement the description and categorization of no-shows at hospitals. Obtaining comprehensive knowledge about the causes of missed patient appointments will yield practical benefits, enhancing the safety, coherence, and quality of treatment in health care.

Introduction

Background

Approximately one-third of all scheduled appointments at Danish hospitals do not succeed—that is, they are unattended by the patients [1]. An unattended or "missed appointment" is "when a patient does not show up for a scheduled appointment without sufficient notification, or any notification at all" [2,3]. At Odense University Hospital (OUH), for instance, every 20th patient does not show up for outpatient visits [1]. At Hospital Lillebælt, 12,424 cases of no-shows were registered during the first 7 months of 2018, which corresponds to approximately 4% of all appointments [4]. In the Capital Region, every fifth patient misses their hospital appointment [5]. No-shows are expensive owing to the large waste of resources that they entail. A single no-show costs health care between DKK 1500 and DKK 2000 (approximately US $227 to US $235). Bispebjerg Hospital spends DKK 40 million (approximately US $6 million) on nonattendances annually, whereas OUH spent as much as DKK 2.4 billion (US $380 million) on nonattendances in 2010 [6]. More importantly, no-shows increase the risk of patient errors and may seriously complicate patient treatment and continuity of care [7]. According to a Danish national report, "patients who do not show up for planned examinations, operations, etc., are a problem for the efficient use of resources in the healthcare system. It prevents other patients from arriving earlier, wastes staff time and prevents technology and operating theaters from being optimally utilised" [8].

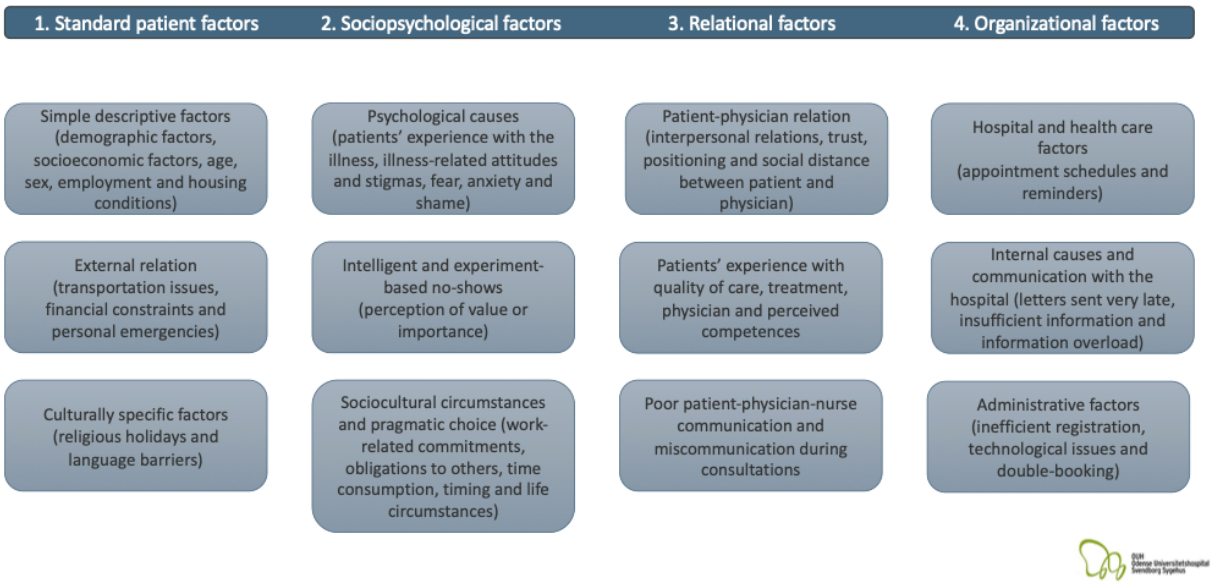
The large number of no-shows for treatment in Danish hospitals has led to a lively debate among Danish politicians and in the daily press. So far, however, most papers that have addressed no-shows in outpatient and hospital appointments adopted an organizational perspective, ascribing no-shows to the faulty behavior of the patients (hence, referred to as "nonattendance"). It is the patient who "does not show up for hospital appointments," "has forgotten to cancel an appointment," or "is unable to show up for an appointment for other reasons" [5]. This is despite the fact that practices surrounding nonattendances vary significantly across various hospitals and sectors. At some clinics, it will be categorized as a missed appointment if a patient is at least 5 minutes late [2]. Such framing of the problem draws our attention toward individual behavior and no-shows as responsibilities of the patient and away from the structural and organizational shortcomings, which are responsibilities of the health care system. This perspective has been widely accepted among Danish policy makers, administrators, and health professionals, who generally view no-shows as a problem caused by patients. Some, for example, have suggested putting nonattending patients at the back of the queue for examination and treatment or giving them fines [9,10].

Most interventions to reduce nonattendance in Danish hospitals and outpatient clinics therefore target the patients: the introduction of web-based appointment systems, reminders via SMS text message, reminder letter, and so on. In Denmark and Great Britain, attempts have also been made to give the nonattendant patients fines. However, interventions such as fines are based on a lack of understanding of the health care system's own role in missed appointments, and their effect is limited [11]. Other studies have claimed that up to 40% of nonattendances in health care are actually caused by errors on the hospital's side [12,13]. It indicates that the many failures to attend hospital appointments may rather be "a symptom" of the shortage within the health care system itself to adequately accommodate patients who are more vulnerable. By "vulnerable patients" we mean those patients who have a low social capital or who belong to marginalized or socially excluded groups because of factors such as ethnicity, age (older people), language, low education level, low income, unemployment, housing conditions (eg, people experiencing homelessness), drug and alcohol addictions [14], people with complex illness (eg, type 2 diabetes) [15], and those individuals who do not have the capacity to take care of themselves (eg, children, people who are physically and mentally disabled, and people with mental illnesses) [14]. Vulnerability may also arise as a result of misunderstandings that lead to failure to fulfill the patient's needs. In other words, it arises in the encounter between the physician and the patient, for example, as a result of misunderstanding or dissimilar points of departure or beliefs for the patient and the physician or health system, or forms of treatment [16].

Despite this, we found no documented interventions that target the health care causes for missed appointments. In the numerous attempts to reduce nonattendances at hospitals in Denmark, the patients' perspective has also been lacking, and in general, we have very sparse knowledge about how relational and clinical factors affect patients' no-shows. National, empirical studies of relational and organizational causes of nonattendances are practically nonexisting. Most no-shows in the Danish health

XSL•FO
RenderX

care system are registered automatically but rarely with documentation of the cause. The causes of nonattendance in, for example, electronic patient records (EPRs), which are a platform that integrates electronic health records from hospitals [17], are not fully documented or not documented at all. The EPR only provides response options that deal with patient causes—not the administrative or clinical causes.



Previous studies that adopt the health care system perspective (with its fundamental understanding that patient are the ones who fail to attend hospital appointments) primarily focuses on (rather limited) sociodemographic descriptions of the patients who "do not show up" for hospital appointments (age, employment, socioeconomic status, ethnicity, etc). Furthermore, many studies have inadequate documentation or ambiguity regarding the reasons for these missed appointments. In addition, only a small number of studies have explored the patient perspective about this issue. Consequently, there is a lack of *a substantial body of research* that adequately explains the reasons behind no-shows. Our aim is to delve deep into the patient perspective and provide a more comprehensive understanding of no-shows at Danish hospitals.

Determinants of Nonattendance (Literature Review)

Overview

This project builds on previous studies of missed appointments or nonattendance and related interventions in hospitals and outpatient settings. Both Danish and international studies were included. In our review of literature, we have singled the following 4 key groups of factors and circumstances of "nonattendance" (refer to Figure 1).

Figure 1. Determinants for nonattendance.

Standard Patient Factors

A large number of studies of no-shows or nonattendances in health care—and particularly no-shows at Danish hospitals and outpatient clinics—focus merely on describing standard patient factors (such as age, sex, education, employment, etc), showing that there is a correspondence of nonattendance with sociodemographic factors such as age, ethnicity, sex, illness, insurance coverage, poor residence areas, socioeconomic status, timing of the appointment, travel time, transportation to and from hospital, and so on [18,19]. According to a Danish study, patients who fail to attend appointments are young people aged between 17 and 40 years, and they come from socially disadvantaged groups or from low-income housing areas, are unskilled, and have a high rate of unemployment [8]. The combination of long transport time and low income or low education are particularly intensifying when it comes to nonattendance [20]. Patients on social benefits, those with low income or short education, and those who have difficulty in finding transportation means (eg, lonely people) are also more likely to miss their appointments and have significantly more absences. Language (eg, patients who do not have Danish as their first language) and specific circumstances, such as religious holidays, may also be associated with nonattendance [8,19,21].

Sociopsychological Factors: Patient Knowledge, Risk Balancing, and Pragmatic Choice

Few qualitative studies of nonattendances similarly point toward themes such as balancing the costs and benefits of the individual attendance (intelligent compliance), lack of trust in the health care system, obligation to other people, stigmatization, anxiety, and patient's attitudes toward the health care staff and toward illness as possible causes of no-shows [22,23]. Studies of nonattendances among patients with chronic disease [23-26], for example, show that there is a direct connection between nonattendance and the patient's knowledge, attitudes, and behavior in relation to illness (eg, the patient's feeling about whether the medicine is working, the patient is not satisfied with the treatment, or the patient does not trust the physician's skills). Stigmatization (eg, obesity stigma) and shame can also act as barriers to comprehensive and effective treatment of type 2 diabetes and can be significant reasons for the patient's no-show for the appointment [27]; health-related anxiety was a primary factor in decisions to discontinue long-term follow-up care among young survivors of cancer [28]. The patient's

XSL•FO
RenderX

willingness and unwillingness to meet up for hospital appointments may similarly depend on the patient's relation with and obligations toward other people (that are framed by norms and beliefs within a particular society), patient's previous experiences with and trust toward the health care system [29], perception about own position in relation to the physician's position and skills [30], and diagnosis [31]. Patients who are vulnerable may further lack the resources and social support they need to establish and maintain their appointments [28,30]. A recent Danish report on social inequality in health care encounters also shows that there are considerable differences in patients' skills and opportunities to search for health information themselves and absorb knowledge about health and illness, partly because patients with low socioeconomic status have low degree of social and cultural capital, which gives them few opportunities to seek knowledge via different sources, for example, internet, professional sources, and social networks [30]. Thus, in contrast to standard patient factors (age, education, housing, and ethnicity), this category is more about the interplay between the sociocultural and psychological factors (eg, moral values, obligations to others, fear, anxiety, and stigmas related to illness) and practical constraints that can influence peoples' pragmatic choice and capacity to attend a hospital appointment.

Relational Factors, Quality of Patient Consultations, and Patient's Relation With the Treating Clinician

Relational factors relate to social interactions and communication in patients' encounters with health professionals. It encompasses elements such as patients and health professionals' competencies, attitudes, and expectations toward the encounter and other communicative mechanisms that create social distancing and distrust between patients and health professionals [30]. The role of the quality of patient-physician conversations and the relationship that clinicians and the patient have before no-show has not been investigated in the Danish context. However, international studies have shown that the patient's perceptions about the treating physician may play an important role in nonattendance [32,33]. Clinical psychologists' patients had the lowest proportion of nonattendances (7.8%), followed by consultant psychiatrists (18.6%), specialist registrars (34%), and senior housekeepers (37.5%) [34]. Some referring physicians have significantly more nonattendances than others, just as patients who are treated by the youngest physicians are most likely not to show up for their appointments [35]. A large study from Australia showed that 50% of patient compliance is related to trust toward the treating physician [36], whereas other studies have shown that the failures to attend appointments were caused by insufficient communication from the physician, for example, when the physician did not explain sufficiently why the given appointment is important for the patient [33].

Organizational Factors and Errors in Hospital Communication

Organizational factors relate to the organization of the health care system and how the conditions in the system enable or prevent the accommodation of some patients [30]. International studies, for instance, reveal that minimum 35% to 40% of nonattendances at hospitals are caused by errors on the part of the hospital—errors in administration of patient appointments (letters not sent, wrong times, wrong bookings, wrong appointment places, changed agreements, very short notices, etc), insignificant or redundant hospital appointments, lack of availability, insulting behavior or speech, slow mail correspondence, and other administrative matters for which patients are not accountable [12,37,38]. A study of nonattendance at surgical control after trauma hospitalization showed, for example, that 37% of nonattendances were solely owing to the lack of communication about the appointment between the surgeon and nurse or between the medical team and the patient, which resulted in miscommunication [39] and not because the patients simply forgot the appointments, as other studies have claimed [40]. Another study claims that 41% of nonattendances are caused by errors on the part of the hospital [41].

The nonattendance rates can also differ significantly among different hospitals and among different units at the same hospital. The nonattendance rate in medical outpatient clinics in Denmark is 12% to 13% compared with 16% to 20% in England [41], and some specialties (eg, orthopedic surgery and type 2 diabetes) are systematically overrepresented among the high nonattendance rates, whereas others most often have low nonattendance rates (eg, in cancer treatment). Although it can be difficult to compare the nonattendance rates across units, both because the percentage can be estimated differently (per patient or per course of treatment and ≥1 nonattendances/course of treatment) and because there is a significant difference in the severity of illness (for instance, being a patient with cancer; being a patient with a chronic illness such as diabetes; or having a disease burden owing to, for example, multimorbidity) [26,42], we see that in chronical specialties, patients with low attendance compliance weigh heavily, whereas very few patients are represented in repeated rehospitalizations [41].

There is also evidence suggesting that comorbidity, an increased number of relationship problems, difficult consultations, and the lack of attendance affect the continuity of care [7,43]. Among the factors that prevent patients from attending, for example, asthma assessment consultations at hospitals are memory loss, reduced mobility owing to poor health, and frustration over the organization of the clinic that results in long waiting times and interruptions of treatment [44]. Attachment is also important for shaping and understanding the clinician-patient relationship and is essential for adherence to treatment and continuity of care [45], whereas social networks can be decisive when it comes to supporting patients who are vulnerable [46].

All of this supports our claim that nonattendance is a complexly determined behavior and is not something purely driven by the patient. To understand this complexity, we therefore need to look beyond purely descriptive patient factors and pay more attention to relational and organizational aspects of health care encounters that may result in no-shows. To further understand cognitive processes (decision-making) behind no-shows, we also need to investigate the relationship between the sociopsychological factors and pragmatic conditions and the patient's conceptual representations (knowledge and values) that influence the generation of no-shows. Such knowledge may also help to develop prevention approaches and interventions

XSL•FO
RenderX

that are appropriate and relevant—that is, target specific causes for no-shows within a particular context and setting.

Interventions That Enhance Attendance

Interestingly, interventions targeting the specific causes for nonattendance at outpatient and hospital appointments work and can significantly reduce the number of nonattendances. We know of 5 well-documented, simple interventions that can reduce nonattendances at hospitals and ensure equality [41,47-49]. However, most interventions related to nonattendances are aimed at patients (they receive a reminder, can book an appointment themselves, or they receive a fine for not showing up) and are not related to the errors and deficiencies triggered by the health care system. A hand surgery clinic, for example, established an open outpatient clinic unit, where patients who missed to attend an appointment could themselves book a new appointment, thereby reducing nonattendance from 16% to 11% [41], whereas the pediatric ward in Viborg achieved analogous results by changing their guidelines and introducing a reminder via SMS text message [48]. A Cochrane review documents that SMS text message, e-mail, postage-paid reply envelopes, and self-booking outpatient clinics all significantly reduce nonattendances [50,51].

In Denmark, different hospital units are currently introducing web-based appointment systems to give patients more responsibility and better opportunity to make decisions about their appointments. Nevertheless, according to the staff, some patients experience barriers related to using web-based booking systems (low computer skills, ignorance of the web-based appointment, distrust of the internet, preference for verbal communication, etc) and may therefore be reluctant to use the system [52].

Having knowledge about the experiences and needs of the specific target group and in-depth insights into organizational processes and methods for creating relationships with and for the patient is, therefore, crucial not only for understanding why health care appointments fail but also for improving patient compliance and continuity of care and for supporting interventions that work well.

Aims of the Study

The intention of this project is to provide a deep and more comprehensive understanding of the causes, mechanisms, and recurring patterns and elements contributing to nonattendance at hospitals and outpatient clinics in Denmark. The key objectives are (1) to describe the pattern of nonattendance and patients' experiences thereof, (2) to identify managerial practices and interactional strategies that work or do not work well, and (3) to identify personal factors and administrative processes that can predict nonattendance and that can support appropriate implementation effort. Keeping this in mind, we ask the following research questions:

1. How do patients explain why they miss their hospital appointments?
2. What is the role of the quality of patient consultation and the physician-patient relationship before nonattendance for whether the patient attends their appointment?
3. How are no-shows handled by hospitals and medical professionals; what actions are taken (or not taken); and how does it affect the outcome, communication, time, and workload?
4. Which interventions do questions 1 to 3 offer possibilities for?

We, thus, put emphasis on some of the determinants presented previously and adding new ones, as we collect both quantitative and qualitative data. To pursue the research objectives, we propose a mixed methods design that combines research methods from health science, anthropology, cognitive science, humanistic interaction research, health care communication, and translational science.

Methods

Overview

Given that the goal of the project is to enhance an understanding of the problems and opportunities associated with missed hospital appointments, it is essential to grasp both the general patterns regarding the occurrence of patients' nonattendance in Danish hospitals, which are available and hold significance from an epidemiological and biostatistical perspective. In addition, we must delve into the atypical instances and trends of no-shows, which come to light through the use of ethnographic approaches. To address these goals, the project uses a mixed quantitative-qualitative approach and is divided into three phases:

1. Quantitative data collection and analysis
2. Qualitative data collection and analysis, organized into 3 subprojects
3. Identifying prevention strategies

In the first phase of the project period, the focus is on quantitative analysis. We will identify the recurring patterns of no-shows in the Region of Southern Denmark and the patients and hospital units eligible for the qualitative studies in the second, qualitative phase of the project. In the last phase, the achieved knowledge will be used to identify relevant prevention strategies and to design context-based, evidence-driven interventions that target specific causes of no-shows (refer to Figure 2 for an overview of the project design and aims of the study).

XSL•FO
RenderX

Figure 2. Overview of the project design and aims of the study.

Quantitative Data Collection and Analysis

Description of the Study Population

The study population of this project comprises all patients who are residents in the Region of Southern Denmark and who were referred with at least 1 contact to a hospital in the period between January 1, 2018, and December 31, 2022. Patients who do not turn up for an appointment owing to death or immigration will be excluded from the study population.

Data for Analysis

To describe the patient population and the pattern of nonattendance, we will retrieve a series of information including the patient's age, sex, diagnostic codes for hospital contact, weight, height, smoking status, alcohol consumption, and information about planned and performed hospital examinations and treatments. In addition, we will investigate whether the patient's other personal factors, such as cohabitation, number of children, working status, socioeconomic status, and medical history affect the risk of nonattendance. Nonattendance at hospital appointments is our primary interest. Information about nonattendance will be retrieved from the EPR system. Information about planned and performed examinations are to be applied as explanatory background variables. This information will be retrieved from the EPR system. Information from the Danish central registries for all patients in the study population will be used to retrieve information about the civil and vital status of the patients and about immigration and emigration from the civil registration system. Furthermore, we will retrieve information about all previous hospital contacts from the Danish National Patient Registry and about prescriptions from the Register of Medicinal Product Statistics. The central registers from Statistics Denmark are tools for retrieving information about the patients' socioeconomic status and additional background variables.

Statistical Analyses

We will divide the patient population according to the nonappearance patterns on several levels: hospital level, department level, disease diagnosis level, and calendar time. The patient characteristics will be assessed according to these levels. We will use descriptive and more advanced analyses. *Chi-square tests* and *Kruskal-Wallistests* will be used to compare the baseline characteristics of the patients across different levels. To estimate the odds ratio for nonattendance, we will conduct both univariate logistic regression analyses and multivariate logistic regression analyses, where we will adjust for various combinations of adjustment variables (including age, sex, socioeconomic status, type of underlying disease, and cohabitation).

Qualitative Data Collection and Analysis, Organized Into 3 Subprojects

Description of the Study Population

The project uses the open approach, which means that units, medical professionals, and patients who are to be included in the qualitative study will be obtained through quantitative analysis. On the basis of the current picture, we will identify and investigate units (and practitioners) that are similar in clinical specialty but that lay on the opposite side of the spectrum regarding no-shows. We will further identify those patients whom we will follow throughout the course of their treatment and with whom we will conduct individual interviews to identify some important barriers and facilitators (even if we do not get hold of those patients who score highest on the no-show). To include ethnic minority individuals, an additional subgroup will be chosen among patients with an ethnic minority background who have been referred to the Migrant Health Outpatient Clinic at OUH during the same period. Ethnic minority individuals are often underrepresented in clinical studies [53] but are, as a rule, overrepresented among the

XSL•FO
RenderX

nonattendances in survey studies—and often for reasons other than those of the majority population: the lack of knowledge about the purpose of control appointments, lack of reading skills, poor economy, transport barriers, and interpreting fees—that is, the fee that the patient has to pay for having an interpreter present during the consultation—are among the key reasons [54]. The inclusion of ethnic minority individuals is vital and will help to secure great validity and equality of the study. Only patients who agree to participate in the study will be included. Patients who die or move during the study period will be excluded from the study, unless we have obtained the necessary data.

Data for Analysis

To achieve more comprehensive data about missed appointments, we will investigate patient knowledge, attitudes and experiences related to missed appointments and identify to what extent organizational factors (tight day programs, excessive documentation, lack of time, etc) and relational dynamics (interpersonal relations between patient and physician or nurse, trust, empathy, attitudes, etc) contribute to the generation of no-shows and shape the pragmatic choice [55,56] and ways in which information is administrated and provided to the patient. It will provide a deep understanding of patient-related and disease-related factors, interactional dynamics, and organizational processes, which cause patients to miss their appointments at Danish hospitals and outpatient settings in the Region of Southern Denmark. It will also identify the role that the quality of patient consultations and the patient-physician relationship before nonattendance plays in the success or failure of attendances. This will help secure appropriate practices at hospitals and support the development of interventions based on situated data and the reasons for nonattendance. To meet the key goals, the qualitative part is divided into 3 independent but interrelated subprojects, focusing on patients' knowledge, attitudes, and behavior (subproject 1); decision-making and management of hospital appointments (subproject 2); and interpersonal relations and communication (subproject 3).

Subproject 1

The *patient's knowledge, attitudes, and behavior* subproject will examine the patient's lived experiences and perceptions about the quality and course of treatment and their reasons, motives, and motivations for not showing up for hospital appointments by drawing on patient-reported outcome data about physical and mental health symptoms and quality of life and on in-depth semistructured qualitative interviews with selected patients [57,58]. To help secure patient perspective, the analysis of the project involves patient and relative representatives who are members of the research committee at the Centre for Clinical Epidemiology and of Center for Research Together with Patients and Relatives (*Center for Forskning Sammen med Patienter og Pårørende*; ForSa-P) [59] throughout the study to discuss and comment on the main aspects of the study. They will receive upgrades of the study progress on a regular basis and will be included in the evaluation of study results and relevance. To include ethnic minority patients and gain insight into their experiences with hospital agreements (and possible side effects), 3 separate focus group interviews with patients referred to the Migrant Health Outpatient Clinic at OUH during the same period as the main cohort will be conducted. We will focus on patients within 3 different languages and ethnic backgrounds, as these will overlap for most participants: Arabic, Somali, and Farsi or Turkish, as these immigrant groups are the largest within the Danish context. The number of participants for each group will be limited to 8. The focus groups will be facilitated by a Doctor of Philosophy student and conducted with the assistance of an interpreter and will focus on barriers related to and implications of no-shows experienced by those patients.

Subproject 2

The *decision-making and management of hospital agreements* subproject will explore how no-shows are managed by hospitals, hospital units, and medical professionals and the implications it has for the number of registered cases and for the frequency of nonattendance. A Danish study has claimed that the health care system's capacity to accommodate some patients often relates to the limited resources within the health care system and may be explained by, for example, the time that is available for health professionals, their educational prerequisites for communicating with socially (and ethnically) diverse patients, and their knowledge about the available referential options and offers, which places demands on patients and any relatives to be able to navigate their course of treatment themselves [30]. The experience from a pilot study at OUH further shows that the management of hospital agreements often lies with the individual physicians and that certain structural factors (tight day programs, excessive documentation, and lack of time) can prevent the individual physicians from examining the individual cases further or contacting the absent patients. Moreover, physicians often use time to attend to other tasks. This raises the question about whether the time lost as a result of no-shows is actually wasted or whether opportunities arise instead to solve other tasks, such as, for example, documentation of patient progress or professional sparring.

To document how patient appointments and no-shows are managed locally (ie, when is the patient registered as "absent"; has the patient been contacted via phone and by whom; how many times should the patient be registered as "absent" before the case is closed; who closes the case; and what are the strategies, norms, and procedures; and what are the challenges?), this study will rely on systematic observations applied in cognitive ethnography [60,61]. Observation at the reception desk will be conducted by a research assistant or postdoc at 4 hospital units, identified in the first phase. They will be integrated into the clinic for a period of 1 month at each unit [58,60,62], producing a running record of mundane practices surrounding no-shows. To supplement observational data and secure their validity, the researcher will conduct individual semistructured ethnographic interviews [63] with medical secretaries and other medical professionals at each unit, to investigate their attitudes and how they handle no-shows (approximately 5-10 interviews at each site or unit, depending on the size of the unit). The study will be conducted in collaboration with the units, and the core informants will be identified by the researcher, in collaboration with the management team, in the course of fieldwork. We anticipate

XSL•FO
RenderX

that the examination will enable us to identify gaps in the statistical data and provide insight into which actions are taken in connection with such situations. Administrator perspective can further provide key insights into organizational factors that influence no-shows. It can also help outline best practices, that is, define the managerial strategies that work best.

Subproject 3

The *interpersonal relations and communication* subproject will focus on patient consultations and examines how clinicians communicate with the patient in situated, real-time, real-life interaction. Communication (how we meet the patient; whether we manage to listen, communicate interest and care, and create security and trust; etc) is crucial to how patients experience their encounter with the health care system. Communication can both help to address nonattendance and cause it. It may also produce social inequality, for example, owing to patient's ethnicity, poor hygiene, or poor language skills [64] or owing to social distance between the patient and the treating physician [31], which may then contribute to the patient's no-shows. Subproject 3 seeks to examine the communicative strategies that may influence the patient-clinician relationship and trust (eg, time to listen, ability to read the patient or communication cues, ability to include and recognize the patient and the patient's needs, interruptions, etc). In contrast to subproject 2, which aims to map managerial strategies and challenges within respective hospital units and therefore focuses on communication more broadly ("a focus on equal access to care for all") than the patient-clinician relation, the objective of subproject 3 is to understand the extent to which the quality of patient consultation and the patient-clinician relationship (in particular, the one before no-show) plays a role in nonattendance. It therefore focuses more specifically on situated interactions and observations of live medical appointments between providers and patients, which can be examined through the application of video ethnography [65] and interpersonal dynamics that can contribute to a positive (or negative) dialectic relation between the clinician and the patient [66,67]. The video consultations will be conducted at 2 chosen hospital units, which will be identified based on quantitative analysis. The anticipated size of video sample is 60 to 100 patient consultations, depending on the number of participating units and medical professionals and the obtained consent. Combined with statistical data about the frequency of no-shows, these data may enlighten our understandings of the relational aspect of nonattendance. It may also help us to identify the strategies that work well.

Analytic Tools and Procedures

The 3 subprojects will share a common data pool consisting of ethnographic observational data (field notes), individual interviews with patients and practitioners, questionnaires regarding the patients' satisfaction with consultations or patient-reported outcomes, and video recordings of patient consultations. In the analysis of the data, we rely on phenomenological-hermeneutic tradition [58] and the thematic analysis used in traditional ethnography [68,69] and medical anthropology [33,70,71] and on cognitive ethnography [72], which is a method for studying distributed cognition in organizational contexts. A distributed approach means that cognitive processes (eg, decision-making) are examined in relation to the sociocultural context in which they occur, as opposed to classical approaches focusing on mental processes in individuals [60]. A cognitive ethnographic approach provides an opportunity to scrutinize both the conditions and the implications that the cognitive processes have in a particular organization. It allows to scrutinize no-shows as a dynamic dialogical process, that is, something that unfolds in the interaction among the patient, the health care professionals, and the environment. Cognitive ethnography can also provide insights into existing challenges in coordination of, for example, patient agreements across hospital units and across sectors (sector transition) and can be particularly useful in addressing situated choice and decision-making regarding no-shows. We analyze experiences, perceptions, and behaviors through the lens of medical anthropology, identifying the key themes, recurring patterns, variations, and contradictions within and across the data [73]. We draw on cognitive ethnography [74-78] when analyzing how no-shows are managed in the clinical setting [75]. In our analysis of video data, we rely on multimodal interactional analysis [79] and on embodied participation framework [66,80]. To better understand the multifaceted aspects of interaction, we treat consultations as a multiactivity setting, where people engage simultaneously in >1 activity, involving "complex configurations of spatiality (built spaces that both afford and constrain), materiality (objects, artefacts, tools, representations, etc), and participation (varying levels of involvement, shifting orientations, and more)" [66]. Taken together, the ethnographic data will provide more comprehensive knowledge about the reasons, patterns, and processes behind no-shows.

Identifying Prevention Strategies

This study intends to use a *positive deviance* approach to ensure the translation of the research to practice. The positive deviance method recognizes that within any society or organization, certain individuals or groups exhibit exceptional behavior and strategy that enable them to find better solutions to problems, despite having access to similar resources and facing similar or worse challenges. In other words, it focuses on those individuals (and, in our case, medical teams and hospital units) who demonstrate exceptional performance, despite facing the same constraints as others [81]. Positive deviance approach is increasingly used in health care organizations because it has the potential to solve many of the challenges faced by the organizations in the effort of enhancing quality [82]. A four-step process has been proposed to apply the positive deviation approach in health care: (1) positive deviations are identified using routinely collected data; (2) qualitative methods are used to generate hypotheses about how positive deviants succeed; (3) these hypotheses are tested in large, more representative samples; and finally, (4) the successful, positively deviant practices are widely disseminated [81,83].

Consistent with this approach, this part of the project aims to use the collected data to identify units, clinics, and individuals that exhibit exceptional performance and to identify practices and strategies that work well. Subsequently, a pilot study will be designed to test the effectiveness of the identified prevention strategies.

RenderX

Ethical Considerations

As of January 2023, the study was registered with the Danish Data Protection Agency—Datatilsynet (registry ID 22/54791) and with the Open Patient Data Explorative Network (registry ID OP_1800). Request for ethics approval was sent to the Regional Committees on Health Research Ethics for Southern Denmark [84]. The request has been given the case number 20222000–133. On October 26, 2022, the committee replied that, based on the available information, the committee has assessed that the project could not be considered as health science research with an obligation to report to the Health Research Ethics Committee System, as found in Committee Act Article paragraph 14, section 1. In the decision, emphasis has been placed on the fact that it appears to be a quality development project, where the trial-related procedures cannot be considered as an intervention within the meaning of the Committee Act. The project, therefore, falls outside the scope of the Committee Act's definition of a reportable health science research project. Pursuant to the Committee Act Article paragraph 14, section 2, questionnaire surveys and register-based research projects must only be reported to the Research Ethics Committee System if the project includes human biological material. If a health research project is to fall within the framework for reporting to the committee system, the project must, as found in the guidelines from the National Committee on Health Research Ethics, both have a health scientific purpose and involve intervention.

Results

Given that this paper is a study protocol, we do not yet have any results to report from the study. The study was funded by the Novo Nordisk Foundation and will be conducted for a period of 48 months (January 1, 2023, to December 31, 2026). The original title of the research application, funded by the Novo Nordisk Foundation, was "Non-attendant or not invited? A cross-disciplinary study about why healthcare appointments fail and how this can be prevented." As of January 2023, the request for permission to use information from patient records has been directed to the Region of Southern Denmark [85], in accordance with the Health Act (Sundhedsloven) Article §46, section 2, and Article §47, section 1. Recruitment commenced in February 2023. It is anticipated that the quantitative data analysis will be completed by the end of September 2023, with the qualitative investigation beginning in October 2023 and the first study findings being available by the end of 2024. An overview of the project timeline and key activities is presented in Figure 2.

Discussion

Expected Outcomes

We are proposing an ambiguous study design, combining national registries and EPR with a longitudinal ethnographic study to explore a broad range of no-shows management, patient-specific experiences, and relational dynamics that cause no-shows. Rather than focusing on purely descriptive factors, this study rests on the idea that "nonattendance" is a complex problem—it implies societal and communicative or interactive challenges that are also tied to relational, sociocultural, and organizational factors. It further assumes that the long-lasting, narrow focus on the patient as the major problem and the key cause for nonattendance has prevented effective interventions to reduce the nonattendance waste, and it has produced more inequality with respect to patients, who are vulnerable; lack resources; or have previously been overlooked, excluded, or stigmatized.

The study aims to fill the major gap of knowledge about no-shows in the Danish health care context. It addresses structural, relational, and pragmatic dimensions of no-shows to provide a broad and more operational knowledge base for unsuccessful encounters between patients and health care professionals. In addition to providing a holistic picture of no-shows within the Danish context, this study also aims to identify the personal and organizational factors and administrative strategies that work well. We anticipate that such knowledge will yield significant practical advantages for health professionals and can be foundational in scaffolding better-informed development and implementation of interventions and prevention approaches.

Limitations

Obtaining comprehensive and reliable data about no-shows can be challenging. The weakness of this study is that the registration of no-shows varies significantly across hospitals and even among units within the same hospital, and the quality of the data is not known. Hospital records may not always accurately capture the reasons for nonattendance, making it difficult to assess the underlying factors. Moreover, self-reported data rely on individual perceptions, attitudes, and beliefs. It may be biased and may not always provide an objective view of the reality [58,68]. To achieve more valid data, we combine methods such as ethnographic interviews [58], focus group interviews [86], systematic observations and video ethnography [65].

Implications for Practice

The project will offer a methodological and empirical contribution to health science, humanities scholars, and medical professionals. It will contribute new insight by involving the patient perspective and analyzing the relational and organizational processes around no-show at hospitals and outpatient clinics in the Region of Southern Denmark. By incorporating various data sources and by linking national registers, EPR data, and patient satisfaction questionnaires with rich ethnographic (and video) data, it will create a comprehensive and multifaceted data pool. Taken together, these data will strengthen Danish health care by providing new and more comprehensive knowledge about the reasons, patterns, and processes behind no-shows. More comprehensive knowledge about problems and intervention possibilities (1) can partly be used to make predictions about nonattendances; (2) can help to identify interventions grounded in specific causes that trigger failures at hospital appointments; and (3) can identify patient perspectives and strategies that can lead to interventions in health care interaction with patients who are vulnerable, where the risk of misunderstandings and missed appointments is high. This will yield significant practical advantages at least in 4 different ways, with potential for creating more appropriate and effective interventions. It will allow us to do the following:

XSL•FO
RenderX

1. Identify specific areas within the health care system where interventions can be implemented to reduce resource wastage effectively
2. Address social inequalities related to missed appointments, ensuring that populations that are vulnerable receive equitable access to health care services
3. Enable active participation of the health care system by using patient-reported information and engaging in cocreation with patients to optimize resource allocation
4. Foster cross-sector collaboration, enhancing the overall coherence and quality of treatment

An approach to interventions that focus on "the good examples" can then be applied to others in the health care system and give clinicians and managements the opportunity to optimize organizational processes through targeted interventions. The project thus has the potential to reduce waste and clinical errors in health care, which will be beneficial for both the patients and the health care system. It also has the potential to cast light on how health care professionals can improve their skills for detecting potential nonattendants early in the process, for example, by articulating and responding to what matters to the individual patient.

In the future, the expanded model for determinants of no-shows could form the basis for algorithms created by machine learning, among other methods [87]. However, as artificial intelligence method of cogitation is mechanically distinct from human intelligence—computers lack emotion; thus, they cannot literally be courageous and their logic boards cannot process narrative [88]—jumping straight to machine learning is methodologically immature. It requires massive analytical resources, and it reproduces and intensifies the health care system's own misconceptions and the existing administrative and professional discourses behind no-shows [89,90].

Finally, the project will also contribute to a new Research Portfolio for Human Factors and Patient Safety, established as part of a collaboration between the University of Southern Denmark and OUH. The portfolio is the first of its kind in Denmark, and it will enable researchers in close cooperation with clinicians to test and implement successful interventions and to further develop original ways of communicating and collaborating, to produce a more informed scholarly understanding of nonattendances in health care and the interaction of core biological, social, and cultural factors.

Acknowledgments

The authors would like to acknowledge the Novo Nordisk Foundation in Denmark for funding this study and the Odense University Hospital and the University of Southern Denmark for their support for the study. The authors would also like to thank, in advance, all units and patients participating in the study.

Data Availability

According to Danish legislation, our approvals to use register data for this study do not allow us to distribute or make patient data available to other parties. Any interested researchers may apply for access to data through an application to the Research Service at Statistics Denmark and at the Danish Health Data Authority. Moreover, access to data from the Danish health data authorities requires approval from the Danish Data Protection Agency. The authors of this project do not have special access privileges to the data used in this study. The data that support the findings will be available from the Centre for Research in Patient Communication, University of Southern Denmark, but restrictions apply to the availability of these data, which were used under license for this study, and thus are not publicly available. Data available from the authors could be made available upon reasonable request and with permission of the University of Southern Denmark.

Conflicts of Interest

None declared.

Abstract

Background: Metabolic and bariatric surgery (MBS) is the most effective and durable obesity treatment. However, there is heterogeneity in weight outcomes, which is partially attributed to variability in appetite and eating regulation. Patients with a strong desire to eat in response to the reward of palatable foods are more likely to overeat and experience suboptimal outcomes. This subgroup, classified as at risk, may benefit from repetitive transcranial magnetic stimulation (rTMS), a noninvasive brain stimulation technique that shows promise for reducing cravings and consumption of addictive drugs and food; no study has evaluated how rTMS affects the reinforcing value of food and brain reward processing in the context of MBS.

Objective: The goal of the *Transcranial Magnetic Stimulation to Reduce the Relative Reinforcing Value of Food (RESTRAIN)* study is to perform an initial rTMS test on the relative reinforcing value (RRV) of food (the reinforcing value of palatable food compared with money) among adult patients who are pursuing MBS and report high food reinforcement. Using a within-participants sham-controlled crossover design, we will compare the active and sham rTMS conditions on pre- to posttest changes in the RRV of food (primary objective) and the neural modulation of reward, measured via electroencephalography (EEG; secondary objective). We hypothesize that participants will show larger decreases in food reinforcement and increases in brain reward processing after active versus sham rTMS.

Methods: Participants (n=10) will attend 2 study sessions separated by a washout period. They will be randomized to active rTMS on 1 day and sham rTMS on the other day using a counterbalanced schedule. For both sessions, participants will arrive fasted in the morning and consume a standardized breakfast before being assessed on the RRV of food and reward tasks via EEG before and after rTMS of the left dorsolateral prefrontal cortex.

Results: Recruitment and data collection began in December 2022. As of October 2023, overall, 52 patients have been screened; 36 (69%) screened eligible, and 17 (47%) were enrolled. Of these 17 patients, 3 (18%) were excluded before rTMS, 5 (29%) withdrew, 4 (24%) are in the process of completing the protocol, and 5 (29%) completed the protocol.

Conclusions: The RESTRAIN study is the first to test whether rTMS can target neural reward circuits to reduce behavioral (RRV) and neural (EEG) measures of food reward in patients who are pursuing MBS. If successful, the results would provide a rationale for a fully powered trial to examine whether rTMS-related changes in food reinforcement translate into healthier eating patterns and improved MBS outcomes. If the results do not support our hypotheses, we will continue this line of research to

XSL•FO
RenderX

evaluate whether additional rTMS sessions and pulses as well as different stimulation locations produce clinically meaningful changes in food reinforcement.

Introduction

Background

Metabolic and bariatric surgery (MBS) is currently the most effective long-term treatment for obesity and its comorbidities [1-3]. However, there is substantial individual variability in the magnitude and durability of these outcomes, and patients who adopt and sustain healthier behaviors achieve better outcomes [3,4]. As a proximal behavioral driver of initial weight loss is reduced energy intake [5-7], there is a need to understand the mechanisms that can be targeted to promote healthier eating behaviors for improved MBS outcomes.

Food reinforcement is an important determinant of energy intake in the context of obesity and MBS [5,8]. Food is a potent primary reinforcer that motivates the initiation of eating [8,9]. By consuming a variety of foods, people learn which foods are pleasant and develop preferences influenced by the sensory qualities of these foods (eg, smell and taste) [8,9]. Eating preferred foods activates brain reward pathways and the release of dopamine that, over time via conditioning processes, promote greater wanting and intake of these foods in the absence of physiological hunger [8-15]. Thus, foods with higher reinforcing value are likely to be consumed more frequently and in greater quantities than foods with low reinforcing value.

Given that foods with higher reinforcing value also tend to be palatable and calorie dense, it is not surprising that higher food reinforcement is related to higher energy intake and obesity [8,16-23]. The reinforcing value of a food can be determined by how much work a person will do (or the number of responses they will make) to access that food [8,18]. The food reinforcer is provided on a progressive-ratio work schedule such that after a person earns a portion of the food, it becomes much more difficult to access the next portion. To better mirror eating in daily life, which involves making choices about whether, what, and how much to eat, the reinforcing value of food can be assessed by providing a choice to work for either a portion of a specified food or an alternative reinforcer such as money (ie, the relative reinforcing value [RRV] of food). The point at which a person makes the choice to switch from working for food to working for money serves as an index of the reinforcing value of food [8,18]. Research using RRV measures has found that people with obesity work harder for food and find food more reinforcing than nonfood alternatives compared with those who have a healthy weight [8,16,18-23]; higher food reinforcement predicts obesity severity and weight gain [8,16,18-24], and the relationship between food reinforcement and obesity is mediated by energy intake [25], suggesting that high food reinforcement leads to excess weight via energy intake.

Reduction in food reinforcement seems to be one of the ways in which MBS effects changes in energy intake [5,26,27]. MBS-induced anatomical and metabolic alterations are hypothesized to reset how rewarding food stimuli in the mesolimbic dopamine system are processed, leading to reduced hedonic hunger (eating for pleasure in the absence of physiological hunger) and related eating behaviors [14,26,28-30]. Support for this hypothesis is derived from studies showing postoperative reductions in questionnaire-based measures of food-seeking behavior and appetite for highly palatable foods as well as from progressive-ratio behavioral tasks of the reinforcing value of sweet and fat candy [27,31,32]. Furthermore, neuroimaging research shows the postsurgical normalization of obesity-induced alterations in brain reward regions (ie, caudate nucleus, putamen, nucleus accumbens, pallidum, and amygdala), improvements in overall functional connectivity, and increased activation of executive regions (ie, dorsolateral prefrontal cortex and ventral anterior cingulate cortex) during response inhibition to high-caloric food [14,28,33].

However, the MBS modulation of the mechanisms that influence food reinforcement is variable, with some patients being more resistant to these effects than others [34,35]. A characteristic of this *resistant* phenotype is greater hedonic hunger and susceptibility to overeating [31,35]. Moreover, changes in food reinforcement seem to be only temporary, with the re-emergence of unhealthy eating behaviors typically occurring approximately 2 years (but as early as 6 mo) after MBS [28,29,36,37]. Thus, strategies are needed that can directly target the neural mechanisms of food reinforcement, ideally before MBS, to prevent suboptimal outcomes.

Noninvasive brain stimulation interventions, such as repetitive transcranial magnetic stimulation (rTMS), are increasingly used to target dysregulated brain reward circuitry in individuals who have substance use disorders (SUDs) and in those who are prone to overeating [14,38-44]. rTMS exerts its neuromodulatory influence via electromagnetic coils that generate repetitive magnetic impulses to induce small electrical currents within a focal area in the superficial brain tissue below the scalp directly under the rTMS coil [43]. The main neural target of rTMS treatment for SUDs and overeating is the left dorsolateral prefrontal cortex (l-dlPFC), which drives mesolimbic dopaminergic regions to initiate motivated behavior [14,43,45]. In both SUDs and dysregulated eating, the l-dlPFC is

XSL•FO
RenderX

hypoactive, contributing to heightened sensitivity to the reinforcing properties of substances and food and the failure of inhibitory control systems to resist temptation to consume them [14,43,45]. The application of excitatory rTMS to the l-dlPFC can upregulate neuronal excitability and alter synaptic plasticity to promote the lowering of the threshold of engagement of this region during exposure to drug and food reinforcers [38-45]. rTMS at this location could affect inhibitory control processes (ie, *top-down* mechanisms) or reward processes (ie, *bottom-up* mechanisms) because the l-dlPFC has structural connections to reward regions such as the dorsal and ventral striata [46]. These neuromodulatory changes, in the context of food reinforcement, could reduce motivated responding to food reinforcers and enhance eating regulation [43,44]. This empirical question has yet to be addressed.

Although a growing number of studies suggest that rTMS can be effective for reducing food cravings (ie, intense desire for a specific food), including among individuals with obesity [43,44], no study to our knowledge has directly examined the effects of rTMS on motivation to obtain a specific food that is reinforcing [8]. Unlike food craving measures, the reinforcing value of food directly measures motivation to eat and eating behavior by assessing how much work a person will do to obtain access to a palatable food. Furthermore, because the natural environment involves making choices between competing food and nonfood reinforcers, it is important to assess not only how much work a person will do to obtain a food but also how they choose to allocate work between reinforcing food and nonfood options [8].

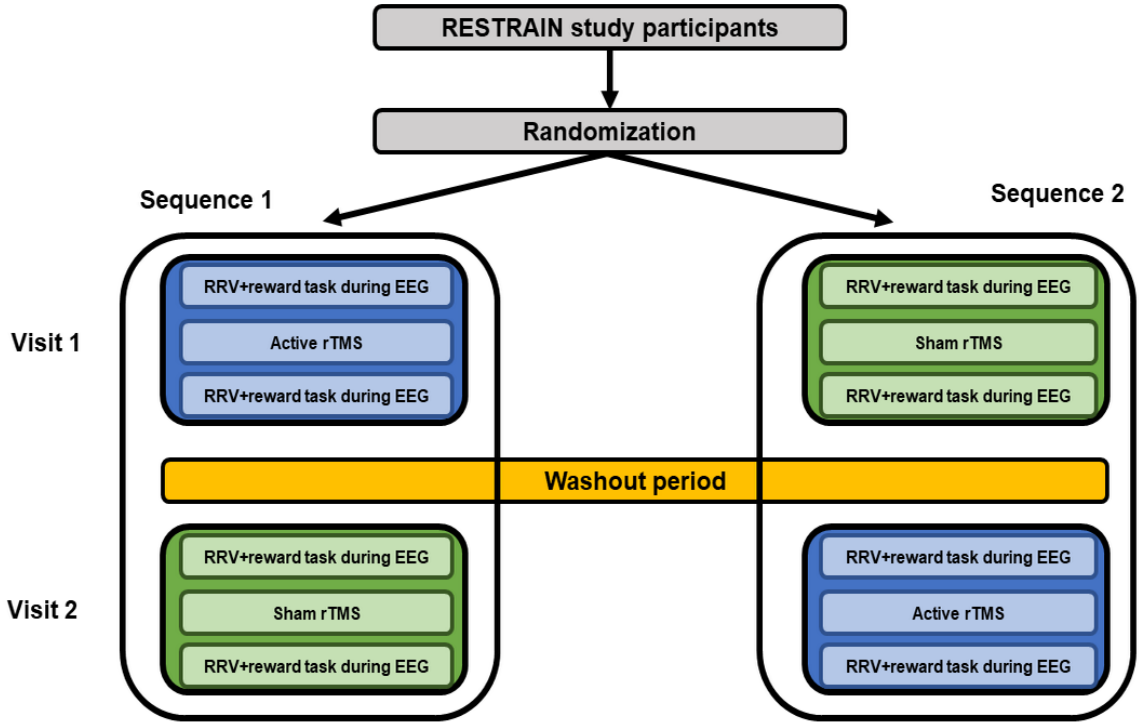
Objectives

Despite the potential benefit of rTMS for patients undergoing MBS, especially those who find food highly reinforcing and are at greater risk for overeating, no study has used rTMS in this clinical context. Thus, the *Transcranial Magnetic Stimulation to Reduce the Relative Reinforcing Value of Food (RESTRAIN)* study is the first to pilot-test the effects of excitatory rTMS applied to the l-dlPFC on food reinforcement using a validated RRV behavioral choice paradigm among patients who are pursuing MBS and have high levels of hedonic hunger. The aims are to compare the effects of active and sham rTMS on changes in the RRV of food via the behavioral choice task and the neuromodulation of reward via electroencephalography (EEG).

Methods

Ethical Considerations

The research and ethics described in this study have been reviewed and approved by the institutional review board (IRB) of Hartford Hospital (HHC-IRB 035431). The study protocol is registered at ClinicalTrials.gov (NCT05522803). All participants provide written informed consent after a thorough review of procedures and questions and are informed of their opportunity to opt out of the study at any time. All study data are deidentified. Participants are compensated at an hourly rate of US $20 for time spent in the laboratory and have the opportunity to earn an additional US $120 bonus for completing all study procedures.



Design and Procedure Overview

A single-blind, within-participants, sham-controlled study is being conducted to perform an initial test of rTMS on the RRV of food, using a behavioral choice paradigm, and the neural modulation of reward, using an EEG (Figure 1).

Participants will attend 2 study visits that are separated by a washout period of at least 1 week (up to 4 weeks). Participants will receive active rTMS on 1 day and sham rTMS on the other day using a randomized and counterbalanced schedule. Participants will arrive at the laboratory fasted by 8 AM where they are asked to provide a urine sample for drug and pregnancy screening, complete an alcohol breath test, have their height and weight measured, and consume a standardized breakfast. During breakfast, participants will complete demographic, health history, and clinical behavioral and psychological questionnaires. After consuming breakfast, participants will complete a small sampling of 4 different palatable snack foods to determine which food will be used for the RRV measure for both study days. Participants will then complete the RRV measure and a reward task while an EEG is collected before rTMS (pre-rTMS EEG), receive rTMS, and complete the RRV measure and reward task again while an EEG is collected after rTMS (post-rTMS EEG). These procedures will allow for the comparison of pre- to posttest changes in the behavioral (RRV) and neural (EEG) modulations of reward between the active and sham rTMS conditions. Study procedures will be identical across study visits and conditions, except for certain baseline measures on the first day and the within-participant manipulation of active versus sham rTMS administration. A telephone follow-up to assess post-rTMS symptoms will be scheduled after the completion of each visit.

Figure 1. The Transcranial Magnetic Stimulation to Reduce the Relative Reinforcing Value of Food (RESTRAIN) study design. EEG: electroencephalography; RRV: relative reinforcing value; rTMS: repetitive transcranial magnetic stimulation.

Participants

Adults pursuing a primary MBS procedure at the Hartford Hospital surgical and medical weight loss center who are aged 18 to 60 years, are able to give valid informed consent in English, are without cognitive impairment, fulfill clinical criteria regarding hedonic hunger, meet safety criteria for an EEG and rTMS, and habitually consume breakfast within 3 hours of waking up will be eligible to participate in this study.

Patients will be ineligible if they have a history of neurological disorders that would increase seizure risk from rTMS (eg, stroke, previous neurosurgery, and head trauma resulting in a significant loss of consciousness); a first-degree family history of epilepsy, schizophrenia, bipolar disorder, or neurological disorders with a potentially hereditary basis that affect rTMS safety or EEG measures; cardiac pacemakers, neural stimulators, implantable defibrillator, implanted medication pumps or sensors, intracardiac lines, or acute and unstable cardiac disease, with intracranial implants (eg, aneurysm clips, shunts, and electrodes) or other metal objects in the body; current use of any investigational drug with anti- or proconvulsive action or medications with psychotropic effects (eg, benzodiazepines) for a disease that is not currently stabilized or with disease symptoms present; a lifetime history of schizophrenia, bipolar disorder, mania, or hypomania; a history of myocardial infarction, angina, congestive heart failure, cardiomyopathy, stroke, or transient ischemic attack; participation in any rTMS sessions ≤2 weeks before enrollment; current pregnancy; a history of self-reported hypoglycemia owing to diabetes in the last 3 months; and allergies to foods that are provided during the research visits.

Screening, Recruitment, and Enrollment

Patients pursuing MBS will be recruited from the Hartford Hospital surgical weight loss center during the initial consultation visit for bariatric surgery. First, patients will receive an explanation of the study concept and a flyer from the surgeon during an office visit. Patients who are interested in being contacted by research staff for the study are asked to sign their name on the flyer and provided with a QR code to complete web-based screening questionnaires (refer to the following paragraphs). Patients will have the option of completing the screening questionnaires via REDCap (Research Electronic Data Capture; Vanderbilt University) at home on their own devices or over the telephone with a trained research assistant.

The screening measures that will be used to determine initial study eligibility are as follows:

1. *Power of Food Scale* (PFS) [47-49]: the PFS consists of 15 items, rated on a 5-point Likert scale, that assess preoccupation with an enhanced motivation to obtain and consume highly palatable foods across three separate but related domains—(1) food available, which assesses general thoughts about food; (2) food present, which assesses attraction to food that is directly available to a person; and (3) food tasted, which assesses desire for, and pleasure derived from, food when first tasted. PFS total and subscale scores are calculated by summing the item scores and dividing by the number of items. Higher PFS total scores relate to a higher drive to consume palatable foods. The PFS total score has good test-retest reliability, is internally consistent, is not affected by hunger states (consistent with the hedonic hunger construct), and is related to higher responsivity to food cues [47-50]. Given that there is no

XSL•FO
RenderX

threshold to determine *high* PFS scores, we identify patients with high hedonic hunger levels as those who score ≥1 SD above the mean PFS total score (2.57, SD 0.45) obtained from a previous study involving a large clinical population of patients with obesity [48]. Thus, only patients who have a PFS total score of ≥3.00 are deemed initially eligible to participate.

2. *rTMS safety and appropriateness*: patients will be administered a questionnaire that the study team has previously used in clinical trials.
3. *Habit of eating breakfast*: patients will answer a question regarding whether they have a habit of eating breakfast in the morning within 3 hours of waking.
4. *Contact preference*: patients will indicate their preferred method of being contacted and provide permission to the research team to send the informed consent and Health Insurance Portability and Accountability Act (HIPAA) forms to their personal email account.

After patients complete the screening form, they will be contacted by the research assistant who will inform them of their eligibility, provide a short description of the study and answer any questions, confirm that they have no allergies to foods provided during the study visits, and schedule a remote verbal informed consent session using a hospital-approved Zoom (Zoom Video Communications, Inc) account.

The remote informed consent session will be conducted with the study research assistant, the patient, and a neutral witness who is not involved with the study. During the session, the research assistant will review the informed consent form with the patient in REDCap. If the patient is willing to participate, they will provide their verbal consent, which is documented on a progress note by the research assistant and the neutral third party. The research assistant and neutral third party will both sign hard copies of the informed consent and HIPAA forms. The patient will then be scheduled for their first study visit. When the patient arrives at the research center for this study visit, they will be asked to sign a hard copy of the informed consent and HIPAA documents.

Study Visits

Each participant will attend 2 study visits (each approximately 7 hours in duration) that are separated by a washout period of at least 1 week (up to 4 weeks). Participants will arrive at the research center between 7 AM and 8 AM after an overnight fast with no food or drink after midnight. Participants will undergo height and weight measurement, provide a urine sample (for drug or pregnancy screening), and consume a standardized breakfast (choice of 3 flavors of a soft-baked breakfast bar with gluten-free options, 2 flavors of yogurt, and orange or apple juice) that is equivalent to 12% of daily caloric needs based on weight and age. Both the standardized breakfast, which is consumed before the first RRV measurement, and the standardized snack (also providing 12% of daily caloric needs), which is consumed before the second RRV measurement, will be provided to diminish the potential influence of physiological hunger or food deprivation and the palatability of foods consumed on food reinforcement measured via the RRV measure [8,51]. During breakfast, participants will complete questionnaires, including the PFS, the Three-Factor Eating Questionnaire [52] (this measure assesses 3 aspects of eating behavior: cognitive restraint [tendency to consciously restrict or control food intake], disinhibition [tendency to overeat in the presence of palatable foods or other disinhibiting stimuli], and hunger [susceptibility to feelings of hunger]), the Food Craving Inventory [53] (this measure assesses subjective food cravings and the consumption of particular foods), Daily Activity Behaviors Questionnaire [54] (this measure assesses time spent in sleep, sedentary behaviors, and physical activity in the past 7 days), rTMS safety screen (this measure assesses the appropriateness of administering rTMS) [55], Patient Health Questionnaire-9 [56] (this measure assesses the severity of depression symptoms over the past 2 weeks), Adult ADHD Self-Report Scale [57] (this measure assesses symptoms related to attention-deficit/hyperactivity disorder), Edinburgh Handedness Inventory [58] (this measure assesses dominant handedness), and the Wide Range Achievement Test-4 [59] (this measure assesses fundamental reading, spelling, and math skills).

After completing the questionnaires, participants will be asked to sample 4 different palatable snack foods (ie, Doritos nacho cheese–flavored tortilla chips [Frito Lay], Lay's original potato chips [Frito Lay], Twix candy bars [Mars, Incorporated], and Chips Ahoy chocolate chip cookies [Mondelez International]) and rank their liking of each on a 100-mm visual analog scale anchored by *dislike very much* and *like very much* at either end. The food that participants rate as their most liked will be used for the RRV measure [60] at both study visits. After food sampling, participants will indicate their current levels of hunger and fullness using visual analog scales before being prepared for EEG procedures and completing the RRV measures and another reward task during the EEG procedure. Participants will consume a snack before undergoing rTMS to limit the potential effects of physiological hunger. After rTMS, they will complete the RRV and reward measures while an EEG is collected (RRV and reward measures as well as EEG and rTMS procedures are described in the following subsections). Participants will then be debriefed and monitored for any side effects, scheduled for their second study visit, compensated for their time, and discharged. After the washout period, participants return to the research center for their second visit. The washout period, identical testing procedures and environments, and counterbalancing procedures are intended to cancel out any carryover effects within the active and sham rTMS conditions. Procedures completed during the first study visit will be extended to the second study visit with the exception of randomization, height measurement, food sampling, and the completion of questionnaires used to determine study eligibility (ie, Patient Health Questionnaire-9, Wide Range Achievement Test-4, Adult ADHD Self-Report Scale, and Edinburgh Handedness Inventory). At the end of study visit 2, a brief rTMS blind assessment will be performed where the participant will be asked whether the rTMS session that day was active or sham. The participant will be asked to rate how confident they are in their choice on a scale ranging from 0 (*not at all confident*) to 10 (*very confident*).

XSL•FO
RenderX

Primary and Secondary Outcome Measures

RRV of Food

The RRV of food will be measured by a validated behavioral choice questionnaire that asks participants to make a choice between receiving the food they rated as their most liked (ie, nacho cheese–flavored tortilla chips, original potato chips, candy bars, or chocolate chip cookies) and receiving money [60]. To determine how reinforcing food is in comparison with money, the behavioral choice questionnaire provides participants with 16 different choices, in which they make a choice between receiving the most liked food (100 kcal serving) and receiving the money (US $0.25). Each choice—food or money—is associated with a different number of button presses (using a tally clicker) required to gain access to the choice. Each of the 16 choices on the questionnaire requires the same number of button presses (ie, 20) for the money, whereas the number of button presses for the food increases with each choice. Choice 1 begins with 20 button presses for either the money or the food. The number of button presses required to receive the food increases in 20 response increments for choices 2 through 16. Thus, by choice 16, participants could have access to the food if they are willing to make 320 presses or receive the money for 20 presses. Participants will select whether they want money or food for choices 1 through 16. To produce valid responses, participants will be informed that they will be performing one of their choices by choosing 1 of 16 numbers from a hat, with the numbers representing the choice from the questionnaire (eg, if a participant randomly selects number 6, the participant will carry out the decision made for choice 6, which is either 120 button presses for the most liked food or 20 button presses for the money). After participants complete the number of button presses associated with the choice drawn, they will receive their choice (food or money). The reinforcing value of food is scored as the choice (1-16) when money is chosen instead of food. The higher the number associated with the choice of money, the higher the RRV of food. This measure has been shown to be valid and reliable for assessing the RRV of food [60].

Reward Task

Participants complete a version of the task described by Gehring and Willoughby [61] in which they choose between 2 monetary options (target stimuli) on each trial and then receive feedback indicating whether the choice resulted in winning or losing money on that trial. In this task, the target stimuli are 2 adjacent squares, each enclosing a number (5 or 25) representing a monetary value (in US cents). These stimuli remain on the screen until a choice is made between the left and right squares. Feedback stimuli follow the choice indicating the outcome of the participant's decision, that is, the chosen box turns either red or green to signify either a win or a loss (with red or green as the winning color counterbalanced across participants), and the unchosen box turns the other color (either green or red) to indicate what the outcome of the trial would have been had that box been chosen. The feedback stimulus appears for 1000 milliseconds, followed by a blank screen for 1500 milliseconds preceding the onset of the next trial. All 4 possible combinations of 5 and 25, (ie, 5-5, 5-25, 25-5, and 25-25) are evenly crossed with the 4 possible win or loss outcomes (ie, win-win, win-loss, loss-win, and loss-loss), resulting in 16 trial types; thus, although the participant's choice produces a designated outcome on each trial, signaled by the feedback, outcomes on future trials are not predictable from outcomes associated with prior choices (analogous to a roulette wheel or slot machine). Two sets of these 16 trial types, ordered randomly, are included in each block. Upon completion of a block, participants will receive feedback about their win or loss ratio within that block. The feedback received by the participant will elicit both a feedback-related negativity (FRN) and a reward positivity (RewP) when coupled with an EEG. The amplitude of the FRN largely indexes the relative loss presented in the feedback (ie, FRN amplitude is greater for trials where the participant loses 5 when the alternative was to gain 25 compared with losing 5 when the alternative was to gain 5). The amplitude of the RewP indexes the relative gain (ie, reward) presented in the feedback (ie, the RewP amplitude is greater in trials where the participant gains 25 when the alternative was to lose 25 compared with gaining 25 when the alternative was to lose 5). Extracting the underlying FRN theta (3-9 Hz) and RewP delta (<3 Hz) time-frequency power better measures these processes than amplitude alone.

EEG and rTMS Procedures

EEG Collection

For the EEG collection, participants are fitted with an elastic cap with embedded electrodes. These electrodes, once they are filled with gel, passively measure electrical brain signals during tasks at a very high resolution (5000 Hz). This high temporal resolution is the key advantage of an EEG as a measure, which produces robust and reliable brain measures across clinical populations. Measures will be collected using a BrainAmp MR Plus 64-channel electrode system (Brain Products GmbH) following standard manufacturer procedures. During data collection, participants will be seated in a comfortable chair 60 cm from the computer screen with access to a button-response box to perform the reward task.

rTMS Sessions

The rTMS sessions will be administered using a MagPro X100 including MagOption (MagVenture, Inc) stimulator equipped with a figure-eight coil. All sessions will be completed in the same laboratory that contains the EEG system used in this study [62]. During the rTMS sessions, participants will be seated comfortably in a chair and place their head on a chin rest for stabilization. Reducing head movement is essential for accurately placing and holding the rTMS coil during rTMS applications. Two separate coils that are similar in appearance and acoustic properties are available. One active unblinded coil will be used to determine the resting motor threshold (RMT); the other coil will be blinded (1 side active and 1 side sham) and used to deliver rTMS. The coils are calibrated quarterly against one another to ensure comparable output. Participants will be monitored throughout the study via staff interactions and a monitoring questionnaire assessing typical rTMS side effects (eg, headache).

After the scalp position closest to the motor representation (ie, the *motor hot spot*) is found, the RMT at this location will be

XSL•FO
RenderX

determined. Using repeated single pulses, the coil will be moved to determine the optimal scalp position for producing visible contralateral movement in the first dorsal interosseous in the right hand. Pulses over this motor cortex location will be administered to identify the RMT using parameter estimation by sequential testing software [63]. The hot spot located during the initial rTMS session (study visit 1) will be saved in the neuronavigation system (Localite GmbH) and verified at the subsequent session (study visit 2), whereas the RMT will be measured from the hot spot at every session. In accordance with manufacturer instructions and accepted standards, hand motor cortex will be stimulated to obtain the RMT [64-66]. As the l-dlPFC is the target, the left hemisphere (right hand) will be used to determine the RMT.

The l-dlPFC will be targeted using the neuronavigation system (Localite GmbH) Montreal Neurological Institute coordinates (−50, 30, 36) thought to modulate the circuit implicated in reward processing. Over 2 sessions, participants will receive excitatory and sham rTMS sessions once in a single-blind fashion. Excitatory rTMS will consist of intermittent theta-burst stimulation parameters that include 3 pulses given at 50 Hz repeated every 200 milliseconds for a 2-second duration followed by 8 seconds of no stimulation. This sequence will be repeated for a total of 20 cycles, lasts 192 seconds, and delivers 600 pulses [67]. Magnetic field intensity will be set at medium intensity, gradually increasing to the goal of 100% of the participant's measured daily RMT.

The coil will be set accordingly (active vs sham) for each study day with the order counterbalanced within participant. The blinded coil has 2 sides that can be placed on the participant's head: 1 side active and 1 side sham (with shielding). These sides look identical to the research staff and the participant, but rTMS pulses are delivered only from the active side. The sham side of the coil is designed to mimic the auditory feedback and scalp pressure evoked by the active side of the coil. The MagVenture system also includes electrodes to be placed on the scalp, near the rTMS stimulation target. This scalp stimulation from the electrodes mimics rTMS administration (ie, causes similar discomfort) but does not modulate brain circuits as rTMS does, thus increasing the likelihood of maintaining the blind without affecting neural signals. The MagVenture sham system is the best commercially available system and can effectively mimic the discomfort of an active rTMS session. To avoid placebo effects, it will be emphasized to the participants that the sensation they feel is related to the stimulation of scalp nerves and muscles and that brain stimulation itself cannot be felt. Such procedures are effective in establishing these sham procedures [68]. Although the aforementioned efforts are taken to preserve the blind, it is possible that the participant will become unblinded to the condition during the study; therefore, a questionnaire assessing the blind and the pain felt will be administered to participants at the end of the study.

rTMS Safety Considerations

Although the anticipated risks and adverse events of rTMS are mostly low or minimal, life support equipment will be made available near the laboratory. All study team members who operate the MagVenture machine will have standard training for procedures, including training in rTMS device operation, supervised repeated practice in rTMS procedures, and testing for interrater reliability in RMT determination.

The rTMS monitoring questionnaire administration, staff observation, and interactions with participants will occur daily. If immediate medical intervention is required, the participant will be referred to an appropriate medical facility; an ambulance may be called as needed. Information on all adverse events will be recorded and reported to the IRB with each continuing review application. Unexpected or serious adverse events will be promptly reported to the IRB. Standard seizure monitoring procedures will be in place [69], and video recordings will be collected during rTMS sessions to help evaluate the session as needed for training or a review of adverse events. In the event a participant reports an rTMS-related symptom (most often, headache), the physician on the protocol will be consulted. If deemed necessary by the physician, a single dose of acetaminophen will be administered.

Statistical Analysis Plan

The statistical analysis will be conducted using Stata 18 (StataCorp LLC). All continuous measures will first be assessed for their distribution characteristics through the use of Shapiro-Wilk tests and the construction of histograms to determine whether assumptions are met for parametric analysis; if not, nonparametric alternatives will be used. Baseline clinical and demographic characteristics of participants will be assessed using descriptive statistical measures of central tendency and dispersion: means and SDs for those variables meeting assumptions for parametric analysis and medians, range, and IQRs for those not meeting assumptions. The primary outcome of changes in RRV (scores after rTMS−scores before rTMS) for both the active and sham conditions will be computed. Tests comparing the pre-post differences for the active and sham rTMS sessions will be conducted using 2-tailed paired *t* tests (if distributions are normal) or Wilcoxon signed rank tests if the assumptions of distribution are not met).

The EEG data, once collected, will be imported into the MATLAB platform (The MathWorks, Inc) for processing. Data will be filtered offline at 0.1 to 30 Hz and epoched (1000 ms before feedback to 2000 ms after feedback) to capture the FRN and RewP time windows and allow for time-frequency analyses (ie, reducing edge effects). Established preprocessing methods (eg, eye-blink correction, additional filtering, and bad-channel identification) will also be applied. Both theta (3-9 Hz) and delta (<3 Hz) power will be extracted and a principal component analysis applied. This data-driven approach helps separate meaningful segments of the time-frequency surface related to the FRN and RewP components. EEG data will be used to determine differences between active and sham rTMS on the neural modulation of reward [62,70,71]. Pearson and Spearman correlational coefficients will be used to evaluate the associations of clinical assessment measures with RRV and task-specific neural measures (eg, correlation between food craving scores and neural activation related to reward processing). We will control for any differences in hunger and fullness ratings before each RRV task in analyses examining changes in RRV.

XSL•FO
RenderX

We do not anticipate any period effects (ie, when the outcome of interest changes with time irrespective of treatment effect) because the condition of the treatment is stable for both active and sham rTMS. Regarding carryover effects, we anticipate that the effect of a single session of rTMS will last no more than 24 hours (the washout period is >5 times the anticipated duration of effects).

Regarding participant and rTMS operator ratings of active versus sham rTMS, we will report descriptive data on the percentage of participants and operators who correctly identified the active condition. Such reporting on the success of blind manipulation is standard in the rTMS field.

Sample Size and Power Considerations

As this is an initial proof-of-concept pilot study, the sample size was based on guidelines for pilot studies and by practical considerations. Guidelines for an appropriate sample size for a 1-group pilot study suggest 10 to 12 participants [72,73]. Assuming 20% study attrition, we will enroll 12 patients to achieve an analyzable sample of 10 (83%) patients. The effect sizes found will be calculated and appropriate power calculations performed to determine the sample needed to fully power a subsequent study.

Results

Study recruitment began in December 2022. As of October 2023, a total of 52 patients have been recruited and screened, of whom 36 (69%) screened positive, and 17 (47%) were enrolled. Of these 17 patients, 3 (18%) withdrew before receiving rTMS, 5 (29%) withdrew after receiving rTMS, 4 (24%) are in the process of completing the protocol, and 5 (29%) completed the protocol. Analysis of data is planned for February 2024, with the manuscript expected to be submitted in April 2024.

Discussion

Principal Findings

Reduction in food reinforcement seems to be a principal way by which MBS lowers energy intake to promote weight loss and other health improvements [5,26,27]. However, the surgical modulation of the mechanisms that influence food reinforcement is variable, with some patients seeming to be more resistant to these effects than others [34,35]. This phenotype, characterized by high levels of hedonic hunger, can undermine MBS efficacy [31,35]. Patients pursuing MBS who demonstrate this high-risk eating phenotype may benefit from strategies that can directly target the neural mechanisms of food reinforcement.

This paper describes the protocol used in the RESTRAIN study. To our knowledge, this is the first study to perform an initial test of whether rTMS, a noninvasive procedure that delivers magnetic pulses to stimulate or inhibit nerve cells in the brain, can successfully target brain reward circuitry to diminish the reinforcing properties of food in patients pursuing MBS who are highly reinforced by food, more likely to overeat, and at risk for suboptimal surgical outcomes. Moreover, although previous studies have shown positive effects of rTMS on food cravings (ie, desire to consume a specific food) [44,45], this study is the first to directly examine the effects of rTMS on motivation to obtain and eat a well-liked food compared with a nonfood reinforcer using a validated behavioral choice task [8,60]. In addition, by measuring the acute rTMS-induced modulation of reward processing with EEG, this study has potential to provide novel insights into the neurobehavioral mechanisms of food reinforcement that can be targeted with rTMS and other interventions to improve eating regulation and weight outcomes after MBS as well as other obesity treatments. The data collected from this initial pilot trial will help determine the feasibility and acceptability of rTMS in patients pursuing MBS as well as an estimate of its effects on the RRV of food and EEG-measured reward processing. These data will be used to calculate the required sample size for a larger fully powered trial to test the effects of rTMS on eating regulation and relationships with weight change after MBS.

Limitations

Although the use of noninvasive brain stimulation techniques such as rTMS in the context of MBS is highly novel and potentially beneficial, some patients may not be open to rTMS and may prefer other treatment options (eg, psychotherapy and medications). Even if rTMS reduces food reinforcement, the scalability of rTMS for this purpose is not clear because rTMS can be costly and needs to be administered by highly trained operators. Although this study involves only 2 study visits to determine whether rTMS has an acute effect on food reinforcement, it is likely that a fuller course of treatment, such as that which has typically been recommended for treatment-resistant depression (ie, several d/wk for 4-6 wk) is required to produce durable changes [74]. Finally, there is a potential that the results do not support our hypotheses. In this event, the data collected will still be valuable in demonstrating the feasibility of conducting rTMS in patients pursuing MBS and provide a rationale for additional studies to determine whether there is an optimal number of rTMS sessions and pulses as well as stimulation locations that can yield clinically meaningful changes in food reinforcement within this patient population.

Conclusions

The RESTRAIN study is the first application of rTMS in MBS and the first study to use rTMS to target motivation to obtain food among people who have a strong drive to eat in response to the reward of palatable foods. Moreover, this study will measure the acute rTMS-induced modulation of brain reward processing with an EEG. If successful, the results would provide a rationale for a fully powered trial to test whether rTMS-related changes in food reinforcement translate into healthier eating patterns and improved weight and health outcomes after MBS. rTMS could potentially provide another treatment for patients who are experiencing suboptimal weight loss or significant weight regain owing to poor regulation of appetite and eating behavior.

If the results do not support our hypotheses, future studies will focus on whether it is possible to modify and refine rTMS to exert greater effects on food reinforcement and related outcomes.

Acknowledgments

The authors would like to acknowledge Tara McLaughlin, PhD, and Yin Wu, PhD, for their assistance in preparing the institutional review board protocol; Patrick Fang, BS, and Kira Gresser, BA, for assisting with the execution of the trial; Darren Tishler, MD, Edward Hannoush, MD, and Devika Umashanker, MD, for assistance in recruiting study participants; and the study participants. This study is supported by a grant from the Hartford Hospital Medical Staff and a donation from the Jim Bowers and Becky Swanson-Bowers Research Fund awarded to DSB. VRS (K12 DA000167 and R01 MH132044), PKP (R01 DK113408), HAR (R01 DK121360), and CG (R01 DK126637 and R01 DK114075) report additional grants from the National Institutes of Health during the conduct of this study.

Data Availability

Data generated or analyzed during the study will be included in the published articles and their supplementary information files. Individual participant data that underlie the results reported in future published articles will be made available, after deidentification, to investigators whose proposed use of the data has been approved by an independent review committee identified for this purpose.

Authors' Contributions

DSB and VRS are equal contributors in study conceptualization, design, execution, and evaluation. PKP, HAR, and CG made substantial contributions to the study concept and design. DSB and VRS wrote the manuscript, and all authors critically revised it and approved the final version.

Conflicts of Interest

DSB reports travel support from the International Federation for the Surgery of Obesity and Metabolic Disorders. All other authors declare no other conflicts of interest.

Abstract

Background: Perimenopausal insomnia (PMI) has a high global incidence, which is common in middle-aged women and is more severe than nonmenopausal insomnia. Effective treatments with fewer side effects and more consistent repeatable results are needed. Acupuncture, a therapy based on traditional Chinese medicine, is safe and may be effective for PMI. It is widely accepted in Western countries, and evidence supports the use of acupuncture as a main or supplementary therapy. Cognitive behavioral therapy is also used to improve sleep quality. It has structured sessions and has been recommended as a first-line treatment for insomnia (cognitive behavioral therapy for insomnia [CBT-I]) by the American Association of Physicians. However, few randomized controlled trials have been conducted to compare the effectiveness of these 2 therapies. This study will be performed in perimenopausal women with insomnia to determine the efficacy of electroacupuncture (EA) versus CBT-I.

Objective: This study aimed to compare the preliminary effectiveness and safety of EA and CBT-I for PMI through a randomized controlled noninferiority study design.

Methods: This study is designed as an assessor-blinded, noninferiority, randomized controlled trial. A total of 160 eligible participants with PMI will be randomly divided into 2 groups to receive either EA or CBT-I. Participants in the EA group will receive electroacupuncture for 8 weeks. The intervention will be delivered 3 times weekly for a total of 12 sessions and 2 times weekly for the next 4 weeks. Meanwhile, participants in the control group will undergo CBT-I (once a week) for 8 weeks. Treatment will use 7 main acupoints (GV20, DU24, EX-HN3, EX-HN18, EX-CA1, RN6, and RN4) and an extra 4 acupoints based on syndrome differentiation. The primary outcome is the Insomnia Severity Index. The secondary outcome measures are the Pittsburgh Sleep Quality Index; Menopause-Specific Quality of Life; Menopause Rating Scale; Hamilton Depression Scale; Hamilton Anxiety Scale; hot flash score; and the level of estradiol, follicle-stimulating hormone, and luteinizing hormone in serum. Sleep architecture will be assessed using polysomnograms.

Results: Participants are currently being recruited. The first participant was enrolled in January 2023, marking the initiation of the recruitment phase. The recruitment process is expected to continue until January 2025, at which point data collection will commence.

Conclusions: This trial represents a pioneering effort to investigate the efficacy and safety of EA and CBT-I as interventions for PMI. It is noteworthy that this study is conducted solely within a single center and involves Chinese participants, which is a

XSL•FO
RenderX

limitation. Nonetheless, the findings of this study are expected to contribute valuable insights for clinicians engaged in the management of PMI.

Introduction

Perimenopause is the period from the onset of menstrual irregularities to 1 year after amenorrhea has occurred and encompasses the physiological changes that occur before and after a woman stops menstruating [1]. During this period, women are prone to perimenopausal insomnia (PMI) due to fluctuations in estradiol, progesterone, and follicle-stimulating hormones that disrupt the central nervous control of the sleep-wake state [2]. The incidence of sleep disorders in perimenopausal women ranges from 43% to 48% [3], and in the United States, the incidence is 31% to 42% [4]. PMI seriously affects the quality of life and physical and mental health of perimenopausal women and is associated with the development of many diseases such as low immunity, diabetes, obesity, inflammation development, cardiovascular disease, mood disorders, cognitive dysfunction, and cancer [5-9].

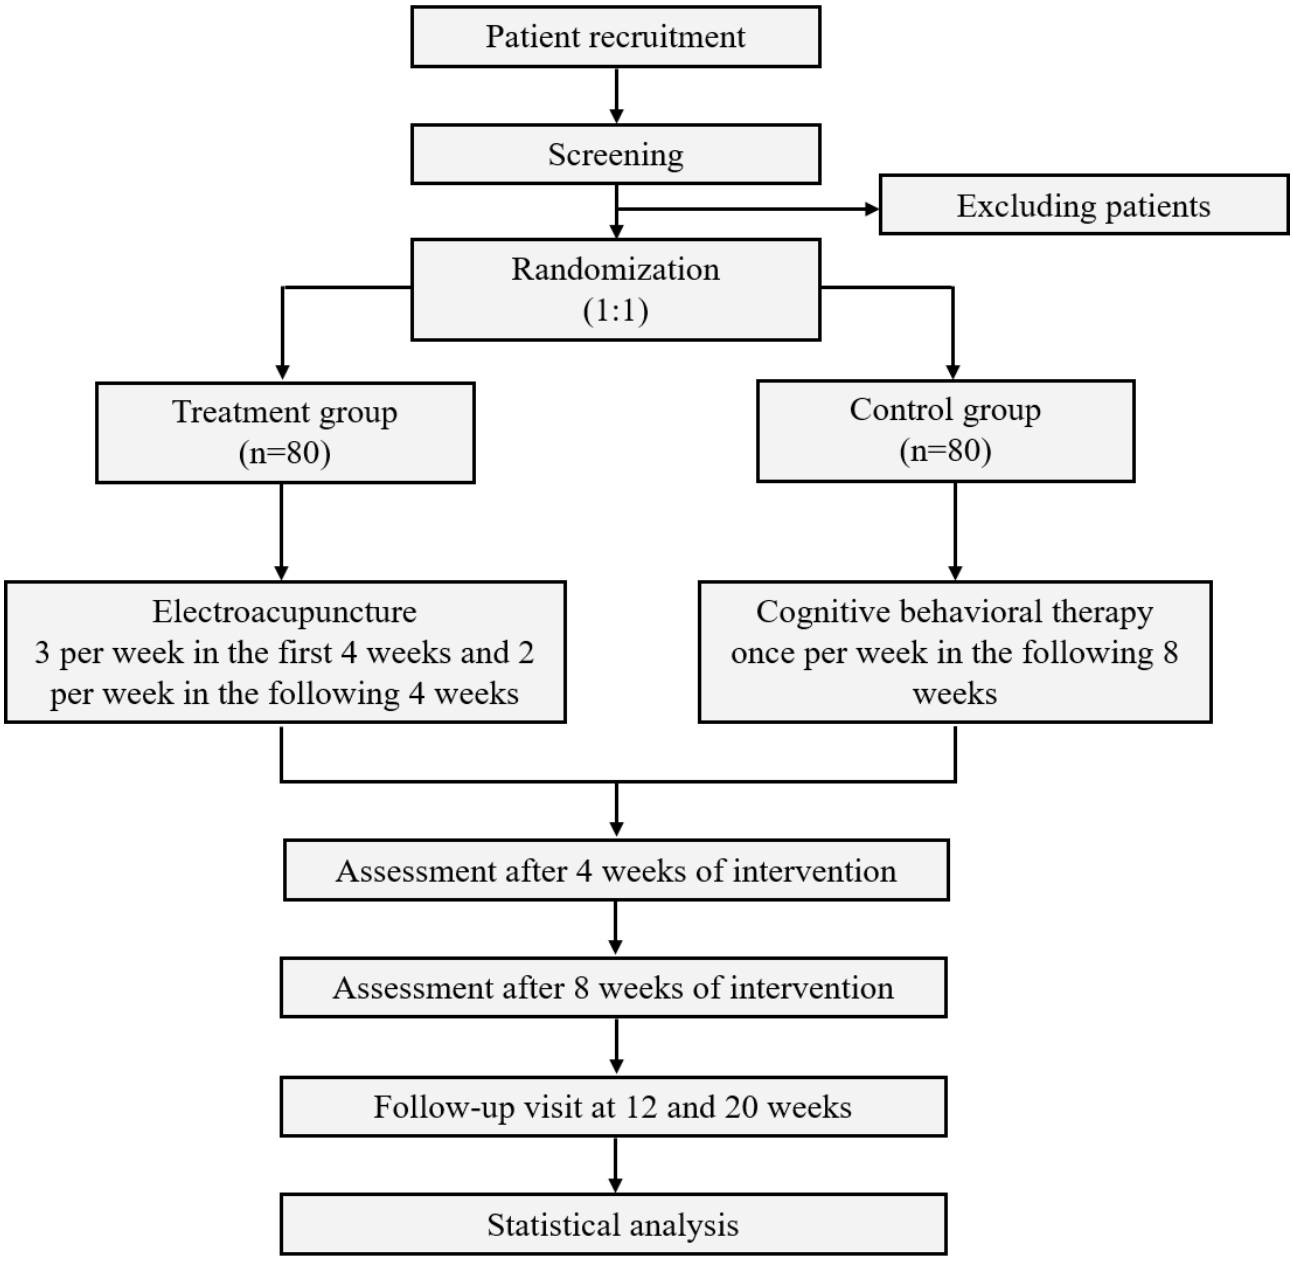
In addition to PMI, perimenopausal syndromes are usually managed with menopausal hormone therapy (MHT) [10-12]. However, some patients are reluctant to choose MHT due to adverse effects [13], such as increasing the risk of uterine fibroids, breast cancer, and thrombosis [14,15]. The main reason for the increased incidence of breast cancer in patients taking hormones is related to the use of synthetic progestins such as dydrogesterone and 17α-hydroxyprogesterone derivatives in MHT regimens [16,17].

Cognitive behavioral therapy (CBT), as the first-line nonpharmacological treatment for insomnia, is an appropriate treatment for PMI without any concerns of drug-related side effects [18,19]. The focus is primarily on sleep problems, but CBT also targets stress, low mood, and vasomotor symptoms. Convincing effects of CBT for insomnia (CBT-I) in menopausal women have been found [20-22]. However, due to its limited availability in the community, the limitations of the psychological expertise of the operator, the high treatment costs, and the cognitive level of the patient, CBT has not been widely implemented in China [23]. It is, therefore, essential to develop treatment strategies to help patients manage PMI and improve their quality of life.

Acupuncture is widely practiced in the prevention and treatment of PMI [24] and is effective in the treatment of PMI and various sleep disorders through significantly reducing Pittsburgh Sleep Quality Index (PSQI) and Insomnia Severity Index (ISI) scores [25-27], improving sleep efficiency and overall nighttime sleep time in insomnia patients and reducing night-time wakefulness. Acupuncture is also a safe and effective treatment for perimenopausal depression with short- to medium-term efficacy [28].

Electroacupuncture (EA) therapy is a product of the combination of modern electrical stimulation and acupuncture therapy, with both stimulation effects, and can effectively and safely improve the sleep quality and quality of life of patients with PMI. Compared to CBT, EA is less expensive, simpler to administer, easier to promote, and has a high level of acceptability and enjoyment [29,30]. Despite the positive effects of EA on improving sleep, no studies have compared EA with CBT in women with PMI. We aimed to compare the effect of CBT-I versus EA for PMI and simultaneously evaluate the safety and acceptance of EA. We hypothesized that EA would not be inferior to CBT in patients with PMI.

Methods



Study Design

This study is an assessor-blinded, randomized controlled trial. Participants will be randomized into the EA group or the control group in a 1:1 ratio. After the baseline assessment and informed consent has been obtained, a randomization number will be sent to the doctor. The statisticians and outcome assessors will be blinded to the allocation.

The duration of the trial is 21 weeks (Figure 1), including a 1-week baseline assessment period (weeks 0-1), an 8-week long treatment period (weeks 1-8), and a 12-week-long follow-up period (weeks 9-21) (Table 1). The trial will be conducted in accordance with the principles of the Declaration of Helsinki and has been approved by the ethics committee of the participating hospitals. The standard protocol items adhere to the Recommendations for Interventional Trials [31] and the checklist of SPIRIT (Standards for Reporting Interventions in Clinical Trials of Acupuncture) is presented in Multimedia Appendix 1).

[a]Patients in the treatment group will be treated with electroacupuncture for a total of 20 times.

[b]Patients in the control group will be treated with cognitive behavioral therapy for a total of 8 sessions.

[c]ISI: Insomnia Severity Index.

[d]MENQOL: Menopause-Specific Quality of Life.

[e]PSQI: Pittsburgh Sleep Quality Index.

[f]MRS: Menopause Rating Scale.

[g]HAMA: Hamilton Anxiety Scale.

[h]HAMD: Hamilton Depression Scale.

[i]PSG: polysomnograms.

Recruitment

This trial will be conducted at Yueyang Hospital of Integrated Traditional Chinese and Western Medicine affiliated with Shanghai University of Traditional Chinese Medicine from January 2023 to January 2025. In total, 160 participants will be recruited through posters, newspapers, and hospital websites. We will publish some advertisements in WeChat through the subscriptions of the acupuncture and gynecology departments. To reach the target sample size, lectures to publicize the project program will be given regularly.

Patients who sign up will initially be screened by phone and then asked to participate in a face-to-face interview to confirm whether they meet the criteria and to conduct further surveys. Written informed consent will be obtained before baseline outcome assessments and data collection.

XSL•FO
RenderX

Participants

The sample size is based on the ISI. After 8 weeks of intervention, the mean ISI score baseline changes are approximately –7.7 (4.18) [21,32]. Assuming that the ISI score of the acupuncture group is slightly lower than that of the CBT group after 8 weeks of treatment, the ISI score should be no more than –2, with a noninferior effect threshold of –4 [33]—assuming that the single-side significant level is α=.025, power of the trial is 1 – β=.80, and the ratio between the EA group and the CBT-I group is 1:1. As calculated by PASS software (IBM Corp), each group requires 71 cases. Assuming that the dropout rate is 10%, the final sample size should be 160.

Eligible patients will be randomly assigned to either the EA or CBT-I group and will receive EA treatment or CBT-I consultation, respectively. The inclusion criteria are the International Classification of Sleep Disorders (Third Edition) criteria for insomnia disorder; women aged 40-60 years; according to STRAW+10 (Stages of Reproductive Aging Workshop + 10), signs of menopausal tendency that began to appear from clinical features, endocrinology, and biology until 1 year after final menopause; insomnia lasting for >3 months; total ISI score >14; and willingness to participate in the investigation and provide written informed consent prior to the trial.

The exclusion criteria are the use of menopause hormone therapy and sedative or antianxiety drugs; nonnatural menopause (due to surgery, radiation, and medication); any diseases that cause sleep disturbance; unknown causes of vaginal hemorrhage; diagnosis of mental disorders or any serious physical illness; receipt of CBT or acupuncture for insomnia; participation in any other clinical trial within the last 6 months; and pregnancy or lactation.

Randomization and Blinding

This study uses a randomized block design. Individual random numbers will be generated with SAS (version 9.4; SAS Institute). The random table is reproducible, and the random seeds will be recorded in the file. A researcher who will not interact with the participants during the recruitment or interventions will take charge of using sealed opaque envelopes to keep the randomized allocation sequence. The trial is designed to be open-ended, but the evaluators will be blinded to patient group assignments. The therapists who administer the treatment are not involved in the evaluation of the trial.

Control Design

An EA (treatment) group and a CBT (control) group will be set up. Parallel controls will be performed between the 2 groups. The CBT group will undergo first-line treatment recommended by the guidelines, and this study has a noninferiority design. The purpose of this clinical study will be achieved by comparisons with first-line therapy.

Interventions

The acupuncturist and psychologist have qualifications and 10 years of clinical work experience. All study participants will receive 7 days of training prior to the trial to familiarize them with the process. The therapist will send a message from a phone account assigned to the study to confirm the session 1 day in advance.

Treatment

Treatment group participants will receive acupuncture treatment from the same acupuncturist. The temperature of the treatment room will not be lower than 25 °C. Patients in the EA group will be treated with 0.25×25 mm and 0.25×40 mm disposable steel needles (Guizhou Andi Medical Instrument Co, Ltd).

Patients will be positioned supine after local skin disinfection with 75% alcohol wipes. The acupuncturist will insert needles into the GV20 (Baihui), DU24 (Shenting), EX-HN3 (Yintang), EX-HN18 (Anmian), EX-CA1 (Zigong), RN6 (Qihai), and RN4 (Guanyuan) acupoints as per the WHO Standard Acupuncture Point Locations [34]. KI3 (Taixi), KI7 (Fuliu), HT7 (Shenmen), and SP6 (Sanyinjiao) may also be used accordingly. KI3 and KI7 may be used for hot flashes; HT7 and SP6 are used for anxiety and depression. The needle is inserted with the double hand-needle insertion technique at a depth adjusted based on the standard permissible depth of insertion for each acupoint. The needle is then twirled, rotated, lifted, and thrust moderately until achieving the *deqi* sensation.

An electric stimulator will be placed on the pair of GV20 and EX-HN3 points with a continuous wave, 2.5 Hz, and 4-5 mA, for 30 minutes in each session. The other needles are retained for 30 minutes and manipulated for 10 seconds, twice every 10 minutes, with intermittent stimulation.

The needles will be removed with clean cotton balls to avoid bleeding. Each patient will receive 20 sessions over 8 weeks as follows: 3 per week in the first 4 weeks, every 2 days, with a 1-day interval; and 2 per week in the following 4 weeks, every 3 days, with a 2-day interval.

Control Group

The 8-week CBT-I intervention consists of 1 face-to-face session weekly for a total of 8 sessions with a certified psychologist. Each session will be 45 minutes at a fixed time including setting objectives, learning skills, class activities, and assigning homework. The CBT-I protocol covers typical CBT-I components. The first face-to-face session will include an introduction by the therapist and CBT. After assessing the patient's condition, the therapist will introduce the insomnia psychological patterns to stimulate the patient's intention for the therapy. In the second session, the therapist will set sleep restriction and stimulation control strategies based on the first conversation and carry out targeted sleep education. Starting with the third session, the therapist will map the patient's sleep diary and assess compliance to determine whether uptitration is allowed. Cognitive therapy for negative sleep beliefs will be performed from session 5. The principles of confidentiality, adherence, and autonomy will be followed throughout. At the end of each session, the therapist will assign homework to the participant and summarize the content of each treatment to provide skill consolidation and relapse prevention.

We will ensure patient confidentiality during the interview process and only mention the questions in treatment; no one

XSL•FO
RenderX

shall disclose relevant information except the medical staff responsible for treatment. The client is expected to actively participate in the treatment process and, although there may be unforeseen events, we trust that the participant will adhere to the complete treatment process. Participants may leave the trial at any time during treatment. If, for some reason, the participant does choose to leave, there will be no effect on future treatment.

Ethical Considerations

The ethics committee has reviewed the research plan, informed consent form, and other relevant clinical trial documents (2021-088). This trial can only be carried out with the written consent of the ethics committee. If unforeseen problems arise during the study, these should be reported to the ethics committee immediately. Patient priorities, experience, and preferences were not involved in the development of the research question and outcome measures, the design of this study, or the recruitment to and conduct of the study. The results will be not disseminated to study participants.

Data Management

This experiment adopts electronic data management as described below and in the data management plan. The plan has been written by the data manager and will be carried out according to the described time, content, and methods. First, the data administrator will design the electronic case report form (eCRF) for the pilot study, a logic verification path is set according to the date verification plan, and the eCRF can be put into use only after passing a test and approval. The data in the eCRF are derived from the original record, and the data entry clerk enters the participant visit data as per the eCRF instructions. An inspector will then check the consistency of the eCRF data with the source data. All queries raised will be dealt with in a timely manner and addressed until the data is "clean." After the database record is signed by the main researchers, bidders, statistical analysts, and data managers, the data administrator will lock the database. The eCRF of each participant will be saved as a PDF electronic document. After the data analysis, the data administrator will close the database.

Quality Control

The trial will be conducted under the supervision of the Yueyang Hospital of Integrated Traditional Chinese and Western Medicine affiliated with the Shanghai University of Traditional Chinese Medicine. The clinicians in this trial have more than 10 years of clinical experience, and all the researchers will undergo training before the trial. A qualified clinical trial expert will be invited to monitor the study to identify any problems, examine the collected data, and control bias. Regarding quality control management, the data will be jointly managed through supervision, audit, and self-inspection. The procedures will be carried out in accordance with the relevant standard operating procedures.

Outcome Measures

The primary outcome will be a mean change in total ISI from baseline to the end of the 8-week intervention. The validated ISI that has a concise design, good reliability, and has become a recognized tool for clinical researchers to evaluate the efficacy of insomnia will be used [35,36]. The ISI is a self-reporting questionnaire, and 7 self-rated items are included that evaluate the severity and impact of insomnia on patients. The total ISI score ranges from 0 to 28 points. The higher the score, the more serious the degree of insomnia, which is classified according to the total score (0-7 points represent clinically nonsignificant insomnia, 8-14 points represent subthreshold insomnia, 15-21 points represent moderately severe clinical insomnia, and 22-28 points represent severe clinical insomnia).

The secondary outcomes include the Menopause-Specific Quality of Life (MENQOL); Menopause Rating Scale; PSQI; Hamilton Depression Scale (HAMD); Hamilton Anxiety Scale (HAMA); hot flash score; and the level of estradiol, follicle-stimulating hormone, and luteinizing hormone in serum. Sleep architecture will be assessed using deep learning on polysomnograms (PSG). The ISI and MENQOL are measured at randomization and 4, 8, 12, and 20 weeks after randomization. The other outcomes are measured before and 8 weeks after randomization.

Menopause Rating Scale is a reliable method to measure the severity of menopausal compliance and contains 11 items in 3 dimensions (psychological, somatic-vegetative, and genitourinary systems). Each symptom is given a score of 0, 1, 2, 3, and 4 according to severity; the total is the sum of the scores of each item [37,38].

The PSQI scale is used to assess the quality of sleep during the previous month [39]. The scale consists of 9 questions, and the overall score ranges from 0 to 21. The higher the score, the worse the sleep quality. PSQI can be used to calculate patient sleep onset latency, time in bed, wake after sleep onset, total sleep time, sleep efficiency, and record the medicine used. Therefore, the combination of sleep quality and quantity can be used to assess sleep conditions and identify any sleep disorders.

The HAMD was developed by Hamilton [40] in 1960 to test the severity of depression in participants. The scale evaluation method is simple and is most used in clinical practice. The time frame for the assessment is the last 1 week. Two trained assessors jointly examine and score the patient by means of a conversation. A version with 17 items will be used in this study with scores of 0-7 regarded as having no depressive symptoms, 8-17 regarded as having mild depression, 18-24 regarded as having moderate depression, and 25-52 regarded as having major depression.

The HAMA scale uses conversation, observation, and independent grading to rate anxiety in the previous week. There are 14 items, and anxiety is scored as 0 to 4 (0: none; 1: mild; 2: moderate; 3: severe, and 4: very severe). The total ranges from 0 to 56 points, and the higher the score, the more severe the anxiety symptoms [41]. HAMA can also be used to assess medication use and the effect of psychological intervention.

Participants will complete validated hot-flash daily diaries for 7 days at baseline and 8 weeks after randomization, by recording the number of hot flashes and severity (mild, moderate, severe, or very severe). A composite score is generated by multiplying the number of mild, moderate, severe, or very severe hot flashes

XSL•FO
RenderX

by 1, 2, 3, and 4, respectively, and summing the values into one score [42].

MENQOL is used to record the symptoms experienced by participants in the past month or to evaluate the clinical efficacy of quality of life in menopausal women. MENQOL includes 29 items, each with a score of 0-6; 0 means the symptom has no impact, and 6 means extreme impact. The scale records symptoms in the 4 domains such as vasomotor, somatic symptoms, psychological symptoms, and sexuality. The higher the score, the worse the patient's quality of life [43].

PSG can objectively monitor sleep structure and efficiency, wakefulness, breathing, and periodic limb movements by recording the time off of lights; time in bed, total sleep time; sleep onset latency; wake-up time after sleep onset; total awake time from sleep onset to lights on; sleep efficiency; and sleep time in each period. Various physiological parameters such as electroencephalogram (EEG), electromyogram, electrooculogram, respiratory airflow, respiratory motion, and oxygen saturation are monitored [44,45]. Sleep staging will be performed by expert sleep technicians in nonoverlapping 30-second epochs as 1 of 5 stages such as wake, nonrapid eye movement (REM) stage 1, non-REM stage 2, non-REM stage 3, and REM.

Safety Assessment

All adverse events (AEs) will be recorded during the trial and ranked as mild (does not affect the normal function of the patient), moderate (affects normal function to a certain extent), or severe (significantly affects normal function). Acupuncture syncope, pain at the acupuncture point, bleeding, hematoma, or infection that may occur during acupuncture; patients developing symptoms that are significantly unrelated to the current disease, including an exacerbation of a preexisting disease; abnormalities in medical detection or physical examination that require clinical treatment or further examination; and injury or accident are considered as AEs.

Any medical conditions (eg, vertigo) and accidents should be reported as 2 different AEs. Abnormalities found by laboratory tests, when related to another reported event or that require clinical treatment or further investigation, should be described in the remark's column of the record and not treated as a separate AE.

Statistical Analysis

If statistical demographic data and other baseline characteristics are continuous variables, they will be represented by the mean (SDs) and median (IQR) values. We will also include count and grade data for frequency and composition ratios. Concomitant medications will be categorized using the Anatomical Therapeutic Chemical code, percentage of patients with concomitant medications, and the incidence of AEs will be compared using the χ^2 test or Fisher precision probability.

After 8 weeks of intervention, the change in the ISI score will be compared with the baseline. The subgroups and baseline are used as covariates to compare the differences between groups by analysis of covariance and the 2-sided 95% CIs of the least squares mean differences between groups. During each visit, the ISI score will be recorded, and mixed-effects model repeated measures will be used to compare the differences between groups. To compare 2 independent samples, a 2-tailed *t* test or nonparametric test will be used for continuous data, and chi-square or Fisher exact or nonparametric tests will be used for categorical data. The times and number of drugs that are taken by participants will be compared between groups using a rank sum test. When a covariance analysis is used for the primary efficacy indicator, missing values will be filled using the last observation carried forward method. When using the mixed-effects model repeated measures method for analysis, the missing data will not be filled. When an outlier is found, the main researcher, the applicant, and the statistician will discuss the processing method together before the database is locked. If necessary, the outlier value will be removed for sensitivity analysis.

Results

Recruitment of participants for the study is presently underway. The inaugural participant was enrolled in January 2023, signifying the commencement of the recruitment phase. It is anticipated that the recruitment process will persist until January 2025, at which juncture data collection will commence.

Discussion

Principal Findings

This will be the first randomized, noninferiority, EA-controlled trial to study the efficacy and safety of EA compared with CBT for PMI. Considering that drugs may cause adverse reactions such as feeling drowsy, lightheaded, and dizzy, medications need to be limited to the lowest necessary dose and shortest necessary duration and nonpharmacological therapies are reasonable to use [18].

CBT-I has a longer duration of treatment and is suitable for patients with cognitive impairment [46]. It is offered in various forms such as one-on-one or in groups via telephone, the internet, or books. During the COVID-19 pandemic, some evidence-based psychotherapy was provided to medical staff to relieve mental pressure and prevent the occurrence of psychological disorders [47]. Web-based CBT has been shown to be effective in treating and preventing many stress-related symptoms among health care workers. Web-based CBT has also shown strengths in breast cancer survivors with clinically significant sleep problems [48].

Actigraphy (ACT) and PSG are commonly used to monitor sleep in clinical studies [49]. We have chosen PSG to monitor sleep as an objective efficacy index, as it makes a comprehensive estimation by monitoring various physiological parameters such as EEG, electromyogram, ECG, respiratory airflow, respiratory motion, and oxygen saturation while being manually analyzed by a sleep technician. Thus, sleep architecture is shown without bias. In addition, PSG is the gold standard for the assessment and diagnosis of sleep disorders [50]. However, PSG must be performed in the laboratory under the supervision of a relevant technician, and the discomfort of the electrodes and harnesses necessary for PSG monitoring brings about the "first night

XSL•FO
RenderX

effect" [51], which also has a higher cost than other tests. Rather than recording EEG activity, ACT combines body movement frequency with the help of gravity sensors [52]. Although ACT is economical and simple to wear, it has a distinct drawback in that it may overestimate sleep time and underestimate wake time [53].

Women who are undergoing menopause transition seem to report more sleep difficulties. The content of some hormone changes dramatically in this stage, which may be associated with decreased melatonin synthesis and secretion. Progesterone reduces arousal and can have a sedative effect, while estrogen increases the turnover of the neurotransmitter norepinephrine and, subsequently, increases time spent in REM sleep and decreases REM latency [54]. Many of the menopausal symptoms (eg, hot flashes and night sweating) are precipitating factors for insomnia, which are in relation to the occurrence of poor sleep quality in menopausal women. Hot flashes are one of the most typical menopausal symptoms and are highly associated with awakening perimenopausal women in particular [55]. Repeated exposure to menopausal symptoms that cause wakefulness at night may perpetuate insomnia symptoms through conditioned arousal.

Limitations

Our study protocol has some limitations. First, PSG brings discomfort to patients and reduces sleep quality. Although it is precise in the definition of wakefulness through accurate measurement with electroencephalography, PSG has insufficient validity for the assessment of wakefulness after sleep onset relative to wrist ACT. Second, we lack a follow-up assessment beyond 3 months. The durability of CBT-I is maintained 10 years after treatment [56]. Third, as our sample groups are going to be recruited from Shanghai, China, the inclusion of participants from different countries and regions would increase the persuasiveness of the trial results. The results may not be generalized to women who were taking certain medications, or who had certain gynecological surgeries (eg, hysterectomy and bilateral oophorectomy).

Conclusions

Acupuncture and CBT-I have been recommended in the guidelines [57]. Indeed, if the efficacy of EA is noninferior to CBT, it could become an empirically assessed viable option specifically suited to the needs of women with PMI. The results of this study will provide knowledge for clinicians in the treatment of PMI.

Acknowledgments

We appreciate the support of all research staff involved in this trial and the ethics committee of Yueyang Hospital of Integrated Traditional Chinese and Western Medicine. This study was supported by the Shanghai Science and Technology Commission (22Y11923100), Shanghai Municipal Health Commission (202140422), and Shanghai Clinical Research Center for Acupuncture and Moxibustion (20MC1920500).

Data Availability

The data sets generated in this study will be made available from the corresponding author. The study team will retain the exclusive use of the trial data until the publication of major outputs has been completed.

Authors' Contributions

YFC and XTY conceived the research plan. HXW and JH drafted the protocol and formed the analysis plan. YFC, XTY, HXW, XQS, YTZ, YR, Jing Hu, and Jia Hu coordinated the study. HXW and YFC recruited the participants. All authors participated in reading and approved the final paper.

Conflicts of Interest

None declared.

Abstract

Background: Head and neck cancers that cause severe aesthetic and functional disorders normally metastasize to the cervical lymph nodes. Patients with cervical lymph node metastasis are undergoing neck dissection. Shoulder complaints are common after neck dissection, with patients reporting symptoms such as pain, weakness, shoulder droop, and disability. However, no safe and effective treatment is available for this condition at present. We will conduct a double-blinded, randomized controlled trial to evaluate the efficacy of carbon dioxide (CO_2) paste in relieving pain in patients after neck dissection.

Objective: This will be the first clinical study to compare the efficacy of CO_2 paste with placebo in relieving postoperative pain in patients who underwent neck dissection.

Methods: We will perform this trial at the Kobe University Hospital in Japan. Patients will be randomized 1:1 into the CO_2 paste and control groups. Patients in the CO_2 paste group will have the CO_2 paste applied to the cervical surface skin for 10 minutes once per day for 14 consecutive days. The primary end point of the study is a change in the visual analog scale (VAS) scores of neck pain from baseline on day 1 (preapplication) to the end of drug application (day 15). Secondary end points include changes in the following parameters from baseline on day 1 to the end of drug application (day 15) or the study (day 29): neck pain VAS score (days 1-29), grip strength (days 1-15 and 1-29), VAS scores for subjective symptoms (the feeling of strangulation, numbness, swelling, and warmth in the neck and shoulder region) for days 1-15 and 1-29, whether the VAS score improved more than 30% (days 1-15), the arm abduction test (days 1-15 and 1-29), shoulder range of motion (abduction and flexion) for days 1-15 and 1-29, occurrence of skin disorders, and occurrence of serious side effects. Periodic monitoring will be conducted for participants during the trial. This study was approved by the certified review board of Kobe University.

Results: The intervention commenced in May 2021 and will continue until March 2024. The collected data will provide information on the efficacy of the CO_2 paste treatment. The primary end point will be compared using the Wilcoxon test, with the 1-sided significance level set at 5%. Each evaluation item will be summarized. Secondary efficacy end points will be analyzed to provide additional insights into the primary analysis. Findings based on the treatment effects are expected to be submitted for publication in 2025.

Conclusions: This trial will provide exploratory evidence of the efficacy and safety of CO_2 paste in relieving pain in patients after neck dissection.

Introduction

Postoperative wound pain in the head and neck region generally improves within 1-2 weeks after surgery. However, patients undergoing cancer treatment often experience continuous, persistent pain, which can cause physical and psychological distress. Surgery and radiation therapy often cause painful scarring and contractures. Musculoskeletal and neuromuscular disabilities after radiotherapy and surgical treatment are major causes of cancer treatment–related side effects. Disabilities in the head and neck region after cancer treatment are related to a patient's ability to communicate, eat, and work [1]. These changes reduce the functioning and social interaction of these patients [1,2].

Shoulder complaints are common (18%-77%) after neck dissection, even if the spinal accessory nerve has been preserved [3,4]. Symptoms such as pain, weakness, shoulder droop, and disability have been reported in patients after neck dissection [5,6]. Pain is an important factor affecting the quality of life (QOL) of cancer survivors [1,7]. Although various drug treatments are available for preventing or improving the management of chronic postsurgical pain [8-10], these treatments have side effects.

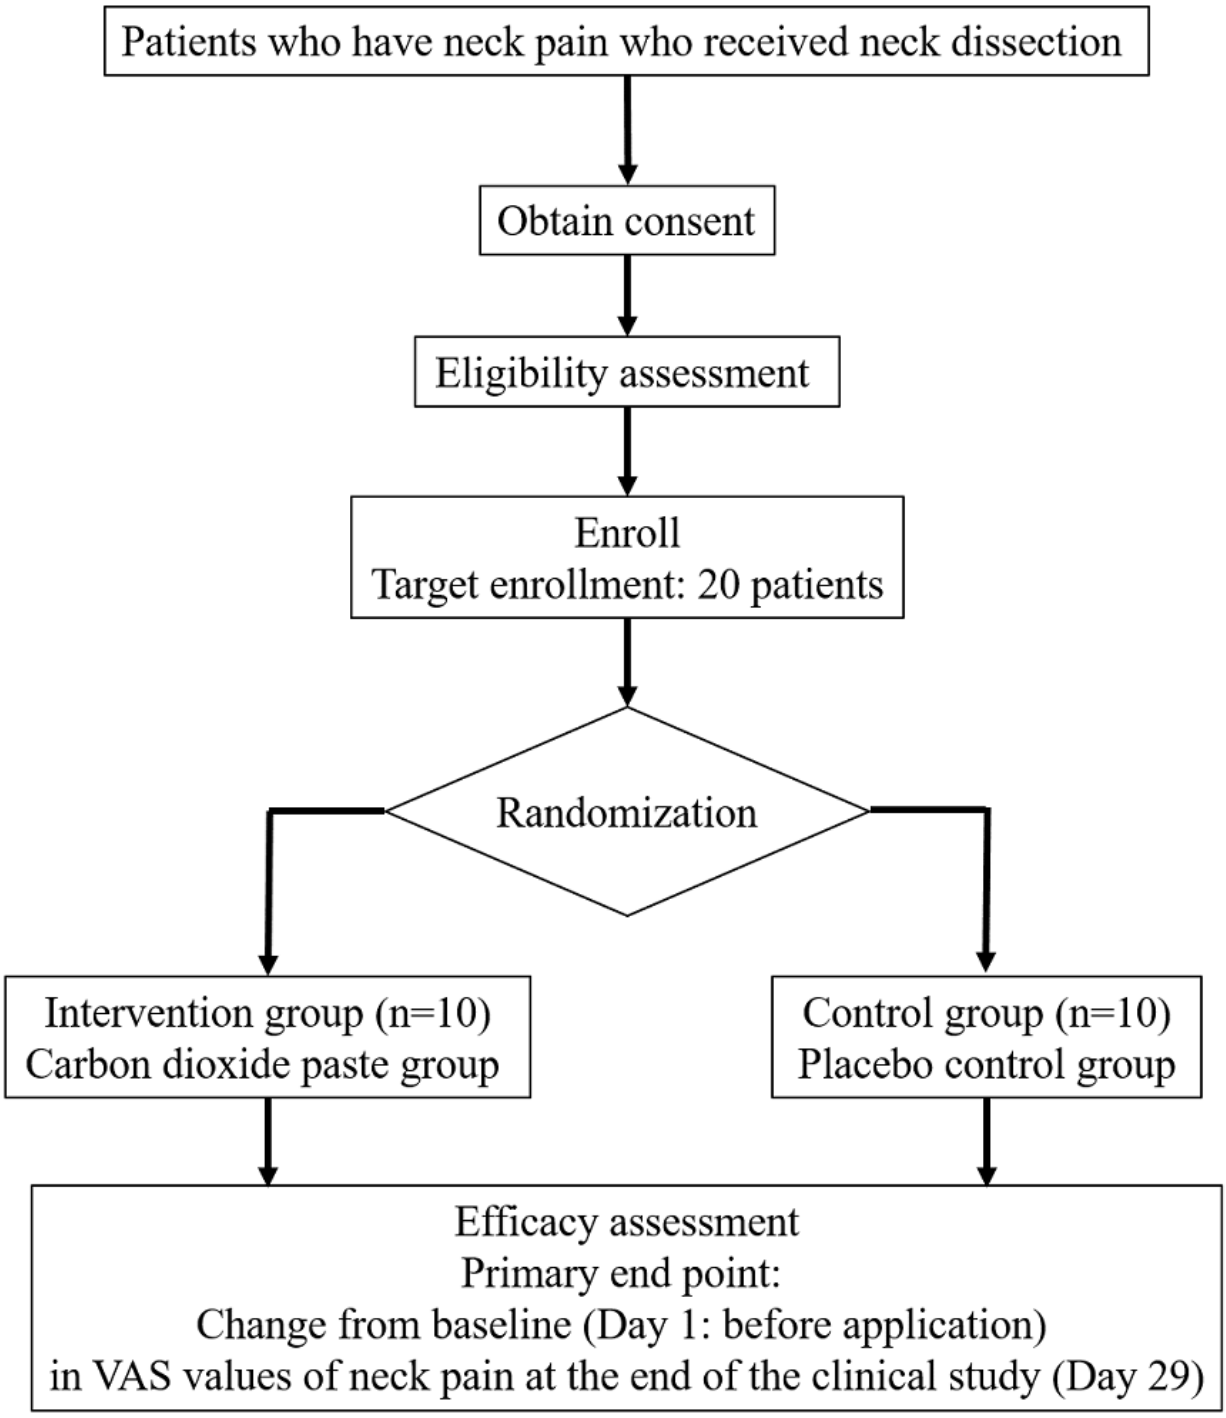
The exact etiology of persistent postsurgical pain remains unclear, but its causes are thought to involve neuropathy [11-13], inflammation [14,15], central sensitization [16,17], and ischemia [18-20]. In rats, decreased blood flow and tissue ischemia cause complex regional pain syndrome–like symptoms [18]. In addition, patients with peripheral arterial diseases experience chronic ischemic pain [20]. Thus, continuous postoperative pain may be reduced by improving the blood flow in the ischemic scar tissue.

We had previously reported the effects of transcutaneous application of carbon dioxide (CO_2) in a hydrogel as an absorption-promoting agent in healthy individuals and various animal models [21-23]. Transcutaneous application of CO_2 improves vascularization and exercise performance in rats; it also increases local oxygenation, causing the dissociation of oxygen from hemoglobin (Bohr effect) [23-25]. However, this method uses CO_2 gas, which is difficult to apply to the head and neck. In a recent study, we investigated the usefulness, safety, and feasibility of a CO_2 paste by analyzing the changes in blood flow in a phase 1 clinical study in healthy individuals [26]. The CO_2 paste reacted with water on the skin surface, could infiltrate CO_2 transcutaneously without the use of external CO_2 gas, and could be applied to the head and neck region. In the phase 1 clinical study, application of the CO_2 paste increased the blood flow in the skin and muscles, as observed by dynamic magnetic resonance imaging, and caused no adverse reactions.

This double-blind, randomized controlled trial aims to evaluate the efficacy and safety of CO_2 paste in decreasing postoperative neck pain in patients undergoing neck dissection.

Methods

Objectives



This study will examine whether the application of a CO_2 paste can reduce postoperative neck pain in patients receiving neck dissection in a double-blinded, randomized controlled trial. The primary objective is to estimate the within-patient differences in visual analog scale (VAS) scores for neck pain ranging from 0 (no pain) to 10 (worst pain) from baseline (day 1: before application) to the end of the study drug application (day 15). The secondary objectives are to evaluate the within-patient differences in the VAS scores for neck pain from baseline (day 1: before application) to the end of study drug application (day 15), grip strength from baseline to the end of the drug application (days 1-15) and the end of the study period (days 1-29), VAS scores for subjective symptoms (the feeling of strangulation, numbness, swelling, and warmth) from baseline to the end of the drug application (days 1-15) and the end of the study (days 1-29), arm abduction [27] from baseline to the end of the drug application (days 1-15) and the end of the study (days 1-29), and shoulder joint range of motion (abduction or flexion) from baseline to the end of the drug application (days 1-15) and the end of the clinical study (days 1-29). In addition, we aim to evaluate whether patients showed a ≥30% improvement in the VAS scores for neck pain from baseline to the end of the drug application (days 1-15) and the end of the study (days 1-29).

Study Design

This study has been designed as a single-center, placebo-controlled, double-blind, randomized controlled trial. The patient flowchart is shown in Figure 1. This study will be conducted at Kobe University Hospital. All data will be stored and archived at the data center of Kobe University Hospital. We will use Research Electronic Data Capture (REDCap; Vanderbilt University), an electronic data system for clinical research, to manage the data and protect confidentiality before, during, and after the trial. The study population will consist of patients undergoing neck dissection and will be selected based on the inclusion and exclusion criteria listed in Textbox 1. Patients will be recruited from Kobe University Hospital from May 24, 2021, to March 31, 2024. All patients will be asked if they wish to participate in the study and will be enrolled after obtaining written informed consent.

Textbox 1. Inclusion and exclusion criteria for the study.

Inclusion criteria

- Aged 20 years or older
- Have complaints of postoperative neck pain after unilateral cervical dissection
- Between 6 months and 3 years after neck dissection
- A visual analog scale score of 1 or higher for neck pain
- Have given voluntary consent to participate in this clinical study

Exclusion criteria

- Hypersensitivity to drugs, including severe allergies
- Peripheral arterial disease, ischemia (Fontaine III-IV), and ischemic cerebral artery disease
- Heart failure (New York Heart Association IV) and ischemic heart disease (Canadian Cardiovascular Society functional classification 3-4)
- Female patients who are pregnant, lactating, wishing to become pregnant during the study period, or are fertile and cannot accept an effective contraceptive method
- Severe respiratory disease with oxygen saturation (SpO2) less than 90% at rest
- Skin ulcers larger than 4 cm × 4 cm × 1 cm or skin diseases making it difficult to apply the paste
- Deemed inappropriate for participation in this clinical study by the investigators

Randomization (Allocation)

Using the permutation random block method stratified by category, participants will be randomly assigned to either the CO_2 paste group or the placebo control group at a 1:1 allocation ratio. To ensure that blinding is maintained, the block size will not be disclosed. The allocation sequence for the randomization method will be generated by a biostatistician. All participants who provide consent to participate, fulfill the inclusion criteria, and do not meet any of the exclusion criteria will be randomized. The eligibility of each participant will be confirmed. A subject-enrollment confirmation form containing the eligibility judgment, randomization assignment results from the generated random sequence, and the enrollment number will be issued.

Experimental Drugs

The CO_2 paste (direCO_2t) is manufactured as an experimental drug at the CO2TECH, a limited liability company. The CO_2 paste contains 1,3-butylene glycol and other components, including sodium hydrogen carbonate, malic acid, sodium dihydrogen phosphate, an alkyl-modified carboxyvinyl polymer, and carboxyvinyl polymer. The placebo paste is a formulation in which the sodium bicarbonate in the CO_2 paste is replaced by a nonreactive material (sodium chloride).

Treatment and Assessment Schedule

Within 4 weeks of enrollment, the VAS score for neck pain will be evaluated 1 week before the administration of the experimental drug during the preobservation period. On the first day of treatment, body temperature, blood pressure, oxygen saturation, and pulse rate will be measured by a physician, dentist, or nurse before and after the application of the experimental drug. The paste will be applied at 0.2 g-0.3 g/100 cm^2 to the affected neck area once per day for 14 consecutive days. The duration of each application will be 10 minutes, and the paste will be wiped off after application.

Data Collection

The data collection schedules are presented in Table 1. The primary investigator or subinvestigator will enter the case report form (CRF) data for each participant into the electronic data capture (EDC) system. The principal investigator will confirm that the entered CRF data are complete and correct, electronically sign the CRF on the EDC system, and print out the signed CRF for filing. The CRF printout will be retained. If any queries about the CRF data are entered by the staff at the data center, the primary investigator or subinvestigator will be required to promptly respond to them.

Main Outcomes

The primary end point for efficacy is the change in the VAS score for neck pain from baseline (day 1: before application) to the end of the study drug application (day 15).

The secondary efficacy end points are as follows:

1. Change in the VAS score for neck pain from baseline (day 1: before application) to the end of the clinical study (day 29).
2. Changes in grip strength from baseline to the end of the drug application (days 1-15) and the end of the study (days 1-29).
3. Changes in VAS scores for subjective symptoms (feeling of strangulation, numbness, swelling, and warmth) from baseline to the end of the drug application (days 1-15) and the end of the study (days 1-29).
4. Whether the VAS score for neck pain showed a ≥30% improvement from baseline to the end of the drug application (days 1-15) and the end of the study (days 1-29).
5. Change in arm abduction [27] from baseline to the end of drug administration (days 1-15) and the end of the study (days 1-29).
6. Change in shoulder joint range of motion (abduction and flexion) from baseline to the end of drug application (days 1-15) and the end of the study (days 1-29).

The secondary end point for safety is the presence or absence of adverse events such as skin disorders and serious diseases. The relationships among the interventions, outcomes, other assessments, and visits associated with the participants in this study are shown in Table 1.

Statistical Analysis

The primary objective of this clinical study was to evaluate the efficacy of the CO_2 paste versus the placebo in terms of the change in VAS scores for neck pain (the primary end point). For the comparison of the primary end point, the Wilcoxon test will be performed for the null hypothesis, “There is no difference in the change in VAS values for neck pain at day 15 between

XSL•FO
RenderX

the placebo group and the CO_2 paste group." The significance level will be set at 5.0% (1-sided). Each evaluation item will be summarized. Secondary efficacy end points will be analyzed to provide additional insights into the primary analysis. No adjustment for multiplicity will be made in the analyses of the secondary efficacy end points. The significance level for hypothesis testing is 5% (2-sided) with 2-sided 95% CIs. The incidence and rate of disease will also be evaluated. The safety end point is the frequency of the occurrence of adverse reactions. Tables will be prepared for the end points, and exact 2-sided 95% CIs of the binomial distribution will be calculated for each group to estimate the proportions.

Sample Size Calculation

Most patients are expected to have a baseline VAS score of 2-3 cm. For the primary end point (the amount of change in VAS values for neck pain), we estimated that the mean difference in change between the CO_2 paste application and placebo groups would be 2 (SD 1.5) cm. A Wilcoxon test (a nonparametric test) will be performed considering the possibility that participants with a baseline score of less than 2 cm might be enrolled. The number of cases based on the Wilcoxon test can be calculated by multiplying the number of cases based on the *t* test [28]. Although the constant for multiplication is 1.045 in the case of a normal distribution, since the participants in this study were not assumed to be normally distributed, the number of cases was calculated by multiplying by 1.2. When conducting a *t* test with a 1-sided significance level of 5.0% and a power of 80%, a total of 7 participants were required per group. When the number of cases was multiplied by 1.2, the total number of cases was 8.4. Therefore, considering drop out cases, 20 cases would be sufficient to maintain power.

Monitoring for Human Rights, Safety, and Adequacy

Monitoring will be conducted periodically to check whether the human rights and safety of the participants are protected and to confirm that the regulatory requirements of the Clinical Trials Act are followed. To ensure an appropriate assessment, the principal investigator is responsible for dealing with personal data and items specified in the written procedure. Any requirements made by the ethics committee will be immediately announced to the participants by the study investigators.

Other Considerations

This study will be conducted without patient or public involvement. Neither the patients nor the public will be involved in the development of the research question, study design, or implementation of the trial. Patients will not be invited to develop patient-relevant outcomes, interpret the results, or participate in the writing or editing of the final manuscript. Since the interventions in this study are routine clinical procedures, the burden of the interventions will be assessed by the patients themselves.

Any protocol changes that affect the study conduct or participant risk-benefit profile will require approval from the relevant institutional review board, including changes in the objectives, design, sample size, participant characteristics, staff changes, or significant administrative features. Minor protocol corrections or clarifications that do not affect the study conduct or the participant risk-benefit profile will be viewed as administrative changes and documented internally. The study investigators will have full access to and ownership of all the data. Anonymized data will be made available to other interested investigators for additional analyses on reasonable request, following reports of primary outcomes and with an appropriate data use agreement. The findings of this study will be disseminated through scientific and professional conferences and a peer-reviewed journal.

Ethical Considerations

The study is being conducted in compliance with the principles of the Declaration of Helsinki (1996), the principles of good clinical practice, and all applicable regulatory requirements. This study has been approved by the Clinical Research Review Board of Kobe University (CRB5180009), and the trial has been registered with the Japan Registry of Clinical Trials (jRCT) (jRCTs051210028). All participants will be required to provide written informed consent before any study procedures are conducted. The participants will have the opportunity to review the consent form and confirm that they have fully understood the details of the study procedures. Secondary use of the data will occur only if the patients provide written informed consent for additional use of their data. Secondary use of the data will adhere to appropriate ethical review and approvals, as per institutional guidelines. No funding was received for this study, including institutional or departmental support. The study is not commissioned, externally peer reviewed.

Results

The subject recruitment began on May 24, 2021. The entry period for participants is up to March 31, 2024, three years after the jRCT registration. Data analyses of all enrolled participants will be conducted in 2024. This manuscript is based on the current version of the protocol (version 3.0), last updated on December 23, 2022.

The data sets generated in this study will be available on the jRCT website. The final report is expected to be published in a peer-reviewed journal in 2025. The findings will be disseminated through scientific and professional conferences and peer-reviewed journal publications in 2025.

Discussion

Expected Findings and Implications

This report describes the protocol for a study evaluating the application of CO_2 paste to patients who undergo neck dissection and experience postoperative complaints. A neck dissection is a surgical procedure performed to remove cervical lymph nodes. During surgery, the blood vessels are ligated to prevent bleeding. In addition, the internal jugular vein, which drains blood from important organs such as the brain, face, and neck, is removed depending on the type of neck dissection. These blood flow interruptions lead to wound ischemia and various postoperative symptoms or dysfunctions.

Pain, the main side effect of neck dissection, often aggravates patient QOL [1,7]. As its pathogenesis remains uncertain, a

XSL•FO
RenderX

treatment strategy for postoperative pain has not yet been established. Analgesics such as nonsteroidal anti-inflammatory drugs and acetaminophen are commonly administered to relieve this pain. Nonsteroidal anti-inflammatory drugs show remarkable efficacy as painkillers; however, they are also associated with serious adverse reactions in the gastric mucosa and cardiovascular, hepatic, renal, and hematological systems [29]. Although almost all patients receive acetaminophen [30], those undergoing neck dissection continue to experience pain. Considering the limitations of drug therapy, effective treatment of every patient with postoperative pain is essential.

In a phase 1 clinical study, we reported that CO_2 paste application increases blood flow to the skin and muscles without any side effects [26]. Since transcutaneous CO_2 application induces angiogenesis by inducing an artificial Bohr effect, we hypothesize that this simple and adaptable treatment can alleviate side effects and improve the QOL of patients undergoing neck dissection.

This study will be the first to apply CO_2 paste to postoperative skin. Since it is composed of food ingredients, the CO_2 paste is considered to have few life-threatening side effects. However, there is no evidence on whether its application may induce dermatitis. Therefore, the occurrence of dermopathies such as erythema and exanthema should be carefully monitored during the trial. To address potential safety concerns, the CO_2 paste will be applied to the postoperative neck for only 10 minutes a day.

Through this study, we aim to determine the curative effect of CO_2 paste application on postoperative neck pain in patients undergoing neck dissection. Since the efficacy of CO_2 paste for neck pain has never been reported, this will be the first well-designed clinical evaluation study on this topic. Our primary hypothesis is that CO_2 paste application can reduce pain in patients undergoing neck dissection. We also expect that the application of this paste will reduce subjective symptoms, including feelings of strangulation, numbness, swelling, and warmth, and will improve grip strength, arm abduction, and shoulder joint range of motion (abduction and flexion).

Study Strengths and Limitations

We previously conducted a clinical trial on a small number of healthy individuals. To explore the adequacy and applicability of CO_2 paste application, this will be the first protocol to be performed as a phase 2, double-blinded, randomized controlled trial, evaluating the efficacy of CO_2 paste in a small number of patients with neck pain after neck dissection. Nonetheless, this clinical trial has some limitations that should be acknowledged. First, the number of evaluated patients is relatively small to conclusively determine the efficacy of the CO_2 paste. Second, since some patients underwent neck dissection as part of larger resections, a small amount of heterogeneity is expected. Finally, this study is limited by its short duration (28 days).

Conclusions

Considering the general condition of the patients and the side effects of drug therapy, postoperative pain after neck dissection is difficult to manage. Therefore, establishing a widely applicable treatment with fewer adverse effects is essential. The results of this study will provide valuable evidence for the future application of CO_2 paste to patients complaining of pain after neck dissection.

Acknowledgments

This trial is supported by CO2TECH, a limited liability company, which has provided the authors with both the CO_2 and the placebo paste. We would like to thank Editage for English language editing.

Data Availability

The data sets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

All authors met the criteria of authorship as outlined in the International Committee of Medical Journal Editors and approved this manuscript for submission. Specific contributions were as follows: The conception or design of the work and the interpretation of the data for the work were done by TH, DT, YK, and MA; acquisition and revising the work critically for important intellectual content: TH, DT, YK, IS, NY, and MA; analysis: TH; and drafting the work: YT, TH, DT, YK, and MA. The final approval of the version to be published and the agreement to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved were given by all the authors.

Conflicts of Interest

None declared.

Abstract

Background: *Mycoplasma genitalium* is an emerging sexually transmitted pathogen associated with increasing antibiotic resistance. The current treatment guidelines recommend moxifloxacin-sequential therapy for macrolide-resistant *Mgenitalium* or strains with unknown resistance profiles. However, it is unclear whether sitafloxacin, a 4th-generation fluoroquinolone antibiotic, is effective against resistant strains.

Objective: This study aims to assess and compare the efficacy and safety of sitafloxacin- and moxifloxacin-based treatment regimens for managing *Mgenitalium* infections.

Methods: We will conduct this randomized controlled trial at multiple centers in Japan. Eligible participants include adults aged 18 years or older with a confirmed *Mgenitalium* infection, as determined through the nucleic acid amplification test. Patients will be randomly assigned using a stratified approach based on the treatment facility and infection site. The interventions comprise oral sitafloxacin (200 mg) daily for 7 days (with optional pretreatment of oral doxycycline, 200 mg, daily for up to 7 days), with a control group receiving oral doxycycline (200 mg) daily for 7 days followed by moxifloxacin (400 mg) daily for another 7 days. The primary outcome is the treatment success rate with a superiority margin of 10%, as confirmed through the nucleic acid amplification test. Secondary outcomes encompass changes in the bacterial load at the urogenital or rectal sites and the emergence of posttreatment-resistant mutant strains.

Results: Enrollment commenced in June 2023 and will conclude in December 2024, with findings anticipated by 2025. The expected success rates fall within the range of 80% for sitafloxacin and 42% for moxifloxacin against *Mgenitalium* carrying the G248T (S83I) mutation, based on previous studies. Accordingly, with a 5% significance level (2-sided) and 80% statistical power, we aim to recruit 50 participants per group, factoring in a 10% expected dropout rate.

Conclusions: This study will provide valuable insights into the efficacy and safety of sitafloxacin- versus moxifloxacin-based sequential therapy in treating *Mgenitalium* infections. These findings have the potential to influence clinical guidelines, favoring more effective therapeutic choices. The multicenter approach enhances the robustness of this study. However, a limitation is the potential insufficiency of statistical power to detect posttreatment-resistant mutant strains in each group, rendering posttreatment-resistance mutations a notable concern. In the future, we may need to increase the sample size to enhance power.

Introduction

The increase in the number of resistant strains of *Mycoplasma genitalium* is a global concern. The global prevalence of *M genitalium* in the general population ranges from 1.3% to 3.9% [1]. The prevalence of macrolide resistance-associated mutations (MRMs) has increased over the decades [2]. Furthermore, regional variations in resistant strains have been observed, with the prevalence of MRMs in the American and Western Pacific regions exceeding that in European countries [2]. The prevalence of quinolone resistance-associated mutations (QRAMs) has been increasing in the Western Pacific regions, including Australia, New Zealand, China, and Japan, making these regions focal points for resistance mutations [3-7]. The current national guidelines recommend resistance-guided sequential therapy for *M genitalium* infections when macrolide resistance testing is available; otherwise, empiric sequential therapy is recommended, commencing with doxycycline followed by fluoroquinolone [8-11]. For macrolide-susceptible strains, sequential therapy involves an initial cycle of doxycycline treatment followed by azithromycin, whereas for macrolide-resistant strains, it entails an initial cycle of doxycycline treatment followed by fluoroquinolone. According to Australian studies, resistance-guided therapy with doxycycline followed by azithromycin attains a high efficacy of 92% to 95.4% against macrolide-susceptible strains, whereas doxycycline followed by moxifloxacin achieves a high efficacy of 95.4% against macrolide-resistant strains, and doxycycline followed by sitafloxacin demonstrates a high efficacy of 95% against macrolide-resistant strains [12-14]. However, the cure rate of fluoroquinolone-based therapies depends on the prevalence of QRAMs, which include *parC* and *gyrA* mutations. Specifically, S83 and D87 mutations in *parC*, as well as M95, G93, and D99 mutations in *gyrA*, have been linked to treatment failure with moxifloxacin and sitafloxacin [15-19]. Additionally, combined *parC* and *gyrA* mutations limit the efficacy of fluoroquinolone-based therapy more significantly than single mutations [19,20]. As sitafloxacin, a newer-generation fluoroquinolone, is not widely available, direct comparisons between moxifloxacin and sitafloxacin treatments are lacking. Sitafloxacin exhibits higher efficacy against QRAM-resistant strains [14,17,18] and demonstrates a lower minimum inhibitory concentration relative to moxifloxacin in QRAM-resistant strains based on minimum inhibitory concentration assays [17,18]. Murray et al [14] conducted a clinical study and demonstrated that sitafloxacin-based sequential therapy for the most common *parC* G248T (S83I) mutant strains achieved a higher success rate than moxifloxacin-based sequential therapy. However, as previously mentioned, they did not directly compare the 2 drugs but instead retrospectively compared them at different times. Given the fluctuating numbers of mutant-resistant strains in recent years, a randomized clinical trial would be a more suitable approach to investigate the efficacy of these 2 drug regimens [14,21].

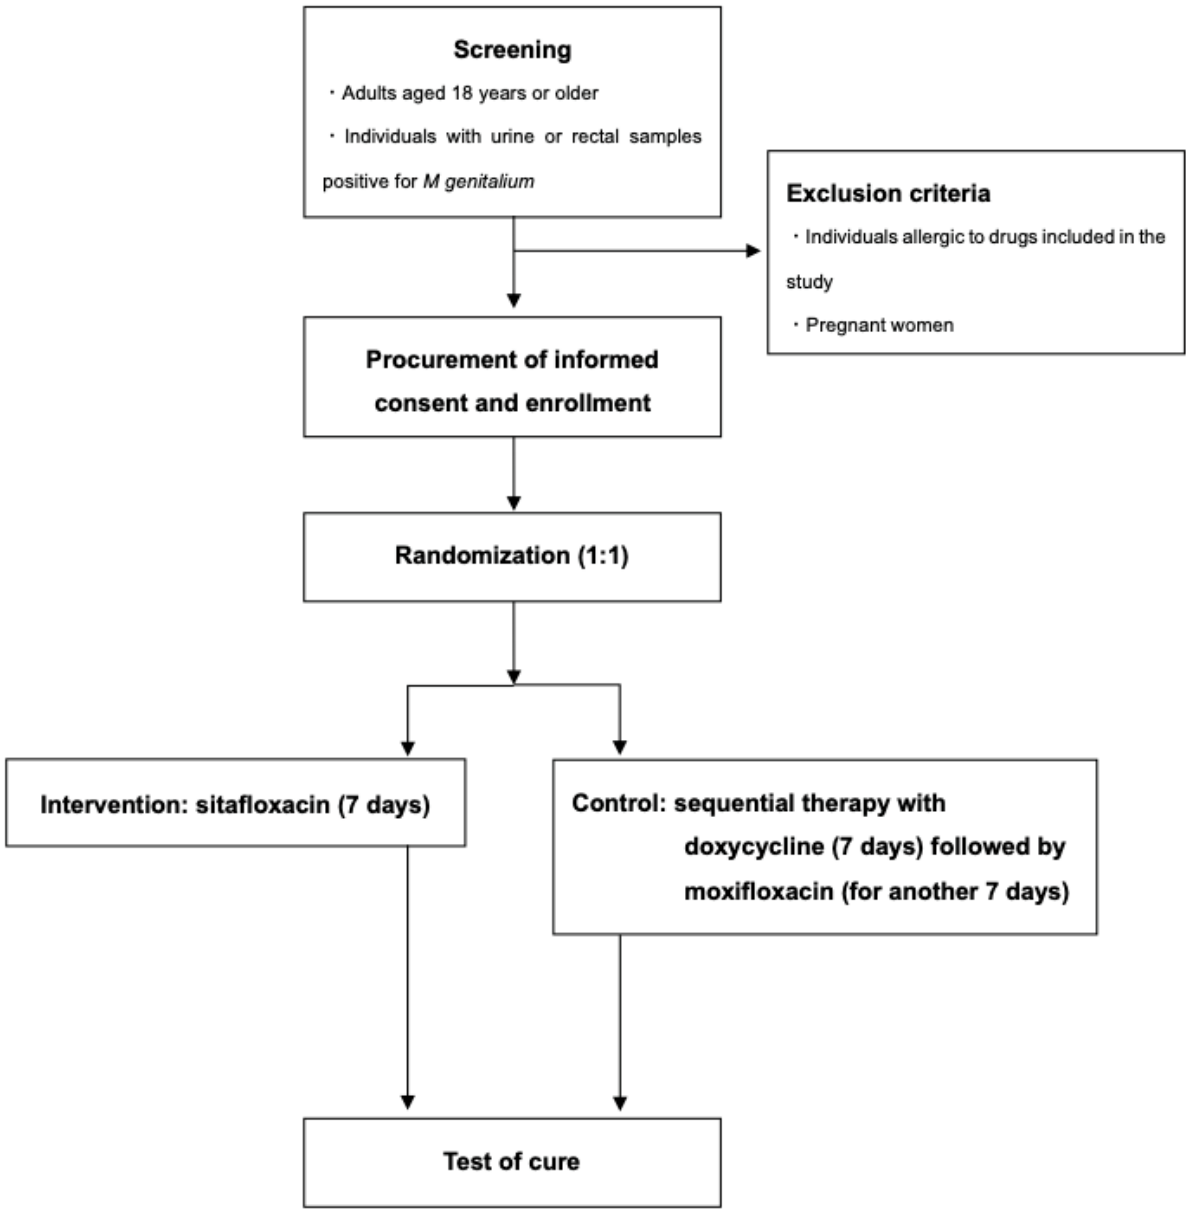
In Japan, the prevalence of resistant strains is high [3,21]. Ando et al [3] reported that 89.6% of strains harbored MRMs, with 68.3% harboring *parC* mutations and 27% harboring *gyrA* mutations. Given the unavailability of resistance testing for MRMs and the high prevalence of strains harboring MRMs (89.6%), sitafloxacin is the preferred treatment for *M genitalium* infections at our facility. Ando et al [20] reported that sitafloxacin monotherapy cleared strains harboring wild-type *parC* and *gyrA*. In addition to resistant strains, sitafloxacin demonstrated high effectiveness (92.9%) in clearing strains harboring *parC* G248T (S83I) mutations and wild-type *gyrA*, with 41.7% of those harboring *parC* G248T (S83I) and *gyrA* mutations. In contrast, moxifloxacin-based therapy cleared 96.5% of the strains harboring wild-type *parC* and *gyrA* [19]. The regimens mainly comprised sequential therapy with doxycycline followed by moxifloxacin and combination therapy with doxycycline and moxifloxacin. However, for strains harboring *parC* G248T (S83I) mutations and wild-type *gyrA*, the effectiveness of moxifloxacin-based therapy was limited to 54.2%. For those harboring *parC* G248T (S83I) and *gyrA* mutations, the effectiveness was further reduced to 18.8% [19]. Both sitafloxacin and moxifloxacin are newer-generation quinolones that exhibit a comparable incidence of gastrointestinal side effects [22,23]. These agents are less frequently associated with tendon rupture than levofloxacin, a prevalent fluoroquinolone drug [24]. Considering that both are broad-spectrum antibiotics, their impact on de novo resistance and the environment remains unclear and requires vigilant monitoring. A 7-day course of doxycycline is generally used to treat sexually transmitted infections with mild side effects, such as gastrointestinal disturbances [25].

Accordingly, we propose to conduct a multicenter, open-label randomized controlled trial aimed at comparing the efficacy and safety profiles of sitafloxacin and standard moxifloxacin-based sequential treatments in managing highly resistant *M genitalium* infections.

Methods

Study Design

This study constitutes a comparative randomized open-label parallel-group trial assessing the efficacy of sitafloxacin- versus



XSL•FO
RenderX

moxifloxacin-based sequential treatment for *M genitalium* infections, particularly those involving resistant strains.

Population and Eligibility Criteria

Participants are currently being recruited at the Sexual Health Clinic, AIDS Clinical Center of the National Center for Global Health and Medicine, and Personal Health Clinic in Japan (Figure 1). The inclusion criteria include several aspects. First, participants must be adults aged 18 years or older. Second, the confirmation of the presence of *M genitalium* in an individual's urine or rectal samples is required through the nucleic acid amplification test (NAAT). Lastly, participants are obligated to provide written informed consent to partake in the study, with exclusion criteria covering individuals with known allergies to the study medications and pregnant women. Additionally, individuals deemed unsuitable for study participation by the attending physician based on various criteria or medical judgments will be excluded. Study participants who need antibiotics that are potentially effective for *M genitalium* infection. This includes quinolones other than the study drugs, as well as minocycline, pristinamycin, and nitroimidazole.

Figure 1. Study flow chart.

Randomization and Blinding

We will use a computer-based stratified randomization approach to ensure an equitable allocation of participants across different treatment groups, stratifying based on 2 factors: the facility where the study participants are enrolled and the anatomical site of *M genitalium* infection (categorized as the urethra, rectum, or a combination of both). Participants will be randomly assigned to groups at a 1:1 ratio. Blinding will not be implemented, as treatment success will be determined using the NAAT, an objective test. After randomization, patients will receive their respective treatments and will be scheduled for a follow-up test of cure 3 weeks after completing the regimen, with a permissible range of 10-100 days. The test-of-cure content of the positive sites will be assessed using the NAAT. When treatment fails, the number of short tandem repeats in

XSL•FO
RenderX

the protein MG309 will be analyzed to differentiate a new infection from a persistent one, as previously reported [26].

Intervention

In the intervention group, participants will be administered 200 mg of oral sitafloxacin daily for 7 days. Additionally, 200 mg oral doxycycline daily for up to 7 days will be administered as pretreatment, depending on the severity, before the definitive diagnosis of *M genitalium*. Severity will be assessed based on patients' complaints.

In the control group, participants will be initially administered 200 mg oral doxycycline daily for 7 days, followed by 400 mg moxifloxacin daily for another 7 days.

Statistical Analysis

The sample size has been determined based on previous treatment success rates and specific assumptions. In a preliminary study, we determined that sitafloxacin achieved a treatment success rate of 92.9% against *M genitalium* with the *parC* G248T (S83I) mutation, in conjunction with wild-type *gyrA* [20]. Furthermore, sitafloxacin demonstrated a 78.9% success rate against strains carrying the *parC* G248T (S83I) mutation based on our preliminary data, and Murray et al [27] reported a moxifloxacin success rate of 41.2% against such strains. Accordingly, the success rates of sitafloxacin and moxifloxacin were anticipated to be 80% and 42%, respectively. With a 5% significance level (2-sided) and 80% statistical power for precise analysis, we aimed to enroll 50 participants per group (totaling 100 cases), considering the prevalence of the G248T mutation. Additionally, an expected dropout rate of approximately 10% was factored in, leading to a calculated sample size of 112 participants, evenly distributed across treatment groups, to robustly assess the efficacy of sitafloxacin and moxifloxacin against specific mutations in *M genitalium*.

Primary analyses regarding efficacy primarily rely on the full analysis set (FAS), which encompasses all registered participants, excluding ineligible participants and those not receiving the study drugs. To evaluate sensitivity, the analysis will be conducted for the per-protocol set, which consists of the study population, excluding cases of major protocol violations and discontinuations from the FAS. To evaluate safety, the analysis will be conducted for the safety analysis set, which includes all registered participants except those not receiving the study drug. Baseline characteristics of the study participants, both discrete and continuous, will be summarized. Discrete data will be presented as frequencies and percentages, whereas continuous data will be presented as descriptive statistics such as the mean and SD. Data will be analyzed with STATA (version 16.0; StataCorp), SAS software (version 9.4; SAS Institute), and R (version 4.1.2; R Foundation for Statistical Computing); the sample size calculation was done using Power Analysis and Sample Size 2022 (NCSS Statistical Software).

Efficacy Outcome

The primary outcome is the treatment success rate, defined as the absence of the pathogen, as indicated through the NAAT. We set the superiority margin at 10%. The secondary outcomes include the change in bacterial load from pre- to posttreatment and the emergence of posttreatment nucleotide polymorphisms in mutant strains compared with those in pretreatment samples. The bacterial load will be measured as previously reported [28]. For the primary outcome in the FAS, with or without the G248T (S83I) mutation, rates and their 95% CIs will be computed. The chi-square test will be used to assess the statistical significance of treatment success between groups. This primary analysis will also be conducted for participants with the G248T mutation in the per-protocol set. In terms of secondary endpoints, differences, and rates of change in the bacterial load will be analyzed using either the 2-tailed Student *t* test or the Mann-Whitney *U* test. The rate and 95% CI of posttreatment resistance mutations in the FAS group will also be estimated using the positive cure confirmation results.

Safety Outcomes

The side effects of each regimen will be reported during visit 2. Any unusual symptom or adverse reaction following the start of the regimens will be documented based on the division of the AIDS table for grading the severity of adult and pediatric adverse events (corrected version 2.1). Safety considerations include documenting adverse events, ranging from allergies and diarrhea to severe conditions such as aortic lesions, which are presented as frequency and group percentages for the safety analysis set.

Data Collection and Management

A case report form (CRF) will be prepared by the appropriate and authorized individuals (investigators and physicians). All data recorded in the CRF must be consistent with the original material unless the data are recorded directly in the CRF as source material. Data will be collected at each visit (Table 1). All study findings and documents will remain strictly confidential, and patients will be identified only by their patient number or birth date, never by name, to protect their anonymity. The following data will be collected: date of birth (age), sex, nationality, race, medical history, history of current disease, complications, and allergies. Additionally, body weight and height will be measured at the first visit, along with vital signs at each visit, including the level of consciousness, body temperature (°C), blood pressure (mm Hg), pulse rate (beats per minute), respiratory rate, and physical condition at every visit, assessed through inspection, palpation, auscultation, and percussion.

Data Monitoring

No external data monitoring committee will be involved in this study. The first author will oversee the progression, completion of the intervention, and follow-up assessment of all participants.

Ethical Considerations

This trial was granted ethical approval by the National Center for Global Health and Medicine of Japan's certified review board (approval NCGM-C-004624-00) in October 2022, registered under jRCTs031230111. The study protocol and informed consent forms were approved by the local ethics committees at each study site before the commencement of the study. Adherence to human subject ethics review approvals was maintained in accordance with institutional guidelines. Informed consent was obtained from all study participants, with the process including clear communication about their right to opt out at any stage without penalty. The data collected during the trial were anonymized to ensure the privacy and confidentiality of participants. While no monetary compensation was provided, participants received the study drug and associated testing free of charge. This provision was documented and justified according to ethical standards and guidelines, ensuring voluntary participation and the integrity of the study.

Results

Enrollment began on June 1, 2023, and will continue until December 31, 2025, followed by participant follow-up. The findings of the study are expected to be released in 2025.

Discussion

Summary

The primary objective of this randomized controlled study is to determine the comparative efficacy and safety of sitafloxacin and moxifloxacin-based sequential treatments in managing *M genitalium* infections, with the primary outcome focusing on the clearance of the pathogen as confirmed by NAAT tests and the secondary outcomes considering bacterial load changes and posttreatment development of resistant strains. Based on previous studies, the expected success rates fall within the range of 80% for sitafloxacin and 42% for moxifloxacin against *M genitalium* carrying the G248T (S83I) mutation. Therefore, sitafloxacin is expected to demonstrate superior efficacy over moxifloxacin-based sequential therapy. The prevalence of strains harboring the G248T (S83I) mutation has increased in certain regions such as Australia, New Zealand, China, and Japan over recent years, with growing concerns in more areas such as the United States [29,30]. Accordingly, the outcomes of this study are poised to have a pivotal role in shaping the evolving treatment landscape for these pathogens, particularly the resistant strains, potentially influencing clinical practice. The multicenter design of this study also enhances its credibility by minimizing bias and broadening the applicability of our findings to a wider population.

Limitations

This study has some limitations. One notable concern is the limited power to detect de novo resistance following the completion of each regimen. Furthermore, our focus extends to urogenital and rectal infections. While previous studies have suggested reduced efficacy of azithromycin against rectal infections, no discernible difference in the effectiveness of sitafloxacin was observed [20,31]. The treatment of rectal infections remains a subject of debate; however, considering that rectal infections may serve as potential reservoirs, assessing their effectiveness at both sites is crucial. Third, determining the optimal treatment for strains with both *parC* and *gyrA* mutations remains challenging owing to limitations in currently available effective regimens [19,20]. Exploring other drugs, such as nitroimidazole, with different mechanisms should be considered [32]. Considering these considerations, future studies, potentially encompassing a broader range of comparative therapies and exploring combinations of various treatments, must be conducted to ensure the best possible outcomes for patients.

Conclusions

As the prevalence of *M genitalium* strains, particularly those with the G248T (S83I) mutation, increases globally, current research is imperative in guiding treatment.

When our hypothesis that sitafloxacin demonstrates superior efficacy over moxifloxacin-based sequential therapy holds, the study will have significant implications, potentially compensating for the practice, especially for resistant strains.

Abstract

Background: Breast reconstruction is an integral part of breast cancer care. There are 2 main types of breast reconstruction: alloplastic (using implants) and autologous (using the patient's own tissue). The latter creates a more natural breast mound and avoids the long-term need for surgical revision—more often associated with implant-based surgery. The deep inferior epigastric perforator (DIEP) flap is considered the gold standard approach in autologous breast reconstruction. However, complications do occur with DIEP flap surgery and can stem from poor flap tissue perfusion/oxygenation. Hence, the development of strategies to enhance flap perfusion (eg, goal-directed perioperative fluid therapy) is essential. Current perioperative fluid therapy is traditionally guided by subjective criteria, which leads to wide variations in clinical practice.

Objective: The main objective of this trial is to determine whether the use of minimally invasive cardiac output (CO) monitoring for guiding intravenous fluid administration, combined with low-dose dobutamine infusion (via a treatment algorithm), will increase tissue oxygenation in patients undergoing DIEP flap surgery.

Methods: With appropriate institutional ethics board and Health Canada approval, patients undergoing DIEP flap surgery are randomly assigned to receive CO monitoring for the guidance of intraoperative fluid therapy in addition to a low-dose dobutamine infusion (which potentially improves flap oxygenation) versus the current standard of care. The primary outcome is tissue oxygenation measured via near-infrared spectroscopy at the perfusion zone furthest from the perforator vessels 45 minutes after vascular reanastomosis of the DIEP flap. Low dose (2.5 µg/kg/hr) dobutamine infusion continues for up to 4 hours postoperatively, provided there are no associated complications (ie, persistent tachycardia). Flap oxygenation, hemodynamic parameters, and any medication-associated side effects/complications are monitored for up to 48 hours postoperatively. Complications, rehospitalizations, and patient satisfaction are also collected until 30 days postoperatively.

Results: Funding and regulatory approvals were obtained in 2019, but the study recruitment was interrupted by the COVID-19 pandemic. As of October 4, 2023, 34 participants have been recruited. Because of the significant delays associated with the pandemic, the expected completion date was extended. We expect the study to be completed and ready for potential news release

XSL•FO
RenderX

(as appropriate) and publication by July 2024. No patients have suffered any adverse effects/complications from participating in this study, and none have been lost to follow-up.

Conclusions: CO-directed fluid therapy in combination with a low-dose dobutamine infusion via a treatment algorithm has the potential to improve DIEP flap tissue oxygenation and reduce complications following DIEP flap breast reconstruction surgery. However, given that the investigators remain blinded to group randomization, no comment can be made regarding the efficacy of this intervention for improving tissue oxygenation at this time. Nevertheless, no patients have been withdrawn for safety concerns thus far, and compliance remains high.

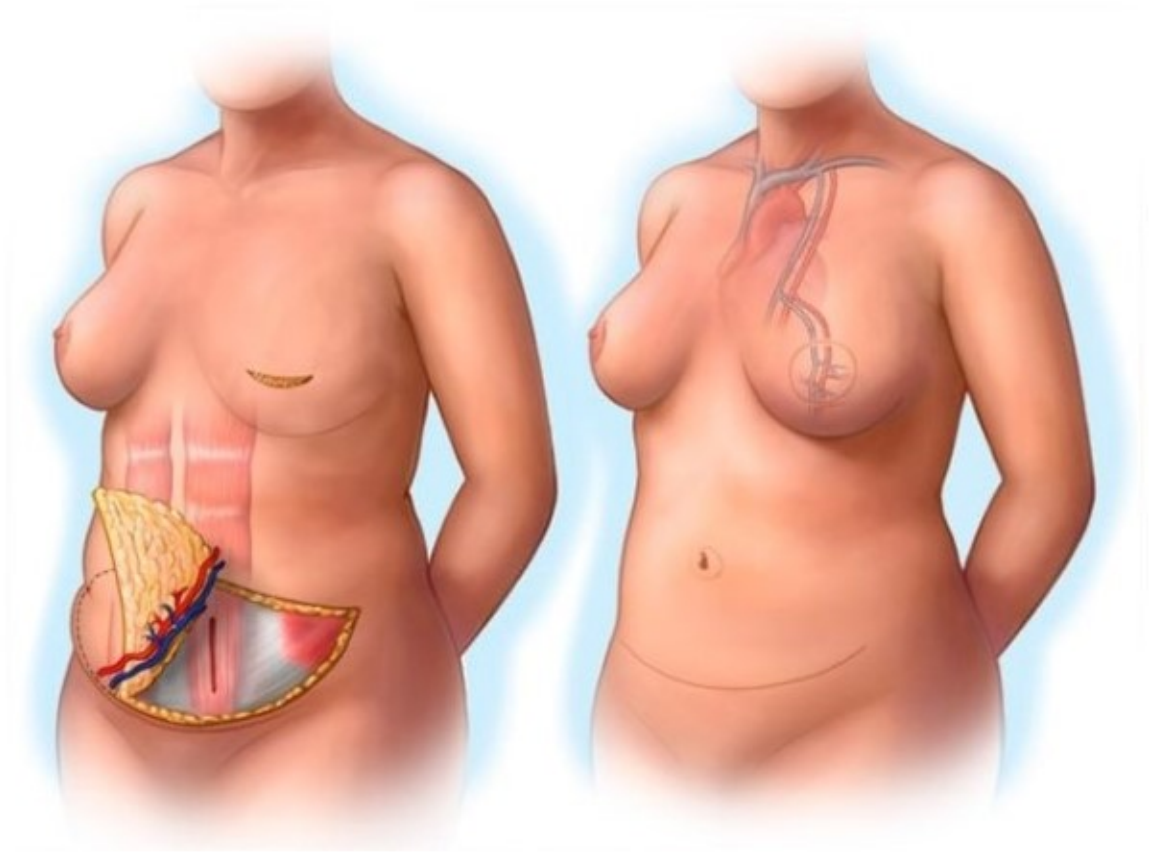
Introduction

Background

Over the last several decades, breast reconstruction has evolved to become an integral part of breast cancer care. In many countries, including Canada, access to breast reconstruction has become a quality indicator for breast cancer care [1]. There are 2 main types of breast reconstruction: alloplastic (ie, using implants), and autologous (ie, using the patient's own tissue). The main advantages of choosing autologous reconstruction include a soft, natural breast mound that can better match a natural breast. Additionally, autologous reconstruction is associated with a lower long-term risk of surgical revision compared to implant-based reconstructions. Patient-reported outcomes measured using the BREAST-Q module indicate improved long-term patient satisfaction following autologous tissue reconstruction [2]. The deep inferior epigastric perforator (DIEP) flap remains the gold standard in autologous breast reconstruction [3], as it generally results in lower donor-site morbidity and optimal outcomes [1,4,5]. The DIEP flap (Figure 1) uses the same lower abdominal island of skin and fat as the pedicled transverse rectus abdominis myocutaneous (TRAM) flap, with the advantage of sparing the rectus abdominis muscle, thus resulting in a lower incidence of abdominal wall laxity and weakness, less postoperative pain, and a shorter recovery period [4,6-10].

However, no surgical procedure is without potential complications. DIEP flap complications include fat necrosis, partial or total flap loss, and abdominal wall laxity or hernia. In a series of 758 DIEP flaps performed for breast reconstruction, 6% of patients were returned to the operating room (OR) for flap-related problems [6]. Partial flap loss occurred in 2.5% of patients and total flap loss in less than 1% [6]. Other complications included fat necrosis (13%), seroma formation at the abdominal donor site (5%), and abdominal hernia (0.7%) [6]. As noted, several complications stem from poor flap perfusion. The current evidence suggests that the rate of perfusion-related complications with DIEP flaps is relatively high and highly variable [11,12], with several factors potentially playing a role, such as patient selection, surgical technique, perioperative fluid management, level of hemodynamic control, and perioperative use of inotropes and/or vasopressors. Hence, providing optimal perioperative management for fluid administration and hemodynamic goals may have a significant impact on the long-term viability of the DIEP flap.



DIEP flaps are typically performed under general anesthesia. Vasoactive agents (eg, phenylephrine) commonly used to counteract the hypotensive effects of general anesthetics are often avoided in flap surgery due to concerns over vasoconstriction, which have been proven in animal models to consistently reduce the pedicle artery blood flow and microvascular perfusion of the flap [13]. Although definitive evidence is lacking in humans, a retrospective investigation suggests a trend toward increased partial flap loss in patients who received vasopressors compared to patients who did not [14]. Conversely, certain inotropes (eg, dobutamine, dopexamine) may be beneficial in enhancing peripheral oxygen delivery through increased cardiac output (CO) and a direct peripheral vasodilatory effect [15].

In DIEP flap surgery, maintaining normovolemia is of particular interest, as hypovolemia may lead to tissue hypoperfusion and hypervolemia may result in tissue edema, both of which can ultimately cause poor flap oxygenation. Indeed, a retrospective analysis of 354 free flaps for breast reconstruction revealed that the extremes of crystalloid infusion significantly predicted postoperative complications [16]. Yet, in current clinical practice, perioperative fluid therapy is commonly prescribed using subjective criteria, leading to wide variations in the total volume of crystalloid administered perioperatively. Therefore, CO monitoring to guide intravenous fluid management as part of a goal-directed hemodynamic therapy algorithm could significantly benefit this patient population. Notably, this approach has been studied for many years in various settings and has been shown to modify inflammatory pathways and improve tissue perfusion and oxygenation [15,17,18]. Specifically, a prospective analysis of 104 DIEP flaps comparing fluid-guided therapy by CO monitoring versus central venous pressure (CVP) found that the fluid input was not different between groups; however, patients in the CVP group had a smaller fluid output (blood loss, urine output, etc) and were in greater positive fluid balance, whereas the CO monitoring group had a reduced anesthetic time (despite similar surgical time between groups) and spent a mean of 1.9 days less in the hospital [19]. No differences were observed concerning core temperature

XSL•FO
RenderX

or flap complications [19]. These findings suggest that meticulous fluid management and tight hemodynamic control, combined with select inotropes, may optimize flap perfusion.

Figure 1. Depiction of deep inferior epigastric perforator (DIEP) flap breast reconstruction surgery in which the lower abdominal island of skin and fat are used to form the tissue flap for breast reconstruction while sparing the rectus abdominis muscle. Although the muscle must be split to dissect out the perforating vessels, the muscle is not transferred. The deep inferior epigastric artery and vein, which provide the vascular supply for the free flap, are anastomosed to local recipient vessel using either the internal mammary or thoracodorsal arteries and veins. Dobutamine (2 to 20 mcg/kg/min) is an inotrope widely used to treat cardiogenic shock and/or congestive heart failure. Its predominantly β-1 adrenergic receptor stimulatory effect increases inotropy and chronotropy and reduces left ventricular filling pressure. Dobutamine also has minimal β-2 adrenergic receptor effects, resulting in peripheral vasodilation. The net effect is increased CO and decreased systemic vascular resistance, with a generally imperceptible effect on blood pressure [20].

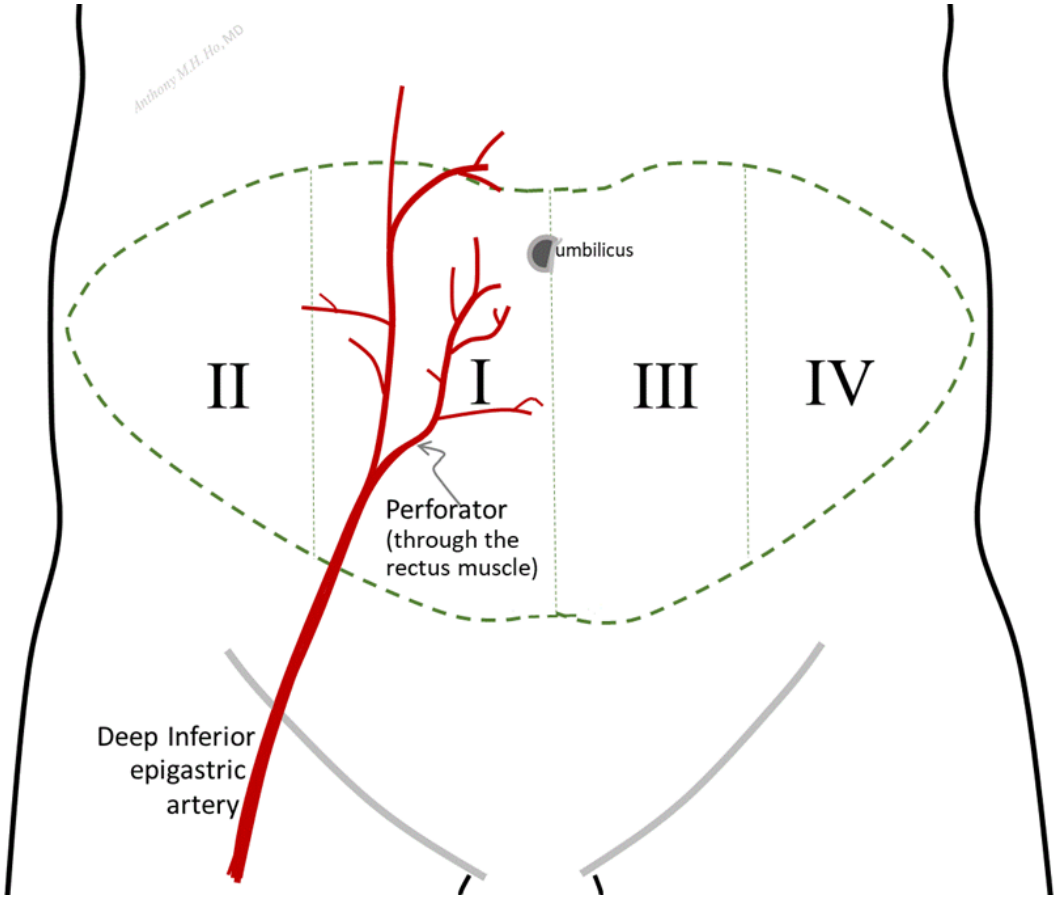
Purpose and Hypothesis



The purpose of this trial is to evaluate the effects of perioperative hemodynamic therapy (guided by CO monitoring) on tissue oxygenation during and after DIEP flap breast reconstruction surgery. We hypothesize that a low-dose, perioperative dobutamine infusion combined with goal-directed fluid therapy guided by CO monitoring will improve flap perfusion, and thus oxygenation, in patients undergoing DIEP surgery.

Objectives and Outcome Measures

The main objective is to determine whether the use of minimally invasive CO monitoring to guide intravenous fluid administration, combined with low-dose dobutamine infusion (via a treatment algorithm), will increase overall tissue oxygenation in patients undergoing DIEP flap surgery. The primary outcome is tissue oxygenation, measured via near-infrared spectroscopy (NIRS), 45 minutes following vascular reanastomosis of the DIEP flap within the perfusion zone farthest from the perforator vessels. This zone is the most vulnerable surgical area to ischemia and therefore the most likely to reflect the potential benefits of the proposed intervention. In the case of bilateral DIEP flaps, this zone will be assessed in both the left and right breasts. The zonal blood supply for DIEP flaps is depicted by Holm (Figure 2) [21]. Zone 1 includes the perforator vessel and is thus the most reliably perfused portion of the flap, while any flow across the midline can be less reliable than ipsilateral flow depending on the location of the perforators in zone 1. As aforementioned, the primary outcome will be tissue oxygenation within the zones farthest from the perforator vessels.

XSL•FO
RenderX

Figure 2. Depiction of the Holm perfusion zones [21]. Zone I is well recognized for being the most richly perfused as it contains the perforator vessels. The use of this zone during deep inferior epigastric perforator (DIEP) flap breast reconstruction surgery may provide optimal tissue flap perfusion.

Our secondary outcomes include (1) tissue oxygenation at baseline (preoperatively), intra-operatively and 1, 2, 4, 8 hours postoperatively, as well as the morning of postoperative days 1 and 2; (2) the amount of intravenous fluids (crystalloids, colloids, blood products) and vasopressors (eg, phenylephrine, ephedrine, norepinephrine, etc) administered intraoperatively and up to 4 hours postoperatively; (3) the need for intraoperative surgical vascular reintervention (ie, reanastomosis); (4) laboratory measures including perioperative pH, serum lactate, and hemoglobin measures; (5) incidence of postoperative nausea and vomiting; (6) hospital length of stay; (7) any postoperative complications including infection, hematoma, and those resulting from flap malperfusion (ie, partial/total flap loss and fat necrosis); (8) the need for postoperative intervention for flap-related issues; (9) overall patient satisfaction; and (10) days alive and out of hospital, all up until 30 days postoperatively.

Methods

Ethical Considerations

This study received institutional ethics board approval (ANAE-341-19) on May 16, 2019, and Health Canada approval (control no 228403) on July 8, 2019. Moreover, it was registered on Clinicaltrials.gov (NCT04020172) on July 12, 2019. This study is being completed in compliance with the current protocol and the Guidelines for Good Clinical Practices. All data collected will be retained for 15 years in a form identified only by study identification numbers linked to the patient's identity through a master list kept separate from the data in a locked cabinet. Only study investigators and governing bodies for regulatory inspections/trial monitoring will have access to the confidential patient data. Should any significant protocol modifications be required that may impact participants' provision of consent or safety, this will be immediately shared with the participants, the ethics board, and Health Canada as appropriate. Such changes will also be documented on the Clinicaltrials.gov registry.

Participants and Recruitment

Overview

Patients scheduled for elective unilateral or bilateral delayed or immediate DIEP flap surgery at a medium-sized academic center will be recruited. Eligible patients will be approached at their preoperative surgical visit with the plastic surgeon (GM or WE). If patients are willing to participate, a research team member will obtain written informed consent after their assessment by the attending surgeon (Multimedia Appendix 1). In all cases, the anesthesiologist will be made aware of the patient's potential study involvement should there be any medical reasons warranting study exclusion.

Sample Size

There are few similar studies in the literature on which to base a valid sample size calculation. However, 1 randomized controlled trial (RCT) [15] compared 3 arms, two of which are similar to what we propose to study in terms of pharmacological intervention (ie, dobutamine/dopexamine) versus none (standard

XSL•FO
RenderX

of care). Eight hours postoperatively, they noted a 1.75 kPa increase in cutaneous tissue oxygen partial pressure (PtO_2) in their stroke volume (SV) + dopexamine arm as compared to a 0.50 kPa increase in the SV-only arm. Using an SD of 1.0, α of 0.05, and a power of 80%, only 11 cases would be required per arm for these differences to attain statistical significance. However, this sample is rather small for valid statistical analyses [22], and because our groups are not identical to those available in the literature, we propose to increase the sample size to 20 per group. Notably, given that their SV group is tightly regulated (and therefore, likely superior) compared to our standard of care group, our sample size estimation is likely overly conservative.

Study Design, Randomization, and Blinding

Overview

This is a prospective RCT. A total of 40 participants will be randomized to one of 2 groups (n=20 per group) using a computer-generated randomization prepared by the institutional biostatistician. Patient randomization will be concealed in envelopes and opened only by the research staff (not otherwise involved with data collection) and/or the attending anesthesiologist prior to anesthesia induction. Blinding will be maintained until study completion and verification that all outcome data have been successfully collected for all study participants.

Surgical Procedure

Patients will be marked in the preoperative holding area for an abdominal-based free-flap breast reconstruction. All procedures are planned as a DIEP reconstruction. For most flaps, the goal is to include 1 to 3 perforators to optimize perfusion. In some cases, the DIEP flap may be converted to a muscle-sparing flap to achieve adequate arterial inflow and venous outflow to the tissue flap. Because the primary outcome is to look at perfusion of the flap most distant from the perforating vessels, in most cases, unilateral breast reconstructions will be performed, and perfusion zones 1, 2, and 3 included, according to the Holm classification (Figure 2). However, in patients with bilateral reconstructions, only Holm zones 1 and 2 will be included in a single flap. The supplying deep inferior epigastric vessels will be harvested at the level of the iliac artery and vein, and a microvascular anastomosis will be performed with the internal mammary artery and vein under a surgical microscope. A single artery and vein will be routinely anastomosed.

Approved Protocol

A tissue oximeter device (SnapshotNIR; Kent Imaging) will be used for all patients. This is a portable noninvasive monitor that measures tissue oxygen saturation using NIRS technology with the capability of saving images to allow for subsequent analyses. Measurements will be taken by holding the monitor at a standardized (30 cm) distance from the skin area where the oxygen levels are to be measured. Upon admission to the OR, preoperative baseline measurements (with patients breathing ambient air without supplemental oxygen) will be recorded over the abdominal flap tissue, followed by recordings immediately postinduction, 1-hour postinduction, when the abdominal flap is free (and still perfused by the chosen perforator arteries), before clamp removal postarterial reanastomosis, and 45 minutes following reanastomosis. All research personnel dedicated to this study will receive prestudy training on the perfusion zones and study outcomes to ensure that oxygenation measures are consistently taken from the same surgical region in relation to the perfusion zones (as described in Figure 2) throughout each case. In addition, the surgical team, led by authors GM and RWE, will assist with guiding the intraoperative oxygenation measurements with respect to flap location. However, the surgical team and attending anesthesiologist will be blinded to the Kent oxygenation measurements throughout the perioperative period, and surgery will be guided as per the standard of care. The ischemic period during which the flap is transferred (reflected by a fall in the oxygen saturation of the flap [23]) as well as the time of flap revascularization (characterized by increased oxygen saturation [23]) will be recorded. Upon completion of the surgical procedure, another NIRS-based monitor (Somanetics INVOS 5100C Cerebral/Somatic Oximeter; Medtronic) may be applied to the freshly reconstructed graft at the surgeon's discretion. If deemed appropriate, a sticker will be applied over the flap for continuous graft oxygenation monitoring up to 48 hours postoperatively. However, if the surgeon requires the entirety of the graft to be exposed for visual monitoring (as per the standard care), a sticker/sensor will not be applied. Nevertheless, postoperative measures will be routinely recorded at 1, 2, 4, and 8 hours postoperatively, as well as on the morning of postoperative days 1 and 2 using the Kent device. All measures will be consistently taken at the same location [24]. Note that continuous intraoperative monitoring with the Somanetics INVOS Oximeter is not possible, as the sensors cannot be sterilized.

All surgical procedures will be performed by one of the 2 surgeons (GM and RWE) to minimize variability in patient selection and surgical technique, both predictors of clinical outcomes in microsurgery [25]. Elective DIEP flap surgical procedures and anesthetic management will be completed in accordance with the standard of care. Perioperative management will be identical in both groups, apart from the hemodynamic monitoring for guiding intravenous fluid therapy and interventions as described below. In the OR, the ambient temperature will be set at 20^{o} C and standard monitors will be applied. Invasive monitoring in the form of an arterial line will be established as per the current practice. General anesthesia will be induced with propofol and fentanyl, followed by rocuronium to facilitate endotracheal intubation, and maintained with end-tidal sevoflurane (Et_{sevo}=1.5%-3%) and additional doses of fentanyl and/or hydromorphone administered at the discretion of the attending anesthesiologist. Extra doses of rocuronium will be administered throughout the case for muscle relaxation. A mean arterial pressure (MAP) ≥65 mmHg will be targeted throughout the perioperative period. Likewise, all patients will receive standard measures to maintain oxygen saturation (SpO_2 ≥95%), end-tidal carbon dioxide (Et_{CO2}) between 35 and 40 mmHg, hemoglobin (>8 g/dl), and a heart rate <100 beats per minute (BPM). A warming device (enFlow IV Fluid/Blood Warming System; GE Healthcare) will be used for intravenous fluids, along with a forced-air patient warming system (Bair Hugger Normothermia System; 3M) to maintain normothermia (core temperature between 36 and 37.5 ^{o}C).

XSL•FO
RenderX

Arterial blood gasses will be checked every 2 hours (or more often at the discretion of the attending anesthesiologist) to specifically monitor the pH, SpO_2, partial pressure of oxygen (PaO_2) in arterial blood, partial pressure of carbon dioxide ($PaCO_2$) in arterial blood, base excess, hemoglobin, and lactate levels as surrogates for tissue perfusion perioperatively. Urine output will be recorded hourly. The total amount of vasopressor, perioperative fluid (crystalloids and albumin 5%), and blood products, if any, will be recorded. In addition, the following demographic and surgical characteristics will be included: age, BMI, preoperative hemoglobin and hematocrit levels, American Society of Anesthesiologists (ASA) classification, Charlson Comorbidity Index, and total surgical and anesthetic time. Subsequently, 4 mg prophylactic intravenous dexamethasone upon the induction of general anesthesia and 4 mg ondansetron 15 minutes prior to completion of the surgical procedure will be administered to prevent nausea and vomiting. All patients will be managed postoperatively in a high-dependency unit (level 2 critical care) and given an intravenous patient-controlled analgesia (IV-PCA) pump containing hydromorphone (or an alternative in the case of adverse reactions) for postoperative pain management, as per the current standard of care. The postoperative goals (up to 48 hours postoperative) will be similar to the intraoperative period, namely: MAP ≥65 mmHg (or within 20% of baseline), SpO_2 ≥95%, $PaCO_2$ between 35 and 45 mmHg, hemoglobin >8 g/dl, core temperature between 36 and 37.5 °C, and heart rate <100 BPM. Research personnel will call patients 30 days postoperatively to document any complications, hospitalizations, and overall satisfaction. If patients cannot be reached via telephone, the patient's family physician may be contacted and their medical record accessed to determine whether the patient experienced postoperative complications or required medical attention (as per the informed consent form).

Intervention Group

The intervention will commence from the induction of general anesthesia and continue until 4 hours after surgery. Ringer lactate (2 ml/kg/h) will be commenced upon admission to the OR to satisfy maintenance fluid requirements. CO and stroke volume index (SVI) will be measured by one of 2 CO monitors: (1) FloTrac system (Edwards Lifesciences Corp), which attaches to the arterial line already in place in this surgical population; or (2) Starling SV system (Cheetah Medical), a noninvasive CO monitor that utilizes 4 stickers placed on the patient's trunk. No more than 500 ml of intravenous fluid will be administered at anesthesia induction. In addition to the maintenance fluid described previously, patients will receive 250 ml fluid challenges with crystalloid as required until they are no longer fluid-responsive. Albumin 5% will also be allowed for fluid challenges at the discretion of the attending anesthesiologist. The absence of fluid responsiveness will be defined as the absence of a sustained rise in SVI of at least 10% for 20 minutes or more, at which point the patient will be considered fluid-optimized. At this point, a low-dose dobutamine infusion at a fixed rate (2.5 µg/kg/min) will be commenced and maintained until 4 hours postoperatively. The infusion rate will be halved and/or discontinued if the patient develops tachycardia (heart rate ≥100 BPM) for more than 30 minutes despite adequate anesthesia/analgesia and fluid status (based on the aforementioned intervention). Further fluid challenges will be performed by the attending anesthesiologist with the aim of maintaining maximal SVI throughout the case. Postoperatively, the patient will remain in the postanesthetic care unit (PACU) for a minimum of 4 hours (as per the current standard of care), after which the CO monitoring and the dobutamine infusion will be discontinued and the patient transferred to a level 2 step-down critical care unit. Ringer lactate at 2 ml/kg/h will be infused to satisfy maintenance fluid requirements until oral fluid intake is permitted by the surgical team, at which point the maintenance infusion will be stopped. Data collection and follow-up for such patients will be performed as per the standard of care.

Control Group

Patients in the control group will also receive a baseline infusion of Ringer lactate at 2 ml/kg/h to satisfy maintenance fluid requirements, which will commence upon admission to the OR. The anesthetic management will otherwise be according to standard practice. This will include 250 ml fluid challenges with a crystalloid administered at the discretion of the attending anesthesiologist, generally guided by pulse rate, arterial pressure, urine output, and/or core-peripheral temperature gradient. Albumin 5% will also be allowed for fluid challenges at the discretion of the attending anesthesiologist. No specific CO monitoring device will be used to guide fluid therapy; however, it will be present in the OR throughout the case to ensure adequate blinding of the surgical team and research staff regarding the 2 patient groups. Likewise, perioperative dobutamine will not be used unless clinically indicated to improve cardiac function, as it is not currently part of our standard practice in these surgeries, and there is no yet documented evidence to support its use in all DIEP flap patients. We expect this study to address this knowledge gap and provide evidence as to whether there is a benefit to using it routinely. Postoperative care will be similar to the intervention group (except for the CO monitoring and dobutamine infusion in PACU).

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria for patient recruitment are outlined in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria for the study recruitment.

Inclusion criteria

- Between 18 and 80 years of age
- Meet the American Society of Anesthesiologists (ASA) physical status classification I-III
- Undergoing elective unilateral/bilateral immediate or delayed deep inferior epigastric perforator (DIEP) flap surgery
- Cognitive ability to provide informed consent

Exclusion criteria

- Have dementia or neurological impairment
- Scheduled for DIEP flap combined with any other secondary surgical procedure
- Documented left ventricular dysfunction (ejection fraction < 40%)
- Contraindication to low-dose dobutamine
- BMI <18 or >40 kg·m-2
- Pregnant or lactating
- Renal insufficiency, with an estimated glomerular filtration rate (eGFR) <30 ml/min/1.73m2)
- Known liver insufficiency (ie, documented cirrhosis, coagulopathy, and/or encephalopathy of hepatic origin)

Premature Withdrawal and Discontinuation Criteria

One of the limitations of dobutamine infusion is tachycardia. The infusion rate will be halved and/or discontinued if a patient develops tachycardia (heart rate ≥100 BPM) for more than 30 minutes despite adequate anesthesia/analgesia and fluid status (based on the aforementioned intervention). If the reduced dose does not correct the tachycardia, the infusion will be turned off. In addition, if at any point the attending staff raises concerns about the patient being at an increased risk because of study participation, the intervention will be stopped and the patient removed from the investigation. Moreover, if the patient decides they want to withdraw their consent at any point prior to publication, they will be excluded from the study and none of the information collected from them will be used for research purposes. The study intervention only applies during surgery and potentially for up to 4 hours postoperatively. All study participants will be fully monitored for the duration of the study intervention and beyond for up to 48 hours postoperatively. They will have immediate access to any additional care or intervention if required.

If patients are withdrawn from the study, we will continue to enroll consecutively until we have met our stipulated sample size of 20 patients per group. For patients who are withdrawn, we will seek permission to retain any data collected (especially demographic information) for comparison between those who were not and those who were withdrawn to determine whether they differ in any respect.

Rescue Medication and Risk Management

All anesthesia and surgical procedures are according to the standard of care except for the low-dose dobutamine infusion intraoperatively and potentially up to 4 hours postoperatively, the use of CO monitoring to guide fluid administration intraoperatively and for up to 4 hours postoperatively, and noninvasive measurements of tissue oxygenation until 48 hours postoperatively. Patients will be intensively monitored, and medications will be administered as considered medically necessary. Conversely, no medications deemed medically necessary will be withheld because of study participation. The main potential side effect associated with dobutamine is tachycardia. To mitigate this risk, our protocol proposes a very low-dose infusion. In addition, the dobutamine infusion rate will be halved and/or discontinued if the patient develops tachycardia (heart rate ≥100 BPM) for more than 30 minutes despite adequate anesthesia/analgesia and fluid status. Additionally, all patients will be intensively monitored while in the hospital for any adverse events/complications, which will be carefully considered in terms of whether they are related to the study intervention or otherwise and action will be taken accordingly.

Adverse Event Reporting

Adverse events and serious adverse events (SAEs) will be monitored and documented. Study staff will mandatorily report all SAEs to the investigator for evaluation as soon as they become aware. All adverse events will be immediately and mandatorily reported to the Queen's University and Affiliated Teaching Hospitals Research Ethics Board and the Therapeutic Products Directorate of Health Canada, as per current guidelines.

If a patient experiences an adverse event due to study participation, medical care will be provided to them until resolution of the problem. Patients will be asked about satisfaction with healing and overall surgical care on the day of discharge. Patients will also receive a 30-day follow-up telephone call from research staff inquiring about complications and patient satisfaction.

Statistical Analysis

Data will be entered into REDCap (Research Electronic Data Capture; version 10.6.12; Vanderbilt University). Upon study completion, the data will be exported to SPSS software (version 29.0; IBM Corp) for analysis. Descriptive analyses, including mean, SD, median, and interquartile range for continuous data,

XSL•FO
RenderX

as well as frequencies and percentages for categorical data, will be completed for all demographic and surgical characteristics and study outcomes. The underlying distributions of all continuous data will be assessed for normality using the Shapiro-Wilk test. Tissue oxygenation will be compared using independent sample *t* tests if the data are normally distributed and the Mann-Whitney *U* test in the event that they are not. Secondary outcomes will be compared between the 2 groups using the Fisher exact or Pearson chi-square tests (as appropriate depending on cell sizes) for categorical data and independent samples *t* tests (or the Mann-Whitney *U* test depending on the underlying distribution) for continuous data. Intent-to-treat analyses will not be conducted, and no adjustments will be made for missing data. Repeated measures analysis of variance (ANOVA), with the group as a factor, will be used to compare the tissue oxygenation over time (baseline, 1, 2, 4, and 8 hours postoperatively, along with baseline and postoperative day 1 and day 2 data). $P<.05$ will be used as the criteria for statistical significance, and no adjustment will be made for multiple comparisons. The possibility of a type I error will be acknowledged, and the actual *P* values will be presented for all comparisons.

Results

This project received funding and all regulatory approvals in 2019, but patient recruitment was interrupted by the COVID-19 pandemic and associated elective surgery cancellations. As of October 4, 2023, 34 participants have been successfully completed. Because of the significant delays associated with the pandemic, the expected completion date was extended, and we now expect study completion and publication (and potential news release as appropriate) by July 2024. Given that investigators remain blinded to group randomization, no statement can be made with respect to the study intervention in terms of tissue oxygenation at this point. At this time, investigators can only state that there have been no study withdrawals for safety concerns, no severe adverse events, and patient compliance remains high.

Discussion

Although no conclusions can be drawn at this time regarding the efficacy of the intraoperative CO monitoring/dobutamine infusion for improving tissue flap oxygenation in DIEP flap surgical patients, it is important to note that no patients have been withdrawn from the study due to safety concerns, there have been no complications attributable to the dobutamine infusion, and compliance remains high. These are important achievements that indicate that this study will be completed successfully within the projected time frame.

Because this is a single-center RCT, the generalizability of the results to all DIEP flap surgical patients may be limited and the numbers too small to make any determinations regarding rare adverse events. However, if we demonstrate that the intervention improves tissue oxygenation, the results from this trial will be used to plan (and acquire funds for) a large multicenter RCT to examine whether the altered oxygen levels have a detectable impact upon rare postoperative complications and for which the results would be generalizable to all DIEP flap surgical patients. Success with this highly novel approach could potentially lead to a change in the perioperative monitoring and management practices of DIEP flap surgical patients, with implications for improved long-term surgical success and patient satisfaction. Given that these microsurgical procedures are of such long duration and high complexity, any improvements in the surgical technique to improve long-term outcomes would be significant, particularly if the modifications are simple and short-term like those described with intraoperative CO monitoring and low-dose dobutamine infusion.

Acknowledgments

This research was funded by the Southeastern Ontario Academic Medical Organization (SEAMO) Academic Health Science Centres (AHSC) Alternate Funding Plan (AFP) Innovation Fund (SEA-19-055, 06/2019). The funding organization played no role in the study design, execution, or publication.

Data Availability

Following study completion, the study results will be made publicly available on Clinicaltrials.gov (NCT04020172).

Authors' Contributions

GBM and AM-HH were involved in the conception, funding acquisition, methodology, data curation, writing the original draft, manuscript revision, and approval of the final version for submission. RP was involved in the funding acquisition, methodology, data curation, manuscript revision, and approval of the final version for submission. DD was involved in the supervision, data collection, data curation, manuscript revision, and approval of the final version for submission. JS and EV were involved in the data collection, data curation, manuscript revision, and approval of the final version for submission. Abstract

Background: Poststroke epilepsy poses a significant clinical challenge for individuals recovering from strokes, leading to a less favorable long-term outlook and increased mortality rates. Existing studies have primarily concentrated on administering antiseizure or anticonvulsant treatments only after the onset of late-onset seizures, without intervening during the epileptogenesis phase following a stroke.

Objective: This research protocol is designed to conduct a randomized controlled trial to assess whether the early, preventive introduction of low-dose antiepileptic drug therapy (levetiracetam [LEV] or perampanel [PER]) in patients who have experienced middle cerebral artery (MCA) infarction can reduce the risk of developing poststroke epilepsy (primary prevention).

Methods: Participants with MCA infarction, either with or without reperfusion treatments, will be recruited and promptly receive preventive intervention within 72 hours of the stroke occurrence. These participants will be randomly assigned to receive either PER (4 mg per day), LEV (1000 mg per day), or a placebo that matches the active drugs. This treatment will continue for 12 weeks after allocation. Brain magnetic resonance imaging will be used to confirm the presence of MCA territory infarction, and an electroencephalography will be used to ensure the absence of epileptiform discharges or electrographic seizures at the time of the stroke. All participants will undergo follow-up assessments for 72 weeks after allocation.

Results: The primary outcome under evaluation will be the incidence of poststroke epilepsy in the 3 groups following the 18-month study period. Secondary outcomes will encompass the time to the occurrence of the first seizure, the severity of seizures, any treatment-related adverse events, and the modified Rankin scale score at 3 and 18 months. Exploratory outcomes will involve comparing the effectiveness and safety of PER and LEV.

Conclusions: We anticipate that the intervention groups will experience a lower incidence and reduced severity of poststroke epilepsy compared to the control group after 18 months. We aim to establish evidence supporting the potential preventive effects of LEV and PER on poststroke seizures and epilepsy in patients with MCA infarction, as well as to explore the antiepileptogenic potential of both LEV and PER in patients with major ischemic strokes.

Introduction

Background

Advances in stroke treatment have caused a considerable reduction in stroke mortality; however, the number of stroke survivors living with disability has increased significantly. Seizures and epilepsy related to ischemic stroke are common, and poststroke epilepsy is a significant clinical problem for stroke survivors. Stroke is the most common cause of epilepsy in older adults and for patients older than 65 years of age, and poststroke epilepsy accounts for 30%-50% of new-onset seizures [1]. The incidence of early seizures (occurring within the first 1-2 weeks of stroke) is 2.4%-5.4%, and the risk of poststroke late seizures (seizures occurring later than after 14 days of stroke) is approximately 7%-18% [1,2]. Late-onset poststroke epilepsy has a higher recurrence rate of up to 71.5% within 10 years after stroke [3]. Our previous study demonstrated that seizures during stroke increase overall morbidity and mortality [4]. The stroke severity, location (for example, middle cerebral artery [MCA] infarcts in our study), and the type of pathological changes, genetic factors, and pre- and postinjury exposure to nongenetic factors influence the susceptibility of patients with ischemic stroke [5,6]. The standardized morbidity rate of developing epilepsy is highest during the first year after stroke. In addition, higher National Institutes of Health Stroke Scale (NIHSS) score [7], cortical involvement, younger age, and central nervous system morbidities are associated with higher risk of poststroke epilepsy [1,8].

The effects of thrombolysis and thrombectomy on long-term poststroke epilepsy remain unclear. A retrospective evaluation of patients with thrombolysis found that 4% developed poststroke seizures during hospitalization and that death during admission was significantly more likely in those with seizures compared to those without seizures [9]. Another study found that 5.5% of patients receiving endovascular therapy had seizures between stroke onset and 3-month follow-up, and early seizures independently predicted a significantly unfavorable outcome [10]. Regarding early postthrombectomy seizures, 2.4% of patients with ischemic stroke treated with thrombectomy developed at least 1 seizure within 7 days of stroke onset, and the occurrence of seizures was associated with higher 90-day mortality and poorer functional outcomes [11]. For patients with stroke, receiving reperfusion treatments was not associated with acute symptomatic poststroke seizures or poststroke epilepsy [7,12].

Ethnicity may be an important factor in the development of poststroke seizures and epilepsy. The prevalence of poststroke seizures in patients without atrial fibrillation is higher in Australia than in China [13]. In Taiwan, 1 study found that atrial fibrillation may cause ischemic stroke that subsequently causes seizure and atrial fibrillation is associated with a higher rate of subsequent seizure [14]. One-year poststroke epilepsy risk is higher in patients staying in the ICU or in patients with seizure at stroke admission, atrial fibrillation, or cognitive impairment [15]. Late poststroke seizure recurrence is more common in patients of young age (younger than 65 years of age), of male sex, with large lesion seizure, or with partial-onset seizure [16].

Concept of Epileptogenesis

Antiepileptic drugs (AEDs) or antiseizure medications may prevent the recurrence of seizures but do not cure epileptogenesis. An epileptogenesis is the process by which the previously normal brain is functionally altered and biased towards the generation of abnormal electrical activity that induces chronic seizures [17]. It involves molecular, anatomical, or circuit-level alterations, such as cell death or dysregulation of an ion channel or neurotransmitter receptor and the impairment of intrinsic plasticity. How these different levels of alteration are regulated remains unclear. Studies have reported that the epigenetic factor chromodomain Y-like protein, a critical regulator of the initiation and maintenance of intrinsic neuroplasticity that works by regulating voltage-gated sodium channels [18], is involved, and epileptic neurons may also develop short- and long-term adaptive changes in sensitivity to gamma-aminobutyric acid (GABA)ergic neurotransmission [19], worsening excitatory or inhibitory imbalance and thus reducing the possibility of successful therapeutic approaches using traditional AEDs. Further, an increasing amount of research, including ours, suggests a major involvement of inflammation in epileptogenesis [20-22]. Seizure activity elicits the release of proinflammatory cytokines and activates immune responses.

We have studied medications with potential antiepileptogenesis effects in pilocarpine-induced seizure animal models, supporting the concept of antiepileptogenesis with intervention immediately following brain insult [21-23].

Studies Regarding Primary Prevention

The clinical trials aimed at the prevention of chronic epilepsy have often produced negative results because they mainly evaluated downstream clinical manifestations instead of monitoring early, specific molecular epileptogenic events and applying early intervention. A 1990 study on primary prevention of posttraumatic seizures with early use of phenytoin [24] indicated that phenytoin exerts a beneficial effect by reducing seizures only during the first week after severe head injury.

American Heart Association guidelines indicate that prophylactic AEDs are not recommended for the prevention of poststroke seizure [25] due to the lack of randomized control trials and some reports indicating that prophylactic AED therapy may be associated with poorer outcomes [26-28]. In addition, valproic acid therapy was found to be ineffective compared with a placebo in preventing the occurrence of late-onset seizures in patients with spontaneous and nonaneurysmal intracerebral hemorrhage [29]. Nevertheless, the lack of success in prophylactic AED therapy trials may be related to the use of traditional AEDs.

XSL•FO
RenderX

Medications With Antiepileptogenetic Potential

Numerous AEDs exist. Based on our clinical experience and laboratory research [21,22,30-33], we have identified 2 newer AEDs with antiepileptogenesis potential. Levetiracetam (LEV), which exhibits a distinct synaptic vesicle modulating mechanism, has exhibited the potential in ameliorating epileptogenesis [1,34,35]. Our earlier research indicates that it has a broad spectrum of modulating neuronal excitability [30]. It exhibits no clinically relevant drug-drug interactions [36]. Perampanel (PER), a standard AED with a distinct mechanism of selective noncompetitive antagonism of alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type receptors, is also effective in treating a wide spectrum of epileptic seizures and has a favorable tolerability profile [37]. Because it blocks glutamate excitotoxicity, PER is theoretically capable of modulating epileptogenesis and has demonstrated potential in ameliorating epileptogenesis [32,38,39]. Thus, it is potentially justified to evaluate whether early prophylactic administration of LEV or PER in patients with acute major stroke hampers the development of epileptogenesis and later poststroke epilepsy.

Methods

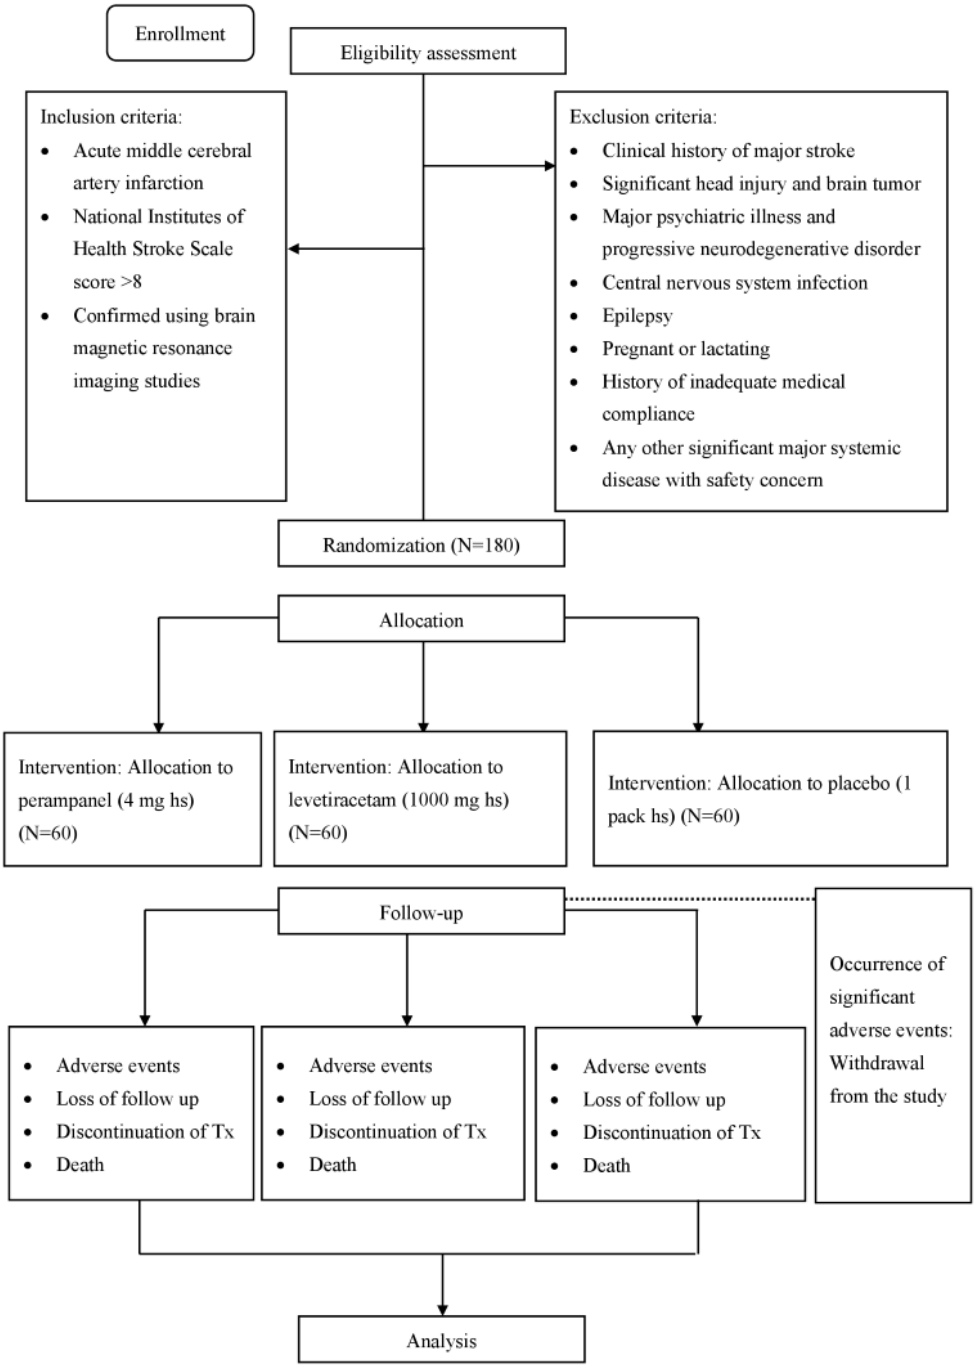
Overview

We will conduct a prospective randomized, triple-blind, and placebo-controlled study. To calculate the appropriate sample size, we took into account various factors including the population size, margin of error, confidence level, expected variance, number of patients with MCA infarcts admitted to our medical center annually, and potential loss rate. We used G*Power software (Heinrich-Heine-Universität Düsseldorf) to perform these calculations. Specifically, we used an effect size ranging from 0.25 to 0.4, α error probability of .05, power of 0.5, 3 groups, 2 measurements, and a correlation of 0.05 between repeated measures. The resulting total sample size ranged from 51 to 120. Based on the potential number of patients admitted to our medical center and the expected loss rate, we estimated that enrolling 180 cases would be reasonable.

Study Participants and Eligibility Criteria

We will recruit patients on the basis of the inclusion criteria of exhibiting acute MCA infarct and an NIHSS score of >8 (based on Diener Law) [40], confirmed using brain magnetic resonance imaging (MRI) studies during hospital admission within 72 hours of symptom onset. The exclusion criteria will be as follows: clinical history of major stroke; significant head injury; brain tumor; major psychiatric illness; progressive neurodegenerative disorder; central nervous system infection; epilepsy that may precipitate seizures; use of AEDs, including LEV or PER; being pregnant or lactating; history of inadequate medical compliance; or any other significant major systemic disease with safety concerns, as determined by a physician.

Intervention



The participants will be divided into 3 groups: the control (placebo) group and the 2 experimental groups (LEV and PER). The patients, investigator, study assessors, and data analysts will remain blind to the treatment assignments from the time of randomization. Because we will conduct block randomization for group allocation, we anticipate that the percentage of patients receiving tissue plasminogen activator or intravenous thrombectomy will be similar in the 3 groups.

The major MCA infarctions typically require the early implantation of a nasogastric tube, and to account for the design of blinding, preventive drugs will be administered in powdered form. The study team works with pharmacists to ensure that medications for the experimental and control groups have similar color, fragrance, and taste. After being ground up, the drugs are packaged in identical medication bags, and a reminder label is affixed to the outer packaging to remind patients to take their medication regularly and for the appropriate duration.

The three groups are described as follows, and the study flowchart is shown in Figure 1: (1) For the control group, a placebo will be administered to patients, and we will maintain standard stroke care during hospital admission if no acute seizure occurs during this period. If an acute seizure occurs, unblinding will be performed, and we will administer AEDs not including LEV or PER; the patient will be maintained on these AEDs. (2) For the LEV group, we will prophylactically administer 1000 mg of LEV per day to patients from the first day of admission in addition to standard stroke treatment. The LEV treatment duration will be 3 months. (3) For the PER group, we will prophylactically administer 4 mg of PER per day to patients from the first day of admission in addition to standard stroke treatment. The PER treatment duration will be 3 months. (4) After the patient is discharged from the hospital, their respective medication will be administered orally for up to 3 months. (5) All patients will receive follow-up for 18 months, and the incidence of late-onset epilepsy will be documented. Seizure characteristics, including semiology, frequency, and severity, will be analyzed in the 3 groups. The relationship of seizure semiology to stroke-related localization will be verified. (6) For those who have acute seizures during hospital admission, unblinding will be performed, and either LEV or PER will be administered for treatment according to their group. The dosage will be adjusted according to real clinical needs. These patients will be treated as having epilepsy based on the 2016 definition of epilepsy [41] and be maintained on LEV or PER after hospital admission. The administration of LEV or PER to patients with acute seizures will still be considered prophylactic therapy because patients with acute seizures have a considerably higher risk of developing poststroke epilepsy. (7) Because up to 20% of patients with anterior circulation ischemic stroke may experience electrographic seizures during the acute stage of stroke without clinically overt seizures [42], we will arrange 1 routine electroencephalogram (EEG) at the acute stage for each patient. Prophylactic AED therapy will be administered according to the group the patient is allocated to if any electrographic seizure, including periodic lateralized epileptiform discharge (PLED), is identified in the EEG. (8) Unblinding will be implemented at 3 months, and the final analysis will be conducted at 18 months.

Randomization and Blinding

Block randomization of eligible participants will be performed to form the LEV, PER, and placebo groups. Blinding of participants, clinicians, and data collectors will be performed so that these individuals do not have access to group assignment details (Figure 2). Before accepting the case, the pharmacist, who is a nonresearch team member, sets the blocks and determines the distribution of random numbers using a random number table. The pharmacist is responsible for conducting all phases of the research. Additionally, the 3 topic groups can be equally distributed among participants through random assignment.

Procedure and Assessment

We will document patients with initial NIHSS scores of >8 [40]. For reperfusion therapy, we will also use a modified Rankin scale for treatment evaluation [43]. For each participant, we will use brain MRI to confirm MCA territory infarction and exclude that of other territories and lacunar infarction. The MRI image depicting the typical case with an MCA infarct enrolled in this study is displayed in Figure 3. Baseline EEG during admission prior to AED administration will be arranged to exclude patients with early or concurrent clinical or electrographic seizures (Figure 2).

Outcome Measures

Primary Outcome

The primary outcome measure will be the incidence of poststroke epilepsy and seizure severity at the end of the study period. Univariate ANOVA of the LEV, PER, and placebo groups will be performed. Intention-to-treat analysis will be performed. Participants will be followed up 1, 3, 6, 9, 12, and 18 months after stroke. If a seizure occurs during the prophylactic medication administration period, individual unblinding and adjustment of AEDs will be implemented. If a seizure occurs after the prophylactic medication administration period, ordinary medical care will be provided. We will record seizure type and duration after stroke onset at seizure occurrence (Table 1 and Figure 2).

[a]NIHSS: National Institute of Health Stroke Scale.

[b]mRs: modified Rankin scale.

[c]MRI: magnetic resonance imaging.

[d]EEG: electroencephalograph.

[e]TEAE: treatment-emergent adverse event.

Secondary Outcomes

The secondary outcomes will include the duration until the occurrence of the first seizure, the severity of seizures, the safety and tolerance of the medication, and the overall stroke outcome. During the 18-month follow-up, we will record mortality, medication safety, and tolerability data at each visit. Stroke outcome will be measured using the modified Rankin scale at 3 and 18 months (Table 1 and Figure 2).

Statistical Analysis

Continuous variables will be assessed using a 2-tailed *t* test or ANOVA, followed by the Fisher least significant difference test. When data are not normally distributed, analyses will be performed using the nonparametric ANOVA Kruskal-Wallis H test followed by Dunn multiple comparison test for nonrepeated measures and the Friedman test for repeated measures. ANOVA will be used where sessions or quadrants will be treated as a within-subject factor and groups as a between-subjects factor. Analyses will be performed using a chi-square test, Yates chi-square test, or Fisher exact test for nominal variables. Differences will be considered statistically significant at a P value <.05, and actual P value will be reported, unless P<.001.

Ethical Considerations

This study received approval from the institutional review board (IRB) at National Cheng Kung University Hospital (A-BR-108-107). Each participant and their families were provided with a comprehensive verbal explanation of the study and were asked to provide informed consent, as authorized by the IRB. Participants completed their signatures on the consent forms to indicate their agreement to participate in the study.

The study data would be kept anonymous and deidentified to protect the participants' privacy. Participants were not offered any form of compensation or reimbursement for their involvement in this human subjects' research.

Results

Participant recruitment began on August 1, 2020 in National Cheng Kung University Hospital. Intervention, postintervention, and follow-up observation are still ongoing for the participants. The study is projected to be completed by January 31, 2025.

Discussion

Principal Findings

Although reports have not supported the role of prophylactic AEDs in the prevention of poststroke seizure because of a lack of randomized control trials, a lack of detected early clinical biomarkers, and worse outcomes with traditional AEDs, we will document the potential prophylactic effect of LEV and PER on poststroke seizures and epilepsy in patients with MCA infarct in this randomized clinical trial and determine the antiepileptogenic potential of LEV and PER in patients with major ischemic stroke in terms of seizure frequency and severity. We will also evaluate the safety and tolerability of these prophylactic treatments. This study will influence both stroke and epilepsy care considerably, including by potentially reducing

XSL•FO
RenderX

long-term care costs and enhancing the quality of life of stroke survivors.

In addition to LEV, previous studies, including our own, have identified PER as a new AED with potential antiepileptogenic properties, attributed to its unique postsynaptic AMPA antagonism [32,38,39]. While it is not yet approved as a first-line treatment for focal epilepsy in many countries, this medication has potential and could be used at an early stage if our study confirms its effectiveness in prophylaxis against poststroke epilepsy.

The administration of AED or placebo for a period of 3 months is intended to intervene in the epileptogenesis phase, based on the relative duration of this phase observed in animal studies. Typically, the epileptogenesis phase in animal studies lasts for around 1 week, although this can vary depending on the animal model of seizure and epilepsy following brain injuries. By extrapolating from rat studies to human years [44], it is estimated that the epileptogenesis phase in rats is similar to around 3-4 months of human life. For the purposes of clinical feasibility, we administer a 3-month duration of AED.

In our trial to provide prophylactic treatment for epilepsy in patients who have not yet experienced seizures and are relatively vulnerable, particularly older patients who have endured stroke with multiple comorbidities, such as renal and liver diseases, we have opted for a relatively low medication dosage. Regarding the inclusion criteria, we do not enroll patients with severe renal or hepatic failure. However, we include patients who are already undergoing dialysis treatment. We assess the severity of liver disease using the Child-Pugh classification, with grade C being categorized as severe liver disease [45]. For the evaluation of renal disease severity, we use the National Kidney Foundation criteria, classifying stage 4 and above as severe renal disease [46]. In accordance with the renal dose adjustments for LEV [47], dosages vary depending on the level of renal impairment. For patients with mild renal impairment (glomerular filtration rate [GFR] 60-89 mL/min/1.73 m^2), the recommended dosage range is 1000-2000 mg per day. For those with moderate renal impairment (GFR 30-59 mL/min/1.73 m^2), the dose ranges from 500 to 1500 mg per day, while patients with severe renal impairment (GFR 15-29 mL/min/1.73 m^2) are prescribed doses of 500-1000 mg per day. For individuals undergoing hemodialysis, the recommended dosage is 500-1000 mg per day with an additional 250-500 mg postdialysis supplement.

Our decision regarding medication dosages is guided by the World Health Organization's Defined Daily Dose (DDD) guidelines [48] and our collective clinical experience. The DDD represents the estimated average daily maintenance dose for a drug when used for its primary indication in adults, taking into account our clinical expertise. For PER, the DDD is 8 mg, while for LEV, it is 1500 mg. In our study, we have chosen to administer PER at a dosage of 4 mg and LEV at 1000 mg. For LEV, this choice is driven by the fact that the majority of our recruited patients have normal renal function, with only a relatively small subset experiencing renal impairment (mild, moderate, or hemodialysis). To ensure randomization and maintain blinding in our triple-blind study, we have opted for a lower dose of 1000 mg per day. Of note, our blinding design excludes the use of postdialysis supplemental dosing.

According to the existing literature, late-onset seizures following a stroke typically exhibit a peak incidence between 6 and 12 months after the initial event [1]. Studies have shown that after an ischemic stroke, the highest risk for the occurrence of the first unprovoked poststroke seizure is observed during the initial follow-up year [5,49]. Furthermore, another study has reported the annual event risk of seizures after the first-ever ischemic stroke, indicating a risk of 6.3% after 1 year, 2.4% after 2 years, 1.3% after 3 years, and 0.3% thereafter [50]. Although the annual risk of seizures may indeed increase in subsequent years, given the highest risk observed during the first year and considering the practical feasibility of our protocol, we have chosen an 18-month follow-up period at this stage.

In terms of stroke severity, minor strokes (those with a small lesion size) are less likely to lead to the development of poststroke epilepsy. For each patient, we routinely arrange for MRI scans as a standard imaging procedure to assess the stroke, including its size, location, and the presence or absence of hemorrhagic transformation during admission. We do not typically perform brain computed tomography (CT) scans. It is worth noting that the absence of hemorrhagic transformation at the onset of the stroke does not eliminate the possibility of it occurring later during the acute stage. In the event of acute deterioration in neurological symptoms and signs, we arrange for follow-up brain MRI or CT scans and provide standard care.

In our protocol, we initiate treatment for patients with PLEDs. PLEDs have been considered to have a high association with seizures [51,52], and among the epileptiform abnormalities, the presence of lateralized periodic discharges was associated with a significantly increased risk of seizure [53]. In addition, PLEDs were associated with an acute process and occurred early during the course of the illness, with stroke being the main etiology [52].

While patients and research teams remain blinded to the allocated medications, the medication list, including cytochrome P450 inducers or inhibitors, is made available to study participants. This allows for vigilance regarding any potential drug-drug interactions. Moreover, given that our study involves a randomized controlled trial with blinding, which necessitates careful control over factors like color, size, and quantity of both the active drug and placebo tablets, the use of a powdered form is the most practical approach for conducting this trial. It is worth noting that the oral suspension form is only available for one of the medications, and furthermore, these oral suspension forms come in different colors. Additionally, the cost associated with preparing a placebo suspension in this context is prohibitively high. Regarding the issue of bioavailability, there has been no direct comparative study on bioavailability between the tablet and powdered forms. We do have clinical experience using the powdered form for patients who face challenges swallowing tablets or those reliant on nasogastric tubes. This practice is consistent with the medication package insert instructions. With their availability in multiple formulations in the future, these AEDs could serve as a potential drug for epilepsy prophylaxis during epileptogenesis.

XSL•FO
RenderX

Conclusions

We anticipate that the intervention group will experience a lower incidence and severity of poststroke epilepsy than the control group. We will be able to document the potential prophylactic effect of LEV and PER in poststroke seizures and epilepsy in patients with MCA infarct and determine the antiepileptogenetic potential of LEV and PER in patients with major ischemic stroke.

Acknowledgments

The work was funded by the National Science and Technology Council, Taiwan (109-2314-B-006-034-MY3) and National Cheng Kung University Hospital (NCKUH-11201005). We would like to acknowledge the staff who have helped in obtaining ethics and operational approval and participated in this study.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

CWH led the effort to acquire funding from the National Science and Technology Council, Taiwan. YSC, PSS, and CWH formulated the research question, study protocol, and are conducting the trial. YSC prepared the first draft of the protocol paper, with contributions and editing of subsequent drafts by PSS, MCL, and CWH. All authors have read and approved the final study.

Abstract

Background: The use of education alone as a technique to change behavior in interventions is usually insufficient, particularly in health interventions. Behavior change techniques have been shown to be effective in fostering positive changes in health behaviors such as diet and physical activity. The upskilling of health professionals can increase perceived capability and motivation toward eliciting change in clients' behaviors. However, to date, dietitians have received limited training in behavior change and have expressed a need for continuous professional development.

Objective: The study objectives are to (1) develop and evaluate the effectiveness and acceptability of two 2-hour behavior change workshops on changing dietitians behavior (ie, range of behavior change techniques used and frequency of use) across 3 time points; (2) determine if participation in these workshops will elicit changes in dietitians' perceived capability, opportunity, and motivation toward using behavior change techniques; and (3) determine the acceptability of the training and its application in practice by dietitians.

Methods: We will recruit registered dietitians (N=140) in Australia to participate in this randomized controlled trial. Participants will be randomly assigned to either the intervention or 3-month waitlist control condition and complete outcome measures at 3 time points: baseline, after the workshop, and follow-up at 3 months. Both groups will complete 2 workshops on behavior change that are guided by the COM-B (Capability, Opportunity, Motivation, and Behavior) Model and embedded with behavior change techniques. The primary outcome is changes in behavior, (ie, the range of behavior change techniques used and their frequency of use). Secondary outcomes include changes in perceived capability, opportunity, motivation, and preparedness as a health professional toward delivering behavior change techniques. The acceptability of the workshops will also be assessed after the workshop through the postworkshop survey and semistructured interviews. A series of 2-way repeated measures ANOVAs and regressions will be used. Qualitative data will be analyzed using thematic analysis.

Results: Participant recruitment commenced in June 2023. The results of the study are expected to be published in November 2024. The results will allow us to assess comparisons between the intervention and waitlist control groups, as well as changes in perceived capability, opportunity, motivation, and preparedness over a 3-month period. It will also provide an understanding of the acceptability of the training as a form of continuous professional development for dietitians.

Conclusions: If found to be effective, the results of this 2-arm randomized controlled trial will guide future training and continuous professional development for health professionals in changing behavior in practice. Our findings will contribute to our understanding of the application of behavior change techniques in practice with clients and identify components of COM-B where dietitians may need future support.

Introduction

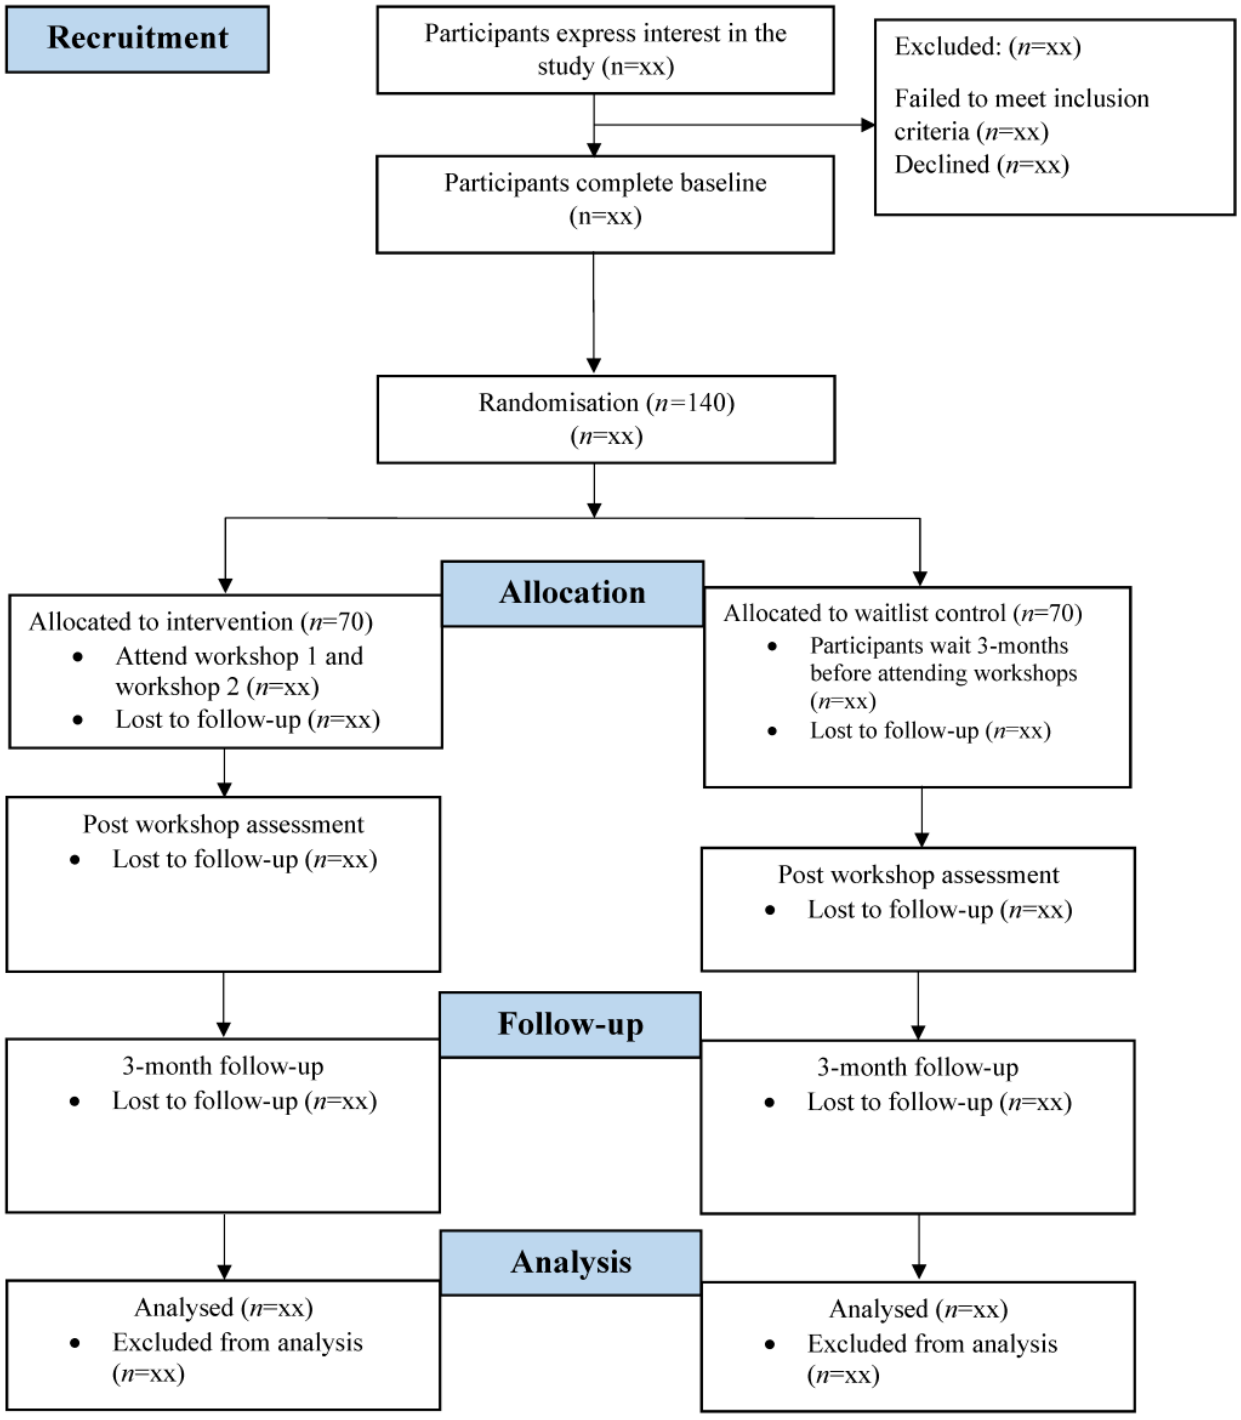
Chronic diseases such as cardiovascular disease, chronic obstructive pulmonary disease, cancer, and diabetes are among the most common noncommunicable diseases, which contribute to the burden of disease in Australia [1]. Approximately 38% of this burden of disease could be prevented by addressing behavioral determinants of disease such as overweight (including obesity) and dietary risk behaviors [2]. The majority of Australians do not meet the Australian government dietary guidelines for fruit and vegetable consumption, with almost 50% of adults eating fewer than 2 serves of fruit and 92% not eating the recommended 5 serves of vegetables daily [3]. Therefore, there is a need for behavior change interventions and health promotion across primary health care settings. However, while health professionals typically focus on education for clients, consumers, or patients (from here forward, any patient, client, or consumer will be referred to as clients), this is usually insufficient for facilitating behavior change and leads to missed opportunities in practice [4]. Behavior change techniques, which are considered the "active ingredients" of intervention design, have been shown to be more effective in improving client outcomes compared to those without, particularly in dietary interventions [5,6]. As such, it is important that health professionals are equipped with the capability and motivation to effectively facilitate behavior change among clients.

Brief opportunistic interventions in routine consultations have been effective for eliciting change in clients' behavior [7,8]. However, health care professionals report barriers to the implementation of behavior change techniques, such as poor confidence in individual skills and knowledge of behavior change, time constraints, priorities, and access to sufficient training [4]. Dietitians engaging in both in-person and telehealth consultations are in an optimal role where they can reach both metropolitan and rural clients to deliver health-behavior change interventions [9]. Additionally, many dietitians have expressed an unmet need for knowledge and skills in behavior change [10,11].

The understanding of behavior change theories and techniques can help health professionals understand behavior and the mechanisms that elicit or facilitate behavior change [12]. Theoretical models, such as the COM-B (Capability, Opportunity, Motivation, and Behavior) model [13] can provide a framework for identifying and explaining the factors enabling or hindering changes in behavior, which can guide intervention design for effective behavior change [14]. The COM-B model posits that an individual's capability (ie, physical and psychological capability), opportunity (ie, social and physical opportunity), and motivation (ie, reflective and automatic) interact in a bidirectional way and can explain behavior [14]. As such, interventions informed by these constructs have been effective in eliciting changes in knowledge and behavior [15,16], alongside the use of behavior change techniques [17,18]. Behavior change techniques can be considered the individual units or "active ingredients" that target components of behavior that need to change [6]. These components or units that form interventions can help us identify the parts of the intervention that work or do not work, providing valuable information for operationalizing effective intervention designs. The use of behavior change techniques can be effective in both changing the behavior of clients and health professionals [19,20]. For example, behavior change techniques such as goal setting, action planning, and self-monitoring have elicited behavior change in physical activity and food-related behaviors [21-24].

Despite the capacity of health professionals to foster behavior change in clients using behavior change techniques, no such training is consistently delivered to dietitians, particularly in formalized education [25]. Currently, the use of behavior change techniques used in dietary practice and dietary-based interventions is based around goal setting, problem-solving, social support, self-monitoring, and education-based techniques (eg, instructions on behavior and credible sources), which are consistent throughout the literature [5,26,27]. Therefore, the primary aim of the study is to develop and evaluate the effectiveness and acceptability of two 2-hour behavior change workshops on changing dietitians' behavior, that is, changes in the number and frequency of behavior change techniques dietitians use in practice. It is anticipated that the workshops will prompt dietitians to use a larger variety and frequency of using these techniques in practice between baseline, after the workshop, and 3-month follow-up. A secondary aim is to determine if attendance at these workshops will demonstrate an increase in dietitians' capability, opportunity, and motivation toward using these techniques. In these workshops, the use of behavior change techniques will underlie workshop material to target dietitians' barriers across capability (eg, persuasion around capability), opportunity (eg, identifying barriers and problem-solving), and motivation (eg, focus on past success). Therefore, we hypothesize that engagement in these workshops will predict dietitians' capability, perceived opportunity, and motivation toward using behavior change techniques from baseline and after the workshop to 3-month follow-up. Lastly, we also aim to determine the acceptability of the training.

Methods



Study Design and Procedure

This study is a 2-arm randomized controlled trial with a 3-month follow-up. Participants will complete a questionnaire at baseline, immediately after the intervention, and 3 months after the intervention. Participants will express their interest to participate in the study through a Qualtrics survey. Informed consent will be obtained at the start of this survey. Following this initial survey, dietitians will be randomized in blocks of 4 into either the intervention or a waitlist control condition (1:1). Block

XSL•FO
RenderX

randomization will be conducted with allocation concealment from the active research team through the use of sealed, opaque envelopes. Emails will be sent to participants with the initial baseline questionnaire, and they will be informed if they can participate in the workshops immediately or if their available workshop will be in 3 months. Once dietitians have been randomized and received their baseline questionnaire, they have been enrolled in the study as participants. Both groups will participate in both workshops and complete a questionnaire immediately after participation in the second workshop and at the 3-month follow-up. The waitlist control group will be debriefed after the final questionnaire regarding their allocation to the waitlist control group. Postworkshop data collected from the waitlist control group will also be included in the final data set. Figure 1 shows a flowchart for each group's progression in the trial. This protocol will adhere to the CONSORT (Consolidated Standards of Reporting Trials) and SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) guidelines for randomized controlled trials [28].

Figure 1. Outline of the trial.

XSL•FO
RenderX

Participants

Participants will be dietitians who are currently working in Australia and hold full membership with Dietitians Australia. Participants will be recruited using purposive sampling, through both social media advertisements and newsletters directed through nutrition and dietetic organizations, and through snowballing. Recruitment of participants will be staggered over a 12-month period. A similar intervention in behavior change for health professionals found medium to large effect sizes for changes in mechanisms of change (eg, perceived knowledge) [16]. Therefore, anticipating medium to large effect sizes, a-priori analysis was conducted in G power (Axel Buchner; $F_{1,82}$=0.2; power =.80; α=.05) indicating that 42 participants in each group would be adequate [29]. This means a total sample size of 84. It is anticipated that there may be high attrition in this study. Therefore, we aim to recruit approximately 140 participants to ensure that if 50% of each group are lost to attrition, the proposed analysis will be sufficiently powered. This dropout rate of 50% is conservative given that similar interventions in training health professionals can report moderate (20%) to high (50%) attrition rates [20,30].

Intervention Components

The workshops have been developed and piloted by a research team of psychology researchers and dietitians with clinical and teaching experience (Textbox 1). The main objectives for these workshops are intended for dietitians to be able to (1) understand the importance of behavior change, (2) define the characteristics of the COM-B model, and (3) identify opportunities to and implement behavior change techniques in practice. The first workshop will focus on developing knowledge of behavior change and the COM-B model [13]. The second workshop is focused on providing dietitians with behavior change techniques from the behavior change taxonomy [6]. These techniques were based on those shown to be effective in dietary interventions [31] and were chosen based on the most relevant techniques for practical use by dietitians. These workshops will be delivered both remotely through Teams (Microsoft Corporation) and in person. The design of these workshops is informed by behavior change techniques to target participants capability, perceived opportunity, and motivation to use behavior change techniques. These are delivered through activities and group discussions to evoke reflection, awareness of their own behavior, and problem-solving to overcome the barriers that exist across their own capability, perceived opportunity, and motivation (Multimedia Appendix 1 [6,19,32-37]).

Textbox 1. Outline of workshops.

Workshop 1

- Understanding behavior
- Exploring behavior and behavior change
- Introduction to the Capability Opportunity Motivation-Behavior Model
- Case study
- Behavior change techniques
  - What are behavior change techniques?
  - Explore goal setting, problem solving, self-monitoring, and social support.
  - Case study in small groups behavior change technique

Workshop 2

- Behavior change techniques
- Further explore 9 additional behavior change techniques and how they might apply in practice (eg, pros and cons and reattribution).
- Case study in small groups
- Relapse management and prevention

Data Collection Methods

Once an expression of interest has been received through the Qualtrics survey, the participant will be asked to complete an initial baseline measure. In this baseline questionnaire, participants will be asked questions on their demographics (eg, age, gender, and highest level of qualification), current perceived knowledge and behavior (ie, use of behavior change techniques), the COM-B questionnaire [38], and preparedness as a health professional to deliver behavior change techniques. The same assessments (excluding demographics) will be repeated at the postworkshop and follow-up time points. At the postworkshop time point, the questionnaire will also include items on the acceptability of the workshops.

Outcomes

The primary outcome of this study will be behavior change, which will be operationalized in 2 ways for dietetic practice. These outcomes include (1) a change in the number of behavior change techniques used and (2) a change in the frequency of behavior change techniques used. This change will be measured across the 3 time points. While this may not be an absolute measure of behavior change technique delivery, however, any change will capture the range of techniques taken from the

XSL•FO
RenderX

workshops, which may be more indicative of the dietitians' understanding and application of the COM-B model. To further capture the uniqueness of the behavior change techniques delivered by dietitians, the type of technique will also be measured across the 3 time points. Secondary outcomes include changes in perceived capability, opportunity, motivation, and preparedness as a health professional toward delivering behavior change techniques.

Measures

Behavior will be measured with two items to determine (1) the use of behavior change techniques and (2) the frequency of use. The first item asks participants "Which of the following behavior change techniques do you use in practice?" Participants will indicate which of the 14 techniques they have used by rating their answer as either yes, no, or unsure. A total of 14 techniques were chosen based upon techniques used for dietary behavior change in the literature [31], as well as consultations with an advisory group of dietitians to determine the appropriateness and practicality of the techniques. A composite score will be calculated to determine the number of techniques used. A second item will also be included to identify how frequently dietitians use these techniques in practice, for example, "How often do you currently use behavior change techniques when interacting with clients?" Participants will rate this item on a 5-point Likert scale from never (0) to always (4).

Capability, opportunity, and motivation will be measured using the COM-B questionnaire [38], which has been adapted for delivering behavior change techniques when interacting with clients in health contexts. This measure includes 6 items and 6 domains that reflect each component of the COM-B model as outlined by Michie et al [13]. Participants will rate their level of agreement with each item on an 11-point scale, with items ranging from strongly disagree (0) to strongly agree (10). An example item includes "I have the PHYSICAL opportunity to deliver behavior change techniques when interacting with clients (eg, time, the necessary materials, reminders, and space)."

Perceived knowledge will be measured using 3 items related to knowledge of behavior change techniques. Each item will be rated on a 7-point slider scale. Participants will rate their level of understanding of behavior change techniques and their knowledge of 9 categories of techniques from "no understanding" (1) to "perfect understanding" (7). These categories are described in the behavior change taxonomy [39]. Scores for each statement will be summed to create a total perceived knowledge score. Item 3 will ask participants to rate their level of agreement with 3 statements relating to the use of behavior change techniques (ie, if they have used them before and if they know why they are useful). These statements are rated from "strongly disagree" (1) to "strongly agree" (7). Perceived knowledge will be assessed at the 3 time points.

The preparedness of dietitians to deliver behavior change techniques will be measured using a 6-item scale. This scale has been used with health professionals, such as pharmacists [40]. This measure is to determine if dietitians feel they are equipped to deliver these techniques as part of their consultations. Statements will be rated on a 5-point Likert scale from (1) strongly disagree to (5) strongly agree. An example includes "Dietitians need training in communication skills to enable them to deliver a behavior change techniques."

Process Evaluation

The process evaluation will assess dietitians' acceptability of the 2 workshops. A total of 2 items will be included at the end of the postworkshop questionnaire, which was developed by Kothe and Mullan [41]. The first question will ask participants their level of agreeance on 14 keywords related to the facilitated workshops. For example, whether they felt the workshops were "needed, useful, appropriate, interesting, exciting, worthwhile, too short." These will be scored on a 5-point Likert scale. The second question asks participants how satisfied they were with the workshops, rated on a 5-point Likert scale ranging from "very dissatisfied" (1) to "very satisfied" (5). At follow-up, participants will also be invited to complete a one-on-one exit interview through Microsoft Teams. These interviews will allow us to assess the experience and impact of the intervention (eg, barriers and enablers) and explore the acceptability and feasibility of the workshops. Interviews will be guided by the COM-B model [13] and are expected to take 30-45 minutes each. In addition, participants who choose to withdraw from the study will also be invited to complete 3 short open-ended questions regarding their reason for withdrawing from the study. This will provide insights into noncompleters experiences and attitudes toward the intervention.

Statistical Analysis

Preliminary Analyses

Missing data will be managed during the data cleaning stage using case-wise deletion for missingness greater than 40%. Considerations for the use of multiple imputations as a method for addressing missing data will be made only if appropriate. Multiple imputation as a method for handling missing data is recommended for use in randomized controlled trials [42]. Assumption testing (eg, homogeneity of variances and normality) will also be conducted. If assumptions are not satisfied, appropriate transformations will be made. Dropout analyses using independent sample *t* tests (2-tailed) will identify any significant differences between participants who complete the study and those who drop out. Per protocol, intention-to-treat analyses will also be conducted as recommended for use in randomized controlled trials to reduce sample bias [43,44].

Primary and Secondary Outcomes

The primary and secondary outcome variables will be assessed at the baseline, postworkshop, and follow-up time points. A chi-square test will be used to assess if there are any differences between the intervention group and waitlist control at baseline. A 2-way repeated measures ANOVA will be conducted to compare the means between the intervention group and waitlist control group (between-subjects factor) over the 3 time points (within-subjects factor) for each of the primary and secondary variables. This analysis will be run to test for any time through conditional interactions. Demographics, such as age, gender, role of dietitian, and consultation delivery mode, will be included as covariates in the analysis. Multiple regression analyses will be used to determine whether changes (residual) in capability, opportunity, motivation, and health professional

XSL•FO
RenderX

preparedness predict changes in behavior (range of use or frequency of use) at each of the 3 time points (while controlling for baseline behavior).

Qualitative Data

Interview data will be analyzed using thematic analysis to identify common themes concerning the impact of the intervention (eg, barriers or enablers experienced in practice) and to inform the acceptability and feasibility of the workshops [45].

Ethical Considerations

Ethics approval was granted for this study by the Human Research Ethics Office on January 20, 2023 (HRE2023-0026). This project has also been approved by the Human Research Ethics Committee (HRE2023-0026) and the Australian and New Zealand Clinical Trials Registry (ACTRN12623000525684). Informed consent to participate in the study will be received during the initial recruitment stage before any data collection. Dietitians who are interested in participating will follow a Qualtrics survey link to the participant information sheet that details their involvement in the trial. Following this information, participants will be asked to consent to participate in the study, and if they choose to withdraw from the study, they will also consent to being contacted with follow-up questions. The workshops provided will be freely accessible and are able to be recorded as continuous professional development under Dietitians Australia.

Research Data Plans

All research data collected as part of this project will be stored on the research drive of the university. Only the research team will have access to this data. Participant data will be collected and matched across the 3 time points based on their name, email address, and participant ID. All the data collected as part of this trial will remain confidential. After data collection, the 3 time points will be matched, and the data will be deidentified. Participants will be sent email reminders for each upcoming workshop and assessment.

Results

Participant recruitment commenced in June 2023. Recruitment will be staggered over 12 months. Data analysis will commence in 2024, with the anticipated publication of results in 2024.

Discussion

Principal Findings

This trial will examine the effectiveness and acceptability of two 2-hour behavior change workshops and, to our knowledge, is the first training workshop to promote behavior change techniques among dietitians. There is evidence to suggest that training health professionals is beneficial in improving capability and motivation for using behavior change techniques in practice [20,33]. It is important that health professionals are confident in eliciting and identifying opportunities to facilitate brief opportunistic interventions with the goal of developing long-term behavioral maintenance. The findings of this study will provide insights into effective strategies for training of allied health professionals, such as dietitians, which could inform efforts to incorporate behavior change education into either formalized training or continuous professional development.

Strengths and Limitations

A strength of this study is the use of a rigorous, co-designed process involving both experienced researchers in behavior change and a supervisory team of dietitians. Dietitians have been involved throughout the workshop design process and provided feedback to ensure terminology is consistent and information is tailored to nutrition and dietetic practice. Co-design provides valuable insights into stakeholders and consumer perspectives, allowing for a more targeted approach to intervention design [46]. A potential limitation that may arise during the study is that participants who do express interest are likely to have high motivation and potential knowledge of behavior change before the workshops. This may lead to only minor or no changes in capability, opportunity, and motivation, even if the workshops are effective, and may limit the generalizability of conclusions concerning uptake and interest in training.

Conclusions

The examination of the effectiveness and acceptability of this trial will inform strategies for continuous professional development in behavior change. If found to be effective and acceptable by dietitians, there is potential for future training and professional development programs across allied health professionals who are in opportunistic and client-facing roles to target chronic disease prevention and management [47,48]. Our findings will also contribute to our understanding of translating skills around behavior change techniques into practice with clients and identifying those components of COM where dietitians may need future support.

Acknowledgments

The authors would like to acknowledge the advisory group of dietitians from Curtin University who were involved in the planning and piloting of the workshops.

Abstract

Background: The recommendations for the use of and selection of covered stent grafts in patients with aortoiliac occlusive disease are limited.

Objective: The GORE VBX FORWARD clinical study aims to demonstrate the superiority of the GORE VIABAHN VBX Balloon Expandable Endoprosthesis (VBX device) for primary patency when compared to bare metal stenting (BMS) for the treatment of complex iliac artery occlusive disease.

Methods: A prospective, multicenter, randomized control study in the United States, European Union, United Kingdom, Australia, and New Zealand will enroll patients with symptomatic, complex iliac artery occlusive disease. In this study, iliac artery occlusive disease is defined as a unilateral or bilateral disease with single or multiple lesions (with >50% stenosis or chronic total occlusion) each between 4 and 11 cm in length. In an attempt to more closely match real-world practices, patients with minor tissue loss (Rutherford class 5) and patients requiring hemodialysis will be included. Baseline aortoiliac angiography will be performed to assess target lesion characteristics and determine final patient eligibility. Once the patient is confirmed and guidewires are in place across the target lesions, the patient will be randomized in a 1:1 format to treatment with either the VBX device or a BMS. The BMS can be balloon- or self-expanding and must be approved for the iliac artery occlusive disease indication. Patients, the independent core laboratory reviewers, and Clinical Events Committee members will be blinded from the assigned treatment. Dual antithrombotic medical therapy is required through a minimum of 3 months post procedure. The primary end point is 12-month primary patency and will be adjudicated by an independent imaging core laboratory and Clinical Events Committee. Key secondary end points will be tested for superiority and include technical, acute procedural, and clinical success;

XSL•FO
RenderX

changes in Ankle-brachial index; patient quality of life; primary patency; freedom from restenosis; primary-assisted patency; secondary patency; freedom from target lesion revascularizations; cumulative reintervention rate; amputation-free survival; survival; and change in Rutherford category. Study follow-up will continue through 5 years.

Results: Outcomes will be reported following study completion. Enrollment is anticipated to start in October 2023.

Conclusions: The results of this study will provide definitive, level 1 clinical evidence to clinicians on the optimal choice of stent device to use for the treatment of complex iliac artery occlusive disease. The FORWARD study is powered for superiority and includes only complex, unilateral, or bilateral lesions involving the common or external iliac arteries. This study is a multidisciplinary endeavor involving vascular surgery, interventional cardiology, and interventional radiology across multiple countries with a blinded core laboratory review of end points in hopes that the outcomes will be widely accepted and incorporated into practice guidelines for optimal treatment of patients with complex iliac artery occlusive disease.

Introduction

Peripheral artery disease (PAD) of the lower extremities affects over 230 million adults worldwide and is the third leading cause of atherosclerotic morbidity behind coronary artery disease and stroke [1]. Symptomatic PAD, including lifestyle limiting claudication, rest pain, and tissue loss, is associated with significant disability, morbidity, and mortality. In the United States, the prevalence of PAD is estimated to be 7% to 10% [2,3], with approximately one-third involving the aortoiliac segment [4].

Endovascular treatment of aortoiliac occlusive disease (AIOD) has been proven to be a safe, durable, and efficient option compared to open repair, independent of the lesion Trans-Atlantic Inter-Society Consensus (TASC) II classification [5,6]. While balloon-expandable bare metal stents (BMS) have demonstrated acceptable technical success and 1-year primary patency in this location, balloon-expandable covered stents have arguably demonstrated more favorable primary patency through 12 months specifically in patients with complex TASC II C and D lesions [7,8]. Meta-analyses comparing BMS to balloon expandable covered stents suggest that covered stents may offer improved primary patency and freedom from reintervention, especially in more complex AIOD [9-11]. Randomized, controlled studies comparing balloon expandable covered stents and BMS in advanced AIOD, such as COBEST [12] and DISCOVER [13,14], have been conducted; however, limitations in these studies have prevented clear and conclusive outcomes. Despite only demonstrating a significant difference in binary restenosis in a subgroup analysis, the COBEST trial is widely referenced as the key evidence that supports the use of covered stents in advanced AIOD. While the COBEST trial subgroup analysis suggested a benefit to covered stenting, it should be considered hypothesis-generating for a future covered versus BMS comparative trial in complex iliac occlusive disease. The key limitations included a noninferiority design with minimal statistical power, limb-level randomization despite enrollment by TASC II classification, no independent core laboratory adjudication of end points, limited experience to 1 country (Australia), and limited follow-up to 18 months [12]. These limitations may contribute to the lack of additional recommendations for the use of covered stents in society consensus guidelines [15-17].

Though the Society of Vascular Surgery has published recommendations for the use of covered stent grafts in instances of severe calcification at risk of vessel rupture [15], there are no additional published guidelines on stent selection for AIOD [15,16,18]. The European Society for Vascular Surgery guidelines do recommend endovascular first treatment for patients with AIOD with severe comorbidities or in experienced teams if it does not compromise subsequent surgical options [16]. More recently, the DISCOVER trial compared the Advanta V12 (iCAST) to balloon-expandable BMS in “advanced” atherosclerotic disease of the common iliac artery [14]. This trial shares similar limitations to the COBEST trial [12] and focuses narrowly on the occlusive disease of the common iliac artery with a large proportion of TASCII A and B lesions (128/174, 73.5%) [14]. As a result, the DISCOVER trial failed to demonstrate any significant difference in primary or secondary outcomes at 2-year follow-up [14]. Other than the 5-year COBEST data [12], the literature for long-term, randomized comparison studies to serve as a guide for clinical practice for the treatment of AIOD remains limited.

The GORE VIABAHN VBX Balloon Expandable Endoprosthesis (VBX device) is a covered stent that has demonstrated favorable performance in patients with complex iliac occlusive disease. The FLEX Trial was a single-arm, nonrandomized study that reported a 1-year primary patency of 94.5%, with the overall cohort consisting of patients with kissing stents (57/134, 43%) and TASC C and D lesions (43/134, 32%) [8]. The GORE-sponsored FORWARD trial (ClinicalTrials.gov NCT05811364) is being conducted to demonstrate the superiority of treatment using the VBX device in patients with complex iliac artery occlusive disease when compared to BMS.

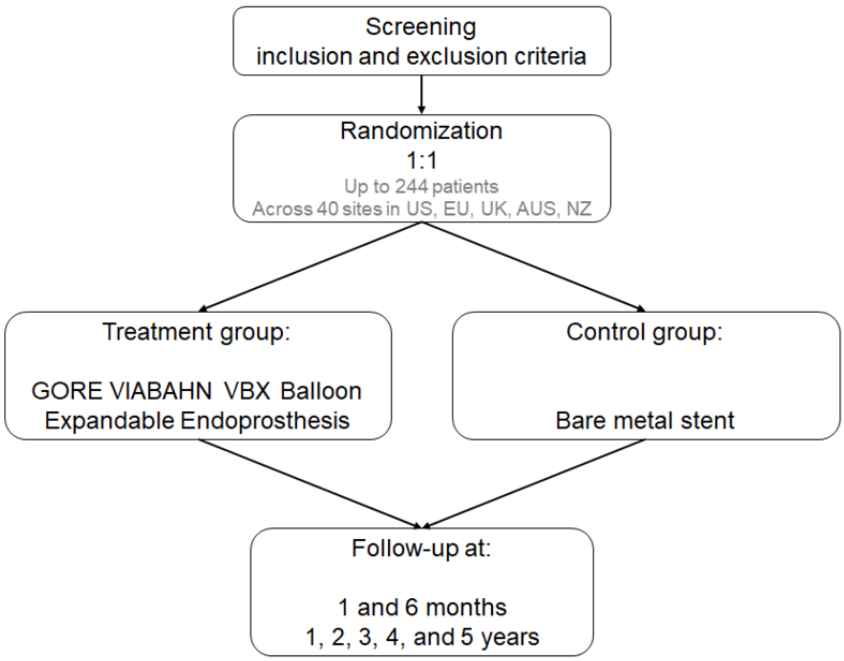
Methods



Study Design

The GORE VBX FORWARD clinical study is a prospective, multicenter, double-blind (patient, outcome assessor), randomized control trial comparing the VBX device to commercially available BMS in patients with complex iliac occlusive disease. The study is designed to randomize 244 patients at up to 40 sites across the United States, European Union, United Kingdom, Australia, and New Zealand.

Ethical Considerations

The study protocol will be reviewed and approved by the institutional review board or ethics committee at each of the study sites. Patients will provide written informed consent before undergoing any study procedures and will be considered enrolled. The study does not involve the collection of identifiable patient information. Human participants enrolled in this study will be compensated in the amount of US $75 for returns to the 1-month, 6-month, 2-, 3- and 4-year follow-ups and US $100 for returns to the 1-year and 5-year follow-ups. The study will be conducted according to Good Clinical Practice, the Declaration of Helsinki guidelines, and in compliance with ISO 14155 (International Organization for Standardization). The study (design illustrated in Figure 1) is registered with ClinicalTrials.gov (NCT05811364).

Figure 1. Study design schema. AUS: Australia; EU: European Union; NZ: New Zealand; UK: United Kingdom; US: United States.

Study Population

The inclusion and exclusion criteria for the study are detailed in Textbox 1. Patients eligible for enrollment will be 18 years or older and have a symptomatic complex iliac occlusive disease with de novo or restenotic lesions in the common or external iliac arteries and with unilateral or bilateral, single or multiple lesions (>50% stenosis or chronic total occlusion) each between 4.0 and 11.0 cm in length (Textbox 1). In addition, clarifications to the specific lesion are (1) bilateral common iliac artery lesions that require kissing stents with at least 1 lesion >4 cm, (2) unilateral common iliac artery lesions that extend into the external iliac artery with a total lesion length >4 cm, (3) unilateral common iliac artery lesion >4 cm that are fully occluded somewhere in the lesion, and (4) multiple unilateral discrete (noncontiguous) lesions each >4 cm.

Preoperative and intraoperative inclusion criteria include symptomatic claudication, rest pain, or minor tissue loss (Rutherford category 2 to 5); reference vessel diameters ranging from 5.0 to 13.0 mm; a sufficient (<50% stenotic) common femoral; a sufficient (<50% stenotic) deep or superficial femoral artery; and a minimum of 1 sufficient (<50% stenotic) infrapopliteal run-off vessel (Textbox 1).

Exclusionary criteria include life expectancy <1 year; pregnancy; known allergy to stent or stent-graft components; nondialyzing patients with severe chronic renal insufficiency; evidence of a systemic infection; known intolerance to antithrombotic medications, vascular surgery, or catheterization of the lower extremities within 30 days of randomization; previous stenting in the iliac arteries; surgical bypass in the target limb; and current participation in another investigative clinical study. Intraoperative exclusions include a lesion requiring adjunctive procedures to facilitate stent delivery (eg, atherectomy and lithotripsy); abdominal aortic artery lesion or aneurysm; lesion requiring stent placement within 2 cm of inguinal ligament; and outflow disease requiring concomitant interventions. In addition, exclusionary are patients with isolated common iliac artery stenosis of any length that can be treated with a single device. For example, common iliac artery stenosis that does not require kissing stents or extending into the external iliac artery (Textbox

XSL•FO
RenderX

1) as these lesions are considered TASC A or B and would not be considered complex. While patients with bilateral disease are not excluded, those requiring concomitant procedures are excluded.

Textbox 1. Study inclusion and exclusion criteria.

Inclusion criteria

- The study population has been defined as adult patients presenting with symptomatic, complex iliac artery occlusive disease. Patients must present with de novo or restenotic lesions (post percutaneous transluminal angioplasty) in the common or external iliac arteries, and complex iliac artery occlusive disease defined as unilateral or bilateral single or multiple lesions (>50% stenosis or chronic total occlusion) each between 4 and 11 cm in length.

Preoperative:

- Aged 18 years or older at the time of informed consent signature
- Informed Consent Form is signed by the patient
- The patient can comply with protocol requirements, including follow-up
- The patient has symptomatic claudication, rest pain, or minor tissue loss (Rutherford category 2-5)

Intraoperative:

- The patient has de novo or restenotic lesions found in the common or external iliac arteries
- The patient has: Unilateral or bilateral single or multiple lesions (>50% stenosis or chronic total occlusion) each between 4 and 11 cm in length
- The patient has a target vessel diameter visually estimated to be approximately between 5 and 13 mm
- The patient has a patent (<50% stenosis) common femoral artery and at least 1 patent (<50% stenosis) femoral artery (deep or superficial)
- The patient has at least 1 sufficient (<50% stenotic) infrapopliteal run-off vessel

Exclusion criteria

Preoperative:

- Life expectancy <1 year
- The patient is pregnant at the time of informed consent
- The patient has a known allergy to stent or stent graft components (including nitinol, stainless steel, or heparin)
- The patient has severe chronic renal insufficiency (serum creatinine level >2.5 mg/dL) and not undergoing hemodialysis
- The patient has evidence of a systemic infection
- The patient has a known intolerance to antithrombotic medications that prevent compliance with study or control device instructions for use
- The patient has had vascular catheterization of the lower extremities within 30 days of randomization (excluding diagnostic angiograms for the study procedure)
- The patient has previous stenting in the iliac arteries
- The patient has a previous surgical bypass in the target limb
- The patient is currently participating in another investigative clinical study unless received written approval from the sponsor

Intraoperative:

- The patient has a lesion requiring drug-coated balloon angioplasty, atherectomy, lithotripsy, or any ablative device to facilitate stent delivery
- The patient has an abdominal aortic artery lesion or aneurysm
- The patient has a lesion that requires stent placement within 2 cm of the inguinal ligament
- The patient has isolated common iliac artery stenosis that can be treated with a single device (ie, common iliac artery stenosis that does not require kissing stents or extend into the external iliac artery)
- The patient has outflow disease that requires concomitant interventions (ie, common femoral endarterectomy or femoral/tibial revascularization)

Study Devices

The VBX device (W. L. Gore & Associates, Inc, Flagstaff, AZ; hereafter, VBX device) is comprised of a balloon-expandable stent graft with a balloon catheter delivery system. The VBX device is made of unconnected stainless-steel rings that are connected and enveloped by expanded polytetrafluoroethylene and fluorinated ethylene propylene film. The comparator device for the study is intended to be any commercially available BMS and can be balloon-expandable or self-expanding and must be approved for iliac artery occlusive disease indication. The use

XSL•FO
RenderX

of interwoven stents or drug-eluting stents is not permitted in this study.

Study Procedures

Patient screening and preprocedural imaging (eg, duplex ultrasound, computed tomography angiography, and diagnostic angiogram) will be performed at the discretion of the investigator and per the institution's standard of care. Study measurements of medical history and demographics, laboratory workup, medication review, and physical examination will be collected. Vascular access, anticoagulation, and introduction of guidewires or catheters will be performed using the standard of care for iliac endovascular procedures at each institution. Baseline aortoiliac angiography will be performed to assess target lesion characteristics and determine final patient eligibility.

Randomization and Blinding

Once study eligibility is confirmed and guidewires are in place across the target lesions, the patient will be randomized (1:1 format) to treatment with either the VBX device or a BMS (balloon-expandable or self-expanding and approved iliac artery occlusive disease indication). Permuted block randomization will be used to promote balance on baseline characteristics across treatment groups. The investigator at each site will be required to select devices that are consistent with the assigned treatment group and proceed with device implantation following the manufacturer's instructions for use. Every effort will be made to limit the number of patient cross-overs (assigned treatment not performed).

Patients, the independent core lab reviewers, and Clinical Events Committee (CEC) members will be blinded from the assigned treatment. Given the nature of the procedure, the implanting investigator will not be blinded.

Index Procedure and Postprocedure

All device implantations will be performed in compliance with the instructions for use for vessel preparation, sizing, delivery, positioning, and deployment. Predilation of each target lesion may be performed with plain balloon angioplasty. After the deployment of the devices, a postdilation may be performed, and a final angiography will be obtained to assess the technical result. Use of closure devices or sheath removal performed in accordance with institutional standard of care is at the investigator's discretion. The procedure time (first incision to access site closure), anesthesia time, reference air kerma, and total fluoroscopic time will be recorded.

Secondary interventions to treat procedural complications requiring intervention will be performed at the discretion of the investigator and these postrandomized patients will continue to be followed at the protocol-specified intervals until study completion. Information about the angiographic images performed, devices and components used, the date of, and the adverse event leading to reintervention will be captured as part of the study record.

Discharge and Follow-Up

At discharge, dual antithrombotic medical therapy is required through a minimum of 3 months post procedure. Additional single antiplatelet therapy (aspirin, clopidogrel, or prasugrel) is required for patients currently prescribed anticoagulant therapy (oral anticoagulation or direct oral anticoagulant). After at least 3 months, antithrombotic medical therapy should be continued post procedure per the investigator's discretion. Patients will be evaluated by duplex ultrasound or angiography (if necessary) for patency at 1-month, 6-months, and annually through 5 years post randomization. Additional study assessments of ankle-brachial index (ABI) [19], Rutherford Classification [20], EQ-5D-5L Questionnaire [21], and the walking impairment questionnaire [22] will be captured.

End Points

The primary end point is 1-year primary patency and is defined as blood flow through the target lesion (no evidence of binary restenosis >50% or occlusion) without target lesion revascularization (TLR). Primary patency will be evaluated and adjudicated by the independent vascular Core laboratory. TLR events will be reviewed and adjudicated by the independent CEC (Table 1).

Secondary end points (defined in Table 1) will include technical success, acute procedural success, clinical success (through 30 days), changes in ABI (hemodynamic status), EQ-5D-5L, and walking impairment questionnaire through 5 years, and the following through 5 years: primary patency, freedom from binary restenosis, primary-assisted patency, secondary patency, freedom from TLR, cumulative reintervention rate (first and recurrent TLR), freedom from clinically-driven TLR, amputation-free survival, survival, and change in Rutherford category.

XSL•FO
RenderX

Table 1. Study end point definitions.

Term	Definition
Primary patency	• Blood flow through the target lesion (no evidence of binary restenosis >50% or occlusion) without a TLR[a]
Binary restenosis	• Evidence of >50% restenosis or occlusion of the target lesions based on core laboratory adjudicated duplex ultrasound or angiography
Primary assisted patency	• Blood flow maintained (no evidence of occlusion) through the target lesion with or without a TLR
Secondary patency	• Blood flow through the target lesion with or without a TLR
Target lesion revascularization	• Endovascular or surgical intervention performed on the target lesions
Clinically driven target lesion revascularization	• Endovascular or surgical intervention performed on the target lesions in response to recurrent symptoms (increase ≥1 Rutherford category)
Amputation-free survival	• Freedom from major amputation (target limb, amputation above the metatarsals) and all-cause mortality
Survival	• Freedom from all-cause mortality
Technical success	• Deployment of device with <30% residual stenosis on final angiography
Acute procedural success	• Technical success and freedom from device or procedure-related SAE[b] requiring intervention
Clinical success	• Improvement from baseline of ≥1 Rutherford category and freedom from device or procedure-related SAE requiring intervention
Hemodynamic status	• Change in ABI[c] as compared to baseline
Rutherford category status	• Change in Rutherford category as compared to baseline
Quality of life assessments	• Change in EQ-5D-5L responses as compared to baseline • Change in WIQ[d] responses as compared to baseline

[a]TLR: target lesion revascularization.

[b]SAE: serious adverse event.

[c]ABI: ankle-brachial index.

[d]WIQ: walking impairment questionnaire.

Statistical Analysis

This study is designed to test the null hypothesis that the VBX device group will demonstrate a primary patency that is less than or equal to the BMS group at 1-year follow-up; versus the alternative hypothesis that the VBX device group will demonstrate a primary patency that is greater than the BMS at 1-year follow-up.

Sample Size Considerations

This study is designed with the assumption that 1-year primary patency will be 88% and 70% for the VBX device group and BMS group, respectively. The study assumptions are based on the FLEX clinical study data and a recent meta-analysis of covered stents and BMS (both balloon-expandable and self-expanding) in patients with TASC II C and D lesions with a minimum of 12-month follow-up [11].

A total sample size of 244 patients would be required to account for a 20% loss to follow-up in order to demonstrate statistical significance (α=.05) at a power of 88%.

Primary and Secondary End Point

The study analysis plan will include the following analysis populations: (1) intent-to-treat population (randomized patients categorized by assigned treatment); (2) as-treated population (randomized patients categorized by treatment received); and (3) per-protocol population. Primary patency at 1 year post implantation of the VBX device and BMS treatment groups will be analyzed with Kaplan-Meier estimates with separate estimates for each group. A 2-sided confidence interval of these estimates (α=.05) will be constructed to test the observed differences in primary patency rates between the treatment groups.

A comparative analysis of secondary end points will be performed. If the null hypothesis for the primary end point is rejected, key secondary end points will be evaluated for superiority using fixed sequential testing. In order, the secondary end points to be tested for superiority are cumulative target revascularization rate (first and recurrent events), the difference in mean ABI, and freedom from TLR.

XSL•FO
RenderX

Time-to-event secondary end points will be analyzed with Kaplan-Meier estimates with separate estimates for each group. Categorical end points for each treatment group will be analyzed with chi-square tests, and continuous end points for the treatment groups will be analyzed with 2-sample *t* tests.

Trial Organization and Oversight

The Executive Steering Committee, consisting of multidisciplinary (vascular surgery, interventional cardiology, and interventional radiology) key opinion leaders, will provide study guidance and clinical oversight. The sponsor will provide study oversight in partnership with contract research organizations for database development, data monitoring, and independent review of study outcomes.

All imaging required by the study including duplex ultrasound and angiography, will be sent to the independent study core laboratory for centralized review and adjudication. An independent CEC will review and adjudicate potential end point–related events. For end point analysis, the sponsor will use data adjudicated by the core laboratory and CEC.

Results

Site enrollment is currently in process, and participant enrollment is anticipated to begin in October of 2023. Participant enrollment is expected to take up to 32 months. Once all participants are enrolled, follow-up will continue through 5 years.

Discussion

Progressive Standards

The literature for long-term, randomized comparison studies for the treatment of AIOD is limited and, therefore, there are no accepted, published guidelines regarding the selection of either bare metal or covered stents. The COBEST trial [12] is the reference data often cited supporting the use of covered stents in complex AIOD. However, the trial was a noninferiority study with minimal statistical power, limited experience in 1 country, only an 18-month follow-up visit, and no independent core laboratory review for adjudication of end points. Furthermore, the COBEST trial was designed to evaluate binary restenosis rather than primary patency. The DISCOVER trial [13,14] failed to show any benefit of covered stents in “advanced” common iliac artery disease across all end points, likely due to the majority of TASC II A and B lesions. The FLEX trial included patients with tortuous iliac arteries, severe calcification, chronic total occlusions, and those who required kissing stents at the aortic bifurcation [7]. Importantly, despite the inclusion of more challenging iliac pathology, the FLEX study demonstrated a 1-year patency of 94.5% for the VBX stent-grafts in the treatment of AIOD involving the common or external iliac arteries [8]. The physician-initiated long-term follow-up of the FLEX study [23], demonstrated a 5-year patency of 89.5% which appears significantly greater than the 5-year patency of 74.7% for covered stents in the COBEST study [12]. While these studies suggest that the primary patency of covered stents may be better than BMS for the treatment of complex AIOD, there is a lack of level 1 evidence and no clear consensus regarding the optimal stent selection in AIOD.

The objective of the FORWARD study is to demonstrate the superiority of the VBX device for primary patency when compared to BMS in complex iliac occlusive disease in a prospective, multicenter, randomized controlled trial. The data from this study aims to provide level 1 evidence that will significantly enhance therapeutic decision-making and help establish a standard of care to guide clinical practice for patients with symptomatic severe aortoiliac disease. The FORWARD study is powered for superiority and includes only complex, unilateral, or bilateral lesions involving the common or external iliac arteries. To mirror real-world practice more closely, patients with minor tissue loss (Rutherford class 5) and patients requiring hemodialysis will be included. This study is a multidisciplinary endeavor involving vascular surgery, interventional cardiology, and radiology across multiple countries with a blinded core laboratory review of end points in hopes that the outcomes will be widely accepted by all parties that treat symptomatic patients with complex AIOD.

Limitations

In the design of this study, multiple considerations were taken to curb the number of limitations. While the study intends to target complex diseases, the results may not be generalizable to populations with less complex diseases. This population is less frequent and may slow enrollment. The study is powered to demonstrate superiority at 1 year, however, longer-term outcomes are also clinically relevant. Additionally, due to the nature of the procedure, blinding of the implanting investigator is not possible which has the potential to induce bias.

Acknowledgments

Medical writing support was provided by Millie Hollandbeck (Phoenix, Arizona) and was funded by W. L. Gore & Associates, Inc (Flagstaff, AZ). Additional paper preparation assistance was provided by Chrystal Redding, an employee of W. L. Gore & Associates.

Data Availability

Data generated or analyzed during this study will be included in peer-reviewed publications. The data sets have yet to be generated or analyzed for this study because no participants have been enrolled.

Protocol

Intravenous Ascorbic Acid for the Prevention of Postreperfusion Syndrome in Orthotopic Liver Transplantation: Protocol for a Randomized Controlled Trial

Abstract

Background: Liver transplantation is the last therapeutic option for patients with end-stage liver disease. Postreperfusion syndrome (PRS), defined as a fall in mean arterial pressure of more than 30% within the first 5 minutes after reperfusion of at least 1 minute, can occur in liver transplantation as a deep hemodynamic instability with associated hyperfibrinolysis immediately after reperfusion of the new graft. Its incidence has remained unchanged since it was first described in 1987. PRS is related to ischemia-reperfusion (I/R) injury, whose pathophysiology involves the release of several mediators from both the donor and the recipient. The antioxidant effect of ascorbic acid has been studied in resuscitating patients with septic shock and burns. Even today, there are publications with conflicting results, and there is a need for further studies to confirm or rule out the usefulness of this drug in this group of patients. The addition of ascorbic acid to preservation solutions used in solid organ transplantation is under investigation to harness its antioxidant effect and mitigate I/R injury. Since PRS could be considered a manifestation of I/R injury, we believe that the possible beneficial effect of ascorbic acid on the occurrence of PRS should be investigated.

Objective: The aim of this randomized controlled trial is to assess the benefits of ascorbic acid over saline in the development of PRS in adult liver transplantation.

Methods: We plan to conduct a single-center randomized controlled trial at the Hospital Universitario Ramo´n y Cajal in Spain. A total of 70 participants aged 18 years or older undergoing liver transplantation will be randomized to receive either ascorbic acid or saline. The primary outcome will be the difference between groups in the incidence of PRS. The randomized controlled trial will be conducted under conditions of respect for fundamental human rights and ethical principles governing biomedical research involving human participants and in accordance with the international recommendations contained in the Declaration of Helsinki and its subsequent revisions.

Results: The enrollment process began in 2020. A total of 35 patients have been recruited so far. Data cleaning and analysis are expected to occur in the first months of 2024. Results are expected around the middle of 2024.

XSL•FO
RenderX

Conclusions: We believe that this study could be particularly relevant because it will be the first to analyze the clinical effect of ascorbic acid in liver transplantation. Moreover, we believe that this study fills an important gap in the knowledge of the potential benefits of ascorbic acid in the field of liver transplantation, particularly in relation to PRS.

Introduction

Scientific Background and Explanation

The first liver transplant (LT) in the world was performed in 1963 [1], but the first successful transplant was carried out by Dr Starzl at the University of Pittsburgh in 1967 [2]. Until the introduction of immunosuppression with cyclosporine in the early 1980s, the survival rate of transplanted patients remained at 20% [3,4]. The 1-year and 5-year patient survival rates have increased to 85% and 70%, respectively, due to advances in surgical and anesthetic techniques and immunosuppression protocols. Despite these advances, hemodynamic changes during surgery remain a challenge for anesthesiologists.

One of the most serious changes during LT can occur at the time of graft reperfusion as an adverse hemodynamic situation known as postreperfusion syndrome (PRS), first described by Aggarwal et al [5] in 1987. They defined PRS as a deep and transient cardiovascular collapse immediately after graft reperfusion, with severe bradycardia, decreased mean arterial pressure (MAP) and systemic vascular resistance, severe arrhythmias, increased pulmonary artery pressure and central venous pressure, and even cardiac arrest. They defined it as a decrease in MAP of more than 30% within the first 5 minutes of graft reperfusion lasting at least 1 minute. The development of PRS is associated with decreased survival, an increased incidence of postoperative renal failure, early graft dysfunction, and the need for blood product transfusion in the setting of severe fibrinolysis [6-8]. Although it was first described in 1987, its incidence has not decreased over the past decades, ranging from 8% to 35% [9-11].

The intrinsic mechanisms of PRS are complex and not fully understood. Several theories have been proposed, including an abrupt accumulation of factors upon reperfusion, such as metabolic acidosis, hyperkalemia, hypokalemia, hypothermia, air emboli, and the release of vasoactive and proinflammatory mediators from both allograft and recipient, which are responsible for decreased systemic vascular resistance and myocardial depression [1,12-19]. During perfusion of the new graft, many proinflammatory cytokines are released from the new liver, such as tumor necrosis factor alpha and interleukins (ILs; IL-1, IL-2, and IL-8), and others from the patient (kallikrein and bradykinin). Other mediators have been found to be elevated after reperfusion (arginase, endotoxins, thromboxane, and monocyte chemoattractant protein-1), but the role of each of these mediators in the onset and severity of PRS is not known [18,20-24].

Ischemia-reperfusion (I/R) injury in LT is associated with graft dysfunction and decreased survival, but its exact role in PRS is controversial. I/R results in cell death due to lack of oxygenation, which occurs during the ischemic period and is exacerbated immediately after reperfusion by the release of proinflammatory cytokines and oxygen free radicals, activation of the complement system leading to sinusoidal vasoconstriction, and local hemoconcentration in the graft with the presence of neutrophils and platelets. All these mechanisms exacerbate the systemic inflammatory response (vasodilation and myocardial depression). The extent to which I/R contributes to the development of PRS and the severity of hemodynamic abnormalities is not entirely clear [25,26], but it seems logical to conclude that PRS is another manifestation of I/R injury. Several randomized controlled trials have been published using different drugs to prevent the onset of PRS (methylene blue, acetylcysteine, antifibrinolytics, and others). However, none of these have shown a beneficial effect.

On the other hand, there has recently been renewed interest in the use of high-dose vitamin C as a supportive treatment in patients with severe septic shock (metabolic resuscitation) [27]. Sepsis has been shown to decrease the levels of some vitamins, such as ascorbic acid, which has been associated with the development of multiorgan failure and death. Intestinal absorption of vitamin C is saturable, so the only way to increase its levels would be by intravenous administration. Tanaka et al [28] reduced resuscitation fluid volumes in patients with burns by administering high doses of intravenous ascorbic acid. This was a randomized controlled trial of 37 patients allocated to receive a dose of 66 mg/kg/hour of vitamin C versus saline during the first 24 hours of resuscitation. Although MAP and central venous pressure were similar at the end of the vitamin C or saline infusion, fluid administration was lower in the intervention group, and patients maintained higher urine output and developed less wound edema with a significant reduction in the duration of mechanical ventilation (12 days vs 21 days; P=.03).

Zabet et al [29] investigated the effect of high doses of vitamin C on vasopressor requirements in septic shock. As ascorbic acid is required for catecholamine synthesis [30], it was investigated

XSL•FO
RenderX

whether it could be useful in shortening vasopressor weaning. A total of 24 patients with vasopressor-dependent septic shock were randomized to receive vitamin C at a dose of 25 mg/kg intravenously every 6 hours versus saline. The dose and duration of vasopressors were significantly reduced in the intervention group, as was mortality.

The most important study in septic patients was conducted by Marik et al [31], who used a combination of hydrocortisone, ascorbic acid (1.5 g every 6 hours), and thiamine (200 mg every 12 hours) in 47 patients with sepsis admitted to the intensive care unit with procalcitonin levels >2 ng/mL. The aim of thiamine was to prevent kidney oxalate accumulation. Mortality decreased in patients treated with vitamin C (P<.001). They were weaned from vasopressors earlier and received less intravenous fluid for resuscitation than the control group.

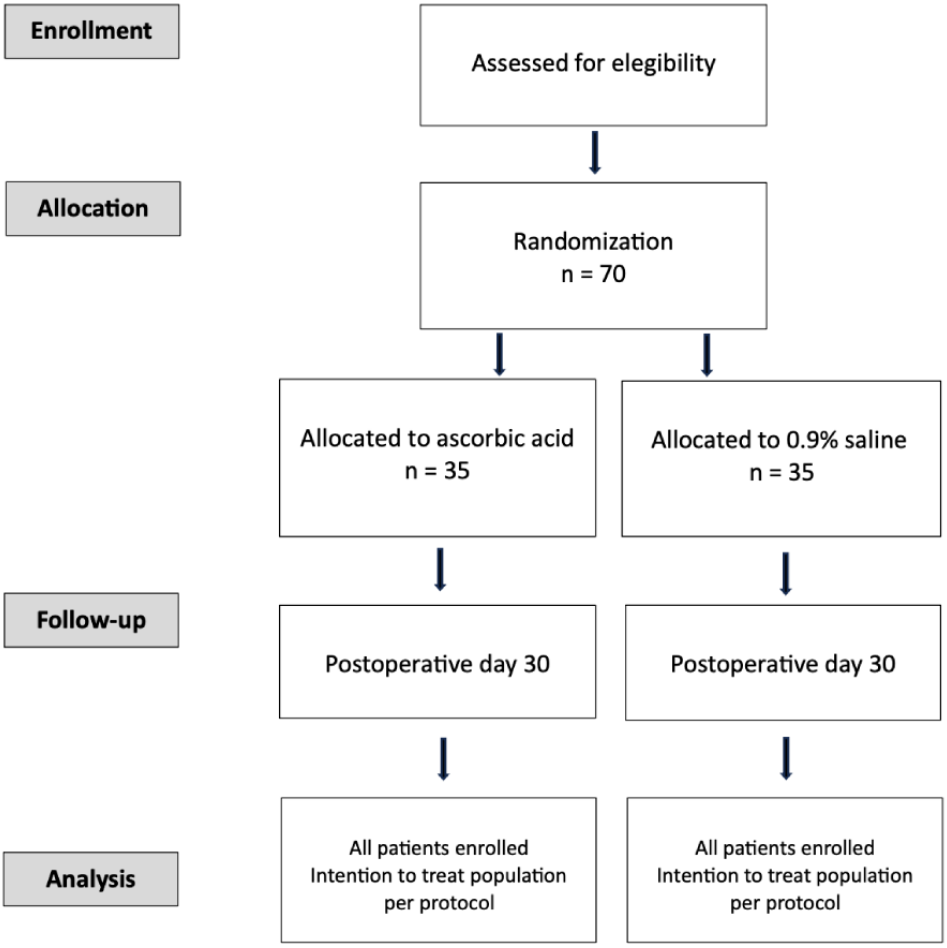
Vitamin C is safe even in very high doses. Fowler et al [32] conducted a safety study of intravenous ascorbic acid in 24 patients with severe sepsis (low dose 12.5 mg/kg every 6 hours vs high dose 50 mg/kg intravenously every 6 hours). No adverse events were observed. No adverse effects were reported in any of the above studies, including the study by Tanaka et al [28], in which the doses were very high (1.6 g/kg over 24 hours). Metabolism of vitamin C to oxalic acid could theoretically cause calcium oxalate nephropathy. However, this does not seem to be a real problem, as renal toxicity is dose-dependent and has only been reported at very high doses (>40 g/day) [33]. In addition, coadministration of thiamine would reduce the conversion of vitamin C to oxalate. In the study by Marik et al [31], the incidence of renal failure requiring renal replacement therapy was significantly lower in the intervention group (33% vs 10%; P=.02).

However, several meta-analyses have been published in recent years with mixed results. In most of them, a reduction in mortality, duration of mechanical ventilation, and hospitalization could not be demonstrated. However, a reduction in the sepsis-related organ failure assessment score and a shorter duration of treatment with vasoactive drugs is a common finding [34-38].

I/R injury plays a pivotal role in the development of graft dysfunction after liver transplantation, and excessive free radical production and massive depletion of endogenous antioxidants are common mechanisms underlying I/R injury. Ascorbic acid is an essential micronutrient involved in the antioxidant response and modulation of apoptosis and inflammation. These properties may, therefore, make it a potential strategy for reducing I/R injuries. In addition, its safety profile, low cost, and ease of administration favor its use in this scenario [39]. As discussed above, we can consider PRS as one of the clinical manifestations of I/R injury. Therefore, if we can prevent or at least attenuate I/R injury, we may be able to reduce the incidence of I/R injury.

Aim

The aim of the study is to determine the possible benefit of vitamin C in reducing the incidence of PRS in liver transplantation.



Methods

Study Setting

The trial has been designed in accordance with the updated CONSORT (Consolidated Standards of Reporting Trials), the Declaration of Helsinki, and the Good Clinical Practice guidelines issued by the Spanish regulatory authorities. The study will be conducted at a single center, the Hospital Universitario Ramon y Cajal in Madrid (Figure 1).

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.

Trial Design

This study is designed as a single-center, double-blind, randomized controlled trial. Participants will be randomized to receive ascorbic acid (intervention group) or saline (0.9%; control group). We will conduct a superiority analysis.

Eligibility Criteria for Participants

All patients over 18 years of age who are on the waiting list for liver transplantation may be eligible to participate in this study. The inclusion and exclusion criteria are detailed in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Aged between 18 and 67 years
- Waiting for a liver transplant
- Negative pregnancy test in women

Exclusion criteria

- Pregnancy
- Allergy to ascorbic acid
- Nephrolithiasis
- Glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Hyperoxaluria
- Hyperuricemia
- Haemochromatosis
- Sickle cell anemia
- Serum creatinine >1.2 mg/dL (women) and 1.3 mg/dL (men)
- Split liver graft
- Acute liver failure
- Living donor liver transplantation
- Grafts from donation after circulatory death
- Treatment with indinavir, vitamin B_{12}, cyclosporine, iron, deferoxamine, or disulfiram

Study Procedures and Intervention

The intervention group will receive a dose of 1500 mg of intravenous ascorbic acid (vitamin C) diluted in 100 mL of 0.9% saline for 30 minutes, to be administered during the anhepatic phase of liver transplantation.

The control group will receive a dose of 100 mL of 0.9% saline for the same period and under the same conditions.

Outcome Measurements

The primary end point of the study is the percentage of patients who develop PRS after liver graft reperfusion. PRS is defined as a 30% decrease in MAP within the first 5 minutes after portal-clamp release that persists for at least 1 minute.

Textbox 2 contains the secondary variables that are also analyzed.

XSL•FO
RenderX

Textbox 2. Secondary variables.

Secondary variables

- The percentage of patients with primary failure and early graft dysfunction. Primary graft failure is defined as the complete absence of liver graft function. The patient will not survive without retransplantation. In the case of early graft dysfunction, patient survival is likely and possible without retransplantation, although morbidity will be greater than in the case of normal function. The following Olthoff criteria are used for its definition (one criterion is enough):
  - Bilirubin ≥10 mg/dL on postoperative day 7.
  - International normalized ratio ≥1.6 on postoperative day 7.
  - Alanine aminotransferase or aspartate aminotransferase >2000 IU/mL in the first 7 postoperative days.
- Length of stay in the intensive care unit and hospitalization. The number of days spent in the surgical intensive care unit and the total number of days spent in the hospital.
- Dose and duration of catecholamines from the time of reperfusion.
- Length of time on mechanical ventilation (hours). Time to extubation of the patient.
- Vitamin C levels before transplantation and 12 hours after transplantation. Measurements are performed by high-pressure liquid chromatography with an ultraviolet detector.
- Levels of inflammatory markers (IL-1β, tumor necrosis factor alpha, IL-6, IL-8, and IFN-γ) before and after transplantation as measured by the high-sensitivity enzyme-linked immunosorbent assay technique.
- Development of postoperative kidney failure (acute kidney injury [AKI]) during the first week. AKI is defined as an increase in serum creatinine (SCr) ≥0.3 mg/dL within 48 hours or an increase in SCr × 1.5 times baseline; known or presumed to have occurred within the previous 7 days.
- Need for postoperative renal replacement therapy during the first week. Need for any type of renal replacement therapy during the first 7 days after transplantation, regardless of the technique used.
- Graft and patient survival 30 days after transplantation.

Participant Timeline

Patients will be monitored from randomization until day 30 post surgery. The team will collect variables daily through postoperative day 7 and a final visit on postoperative day 30. The research team will closely monitor adverse events, including onset, duration, intensity, progression, and outcome, to assess their relationship to the drug.

Sample Size Calculation

The current incidence of PRS at our center is 30%. Assuming a 50% decrease in PRS incidence (from 30% to 15%) with an α risk of 5% and a power of 80%, bilateral testing, and the Fleiss correction with a 10% loss rate, we require 268 participants (134 in each group). Due to the limited number of transplants per year in our center, achieving such a large sample will take 6-8 years. Given that this study will be conducted at a single center, the projected patient enrollment is 35 individuals per year, resulting in a final sample size of 70 participants. To attain 80% power with this sample, it is necessary to achieve a complete elimination of PRS. Although it is unlikely that such a reduction in the incidence of PRS would be achieved, we believe that this is a reasonable number of participants to show differences in the primary outcome that, although not reaching the desired statistical significance, would serve to justify a future multicenter randomized controlled trial. Participants will be randomly assigned to groups using a computer-generated sequence created by SPSS Statistics (SPSS Inc). The computer-generated sequence will allocate 35 participants to the ascorbic acid intervention group and 35 participants to the saline control group. To ensure independence, an unrelated staff member will enroll patients and prepare medication or saline upon arrival.

Analysis

Quantitative variables will be described using mean, median, SD, IQR, 95% CI, and range values. Quantitative data will be presented as absolute and relative frequencies. The significance level in any statistical test will be set at α=.05. Both groups will be assessed to ensure they are balanced in all variables.

A total of 2 populations will be established: one based on intention to treat and the other based on efficacy. The first population will consist of all participants randomized at the start and divided into 2 groups according to the corresponding randomization. The second population will consist of the participants who complete the protocol and end up in the same group in which they were randomized. All analyses will be conducted on both populations; however, the primary analysis will focus on the intention to treat the population. Statistical analyses will be performed using SPSS Statistics.

The comparison between participants who experienced PRS during the intervention will be performed using the chi-square test. Cohort proportions are compared using relative risk with 95% CIs. In a secondary analysis, we will adjust for potentially confounding factors related to the main outcome variable by using a multivariate technique. These factors include variables that showed significant differences (with $P \leq .20$) between the control and treatment groups and have been identified as potential confounds. When dealing with binary factors, we will assess the magnitude of association with odds ratios, while for ordinal or quantitative factors, we will use the Spearman correlation coefficient. A binary logistic regression analysis

XSL•FO
RenderX

will be conducted to examine the presence of PRS. The control variable (ascorbic acid vs saline) and all variables resulting from the previous univariate analysis will serve as independent variables. The same procedure will be applied to secondary efficacy and safety analyses.

Monitoring and Quality Assurance

The data collected in the study will be coded, and only the principal investigator and collaborators will be able to access this information and link it to each patient's clinical history. The information will be stored in a database that adheres to current regulations on personal data protection, including Regulation (EU) 2016/679 of the European Parliament and of the Council of April 27, 2016, on Data Protection, and the Organic Law 3/2018 of December 5, on Personal Data Protection and Guarantee of Digital Rights. Only the data included in the medical file and related to the study will be subject to verification. This verification will be carried out in the presence of the principal investigator or collaborators, who have the responsibility to protect the privacy of data within the clinical records of the participants who take part in the clinical trial.

Therefore, the identity of the participant will not be disclosed to any other person except to the health authorities, when required, or in cases of medical emergencies. The Research Ethics Committees, the representatives of the Health Authority in matters of inspection, and the personnel authorized by the sponsor will only have access to verify the personal data, the procedures of the clinical trial, and compliance with good clinical practice (always maintaining the confidentiality of the information). The principal investigator and the sponsor will keep the data collected for the study for at least 25 years after its completion. Under no circumstances will the identities of study participants be disclosed at the time of publication of the results.

Ethical Considerations

This study has been registered in the European Union Drug Regulating Authorities Clinical Trials Database (EudraCT; 2020-000123-39) and at ClinicalTrials.gov (NCT05754242). The Ethics Committee of Hospital Universitario Ramo´n y Cajal and the Spanish Medicines and Health Products Agency (Agencia Espan˜ola del Medicamento y Productos Sanitarios [AEMPS]) have both approved this study protocol (AEMPS-20-0052).

This clinical trial will adhere to the ethical principles governing biomedical research on human beings and respect their fundamental rights in accordance with international recommendations included in the Declaration of Helsinki and its latest revision of Fortaleza (Brazil, 2013). The guidelines of AEMPS will also be followed, in addition to following national recommendations.

Participants will be given both oral and written information about how the study will be conducted, its objectives, the potential risks involved, and the guidelines to be followed during the monitoring period. If a patient satisfies the inclusion criteria and agrees to participate in the study, they will provide written informed consent. They are free to withdraw their consent and discontinue the study at any point and for any reason.

Results

The enrollment process began in 2020. A total of 35 patients have been recruited so far. Data cleaning and analysis are expected to occur in the first months of 2024. Results are expected by mid-2024.

Discussion

Overview

This study aims to show if ascorbic acid could be useful in preventing PRS during liver transplantation. Improved hemodynamic stability following graft reperfusion, combined with the potential antioxidant effects of vitamin C, may lead to enhanced outcomes in liver transplantation.

The potential protective effect of adding ascorbic acid to transplant preservation solutions before transplantation has been studied with promising results. However, there has been limited research on the benefits of intravenous vitamin C administration for the prevention of I/R injury in solid organ recipients. PRS may be considered a severe clinical manifestation of I/R injury in liver transplant recipients [25,26]. Therefore, we propose that ascorbic acid's antioxidant properties may play a protective role in preventing PRS during liver transplantation.

Vitamin C acts as an antioxidant. It reduces inflammation and modulates the immune response. It also increases the synthesis and sensitivity of endogenous vasopressors, acts as an enzymatic cofactor, and has bacteriostatic and antithrombotic properties [29].

The hallmark of PRS is a depressed state of the cardiovascular system. The pathophysiological mechanisms underlying PRS are thought to involve the release of proinflammatory mediators with vasodilatory effects by both graft and recipient [20-24]. Therefore, vitamin C may have beneficial effects in the prevention and treatment of I/R injury, potentially reducing the incidence of PRS.

We are aware that studies following Marik et al's [31] publication have reduced enthusiasm for the use of vitamin C in the treatment of patients with severe sepsis. In fact, its use is no longer recommended by the Surviving Sepsis Campaign guidelines. However, recent publications, including several meta-analyses, confirm the beneficial effects of this treatment in septic patients. These effects include reducing the number of days on vasopressors and improving the sepsis-related organ failure assessment score [34-38]. We believe that the administration of ascorbic acid to patients with sepsis could potentially have a positive impact, especially considering its minimal side effects. Additional prospective clinical trials are needed to definitively establish the benefits of this treatment in this specific patient population.

Likewise, treating and preventing I/R injury in solid organ transplant recipients may be helpful, given the beneficial effects of ascorbic acid demonstrated in some of these studies in patients with sepsis.

XSL•FO
RenderX

This study is of particular importance because it is the first to evaluate the effects of administering ascorbic acid before reperfusion of the new liver graft to prevent PRS. It will also provide more information about the levels of inflammatory markers before and after reperfusion and how they change with the onset of PRS.

If the study shows positive results, the ideal dose to be used and the exact duration of treatment should be defined and could be applied to other types of solid organ transplantation.

This study aims to address the current gap in knowledge regarding the clinical effectiveness of administering vitamin C during solid organ transplantation, particularly in liver transplantation. We will provide valuable insights into this area of research through rigorous data analysis.

Strength and Limitation of the Study

The main limitation of the study, due to the limited number of participants planned, is that it may not achieve adequate statistical power to establish with sufficient scientific evidence whether vitamin C reduces the PRS and improves the results of LT. However, we believe that if positive results in favor of vitamin C are obtained, the trial would serve as the basis for a larger trial involving other transplant centers, which would allow us to demonstrate the benefit of vitamin C with enough statistical power. It is possible that we may not be able to control for additional variables that may bias the results, including those related to the surgical and anesthesia teams. A forthcoming multicenter trial could address this issue.

Acknowledgments

The authors would like to acknowledge that the researchers and collaborators in this study have not received any financial compensation. Any economic aspects related to the clinical trial are outlined in a contract between the Biomedical Research Foundation of Ramo´n y Cajal University Hospital (Instituto Ramo´n y Cajal de Investigacio´n Sanitaria [IRYCIS]) and the promoter of the study.

Data Availability

The data sets used or examined in this study will be accessible from the corresponding author upon request.

Authors' Contributions

LG, IdlH, and ME designed the study. LG, IdlH, MdCMG, JNV, and MARG performed the literature search. IdlH, LG, MdCMG, AMG, DPR, JV, and CFM recorded the data. LG and IdlH were the major contributors to writing this manuscript. All the authors participated in the design of the study and read, commented upon, and approved the final manuscript.

Abstract

Background: Stroke is a significant public health concern that causes severe and long-lasting disability. The recurrence of stroke is increasing due to lack of patients' knowledge and compliance with treatment to control modifiable risk factors and lifestyle changes. Health education can be an effective way to increase knowledge about behavioral changes in patients who had a stroke.

Objective: The aim of this study is to evaluate the effectiveness of a health education program in Bangladesh for patients who had their first stroke and their family caregivers in order to reduce the recurrence of stroke by controlling modifiable risk factors.

Methods: This is a parallel, open-label, prospective randomized controlled trial conducted at the National Institute of Neurosciences & Hospital in Dhaka, Bangladesh. We enrolled ≥18-year-old patients of both sexes who had a history of first stroke attack (transient ischemic attack, hemorrhagic stroke, lacunar stroke, atherothrombotic stroke, or cardioembolic stroke). We stratified patients into those aged <65 years and those aged ≥65 years and according to types of strokes for randomization. Our estimated sample size was 432. The intervention group receives face-to-face counseling on lifestyle modifications, blood pressure monitoring, and medication compliance–related health education during enrollment and monthly follow-ups. However, the control group receives only usual care from the hospital. The primary end point of this study is the reduction in the stroke recurrence rates at the end of the 12-month follow-up period. The secondary end points are to (1) assess the occurrence of all adverse events such as other cardiac events and all-cause mortality, (2) evaluate the status of the controlling modifiable risk factors such as blood pressure, glycated hemoglobin, and non–high-density lipoprotein cholesterol, (3) assess the knowledge related to stroke by using the investigator-developed questionnaire, (4) evaluate the lifestyle behavior related to stroke by using the investigator-developed questionnaire, (5) assess medication adherence, and (6) evaluate the quality of life of patients who had a stroke and their family caregivers. The evaluation points will be at baseline, 6 months, and 12 months for both groups.

Results: Patients' enrollment started on October 2022, and follow-up will be completed in March 2024. A total of 432 participants were included in both the intervention (n=216) and control groups (n=216). This study was approved by the institutional review board and the ethics review board of the National Institute of Neurosciences & Hospital (IRB/NINSH/2022/151) on August 30, 2022.

XSL•FO
RenderX

Conclusions: Our health education program is expected to reduce the recurrence of stroke and improve the quality of life of patients who have had the first stroke. The results of this study will provide insights into the importance of health education for (self)-management and prevention of stroke.

Introduction

Background

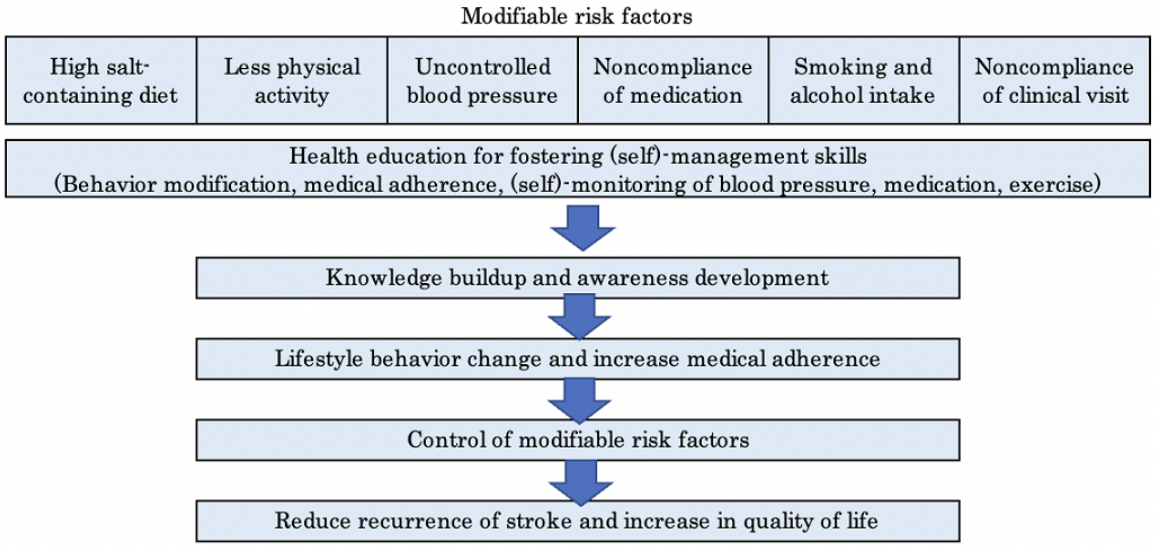
Stroke is a major global health concern, ranked as the second highest cause of death in 2019 [1], with an estimate of 93.2-110.5 million people affected worldwide [2]. This debilitating condition causes long-term physical, mental, and social disability, leading to financial difficulties for patients and their families [2,3]. People are affected by stroke in both low-income and high-income countries, and most cases have been reported in older age groups [4,5], although it has also been reported in younger individuals, especially in low-income countries [6]. In 2019, the burden of stroke increased from 70% to 85% between 1990 and 2019, and the mortality rates rose by 43% during this period. Among them, 62.4% experienced an ischemic stroke, 27.9% had an intracerebral hemorrhage, and 9.7% had subarachnoid hemorrhage, with corresponding mortality rates of 4%, 0.36%, and 0.36%, respectively, resulting in a total death rate of 6% [2]. A meta-analysis of 26 studies from 1997 to 2019 found stroke recurrence rates ranging from 5.7% to 51.3% over 1-10 years, with a 1-year recurrence rate of 5.7%-17.7% [7]. The first 3 months following the initial attack are the most critical for recurrence [8]. Moreover, the meta-analysis indicated that factors such as diabetes mellitus, smoking status, peripheral artery disease, hypercoagulable state, depression, 24-hour minimum systolic blood pressure (BP), 24-hour maximum diastolic BP, age, family history of stroke, National Institutes of Health Stroke Scale score status, hypertension, and history of cardiac disease were found to influence the recurrence of stroke [9,10].

In Bangladesh, stroke is the topmost cause of death, accounting for 82.31 deaths per 100,000 people in 2019 across all age groups and genders [11], with prevalence of approximately 11.39 cases per 1000 people [4]. Among them, 79.7% experienced ischemic stroke, 15.7% had hemorrhagic stroke, and 4.6% were diagnosed with subarachnoid hemorrhage [4]. A hospital-based study in Bangladesh reported cumulative recurrence rates of 14.7% at 3 months, 15.3% at 6 months, 17.3% at 9 months, and 20% at 1 year, predominantly in individuals older than 75 years [8]. Male patients with hypertension, diabetes, and dyslipidemia had a higher risk of recurrence compared to females. Additional risk factors included hypertension (79.2%), dyslipidemia (38.9%), tobacco use and smoking (37.2%), diabetes (28.8%), ischemic heart disease (20.1%), atrial fibrillation (13.9%), and obesity (9.7%) [4].

Secondary preventive measures must be implemented that address comorbidities such as hypertension and diabetes through lifestyle modifications, surgical interventions, and pharmacological interventions to reduce the recurrence of stroke [12]. Health education interventions can effectively enhance knowledge, raise awareness, modify lifestyle behaviors, and control modifiable risk factors, ultimately improving the quality of life (QoL). A study demonstrated that a 6-month health education program reduced stroke recurrence rate by 50% at 30-month follow-up [13]. Furthermore, regular postdischarge checkups and early follow-ups are necessary to prevent complications and further recurrence. Many countries worldwide have implemented stroke prevention efforts [14]. A randomized controlled study showed that both face-to-face and telehealth education programs resulted in significant improvements in health behaviors related to physical activity, nutrition, low-salt diets, and medication adherence. Additionally, the intervention group exhibited decreased systolic BP and cholesterol levels [15,16]. Another similar study using a randomized controlled design found that a web-based stroke education program led to significant increases in exercise, reduced consumption of salty foods, increased intake of fruits and vegetables, enhanced sense of control, improved health motivation, and improved caregiver mastery. However, all these interventions did not result in significant reduction of stroke recurrence [17]. In Bangladesh, a significant challenge for patients who have had a stroke is the absence of a follow-up system after hospital discharge and lack of patient and family education during hospital stay or in postdischarge or primary care settings. As a result, low medication compliance and poor risk factor control have been reported among patients who have had a stroke in Bangladesh [18].

Study Objectives

The objective of this study is to evaluate the effectiveness of a health education program for patients who had their first stroke (transient ischemic attack, hemorrhagic stroke, lacunar stroke, atherothrombotic stroke, or cardioembolic stroke) and their family caregivers in order to reduce the recurrence of stroke.



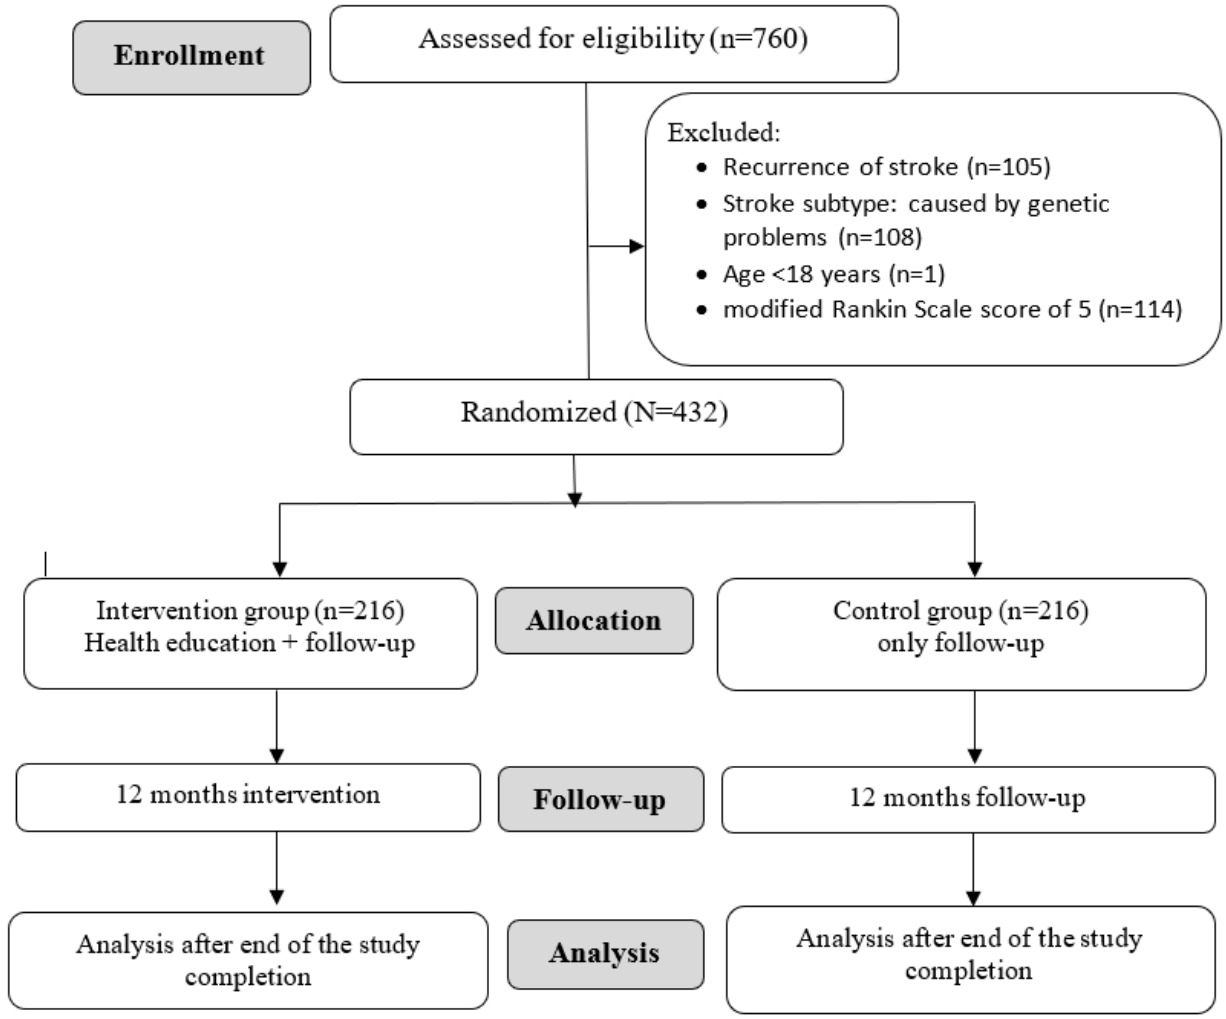
Study Framework and Hypothesis

In Bangladesh, lack of patient and family education during and after hospital discharge has led to poor follow-up, including low compliance with clinical visits, medications, and lifestyle changes, resulting in negative outcomes [18]. From the nursing perspective, this study aims to reduce recurrence by fostering (self)-management skills through health education on modifiable

XSL•FO
RenderX

risk factors of stroke. After patients or caregivers acquire knowledge and are aware the importance of health care management, their lifestyle behaviors can be changed. (Self)-monitoring of BP, medications, and clinical visits will enhance adherence to treatment and consequently control for the risk factors, increase QoL, and reduce stroke recurrence. Therefore, we hypothesized that health education of patients who had their first stroke and their family caregivers could reduce the stroke recurrence rate by controlling the modifiable risk factors compared to patients who did not receive health education. Health education during the hospital stay of patients who had a stroke and their continuous care after discharge are essential. Therefore, we developed a conceptual framework (Figure 1) to illustrate the factors that influence the recurrence of stroke, and we conducted postdischarge education for patients and families to prevent the recurrence of stroke for the first time in Bangladesh. The American Heart Association and Canadian guidelines recommended healthy lifestyle and management of vascular risk factors for the secondary prevention of stroke [19,20]. Meta-analyses of randomized controlled trials on intensive control of systolic BP [21,22] and improved antiplatelet therapy [23] reported significant reduction in the recurrence of stroke. Lifestyle-related behaviors such as diet, physical activity, and smoking contribute to vascular risk factors of stroke; however, there is knowledge gap on if modifying these behaviors significantly reduce stroke recurrence in stroke survivors [19]. Moreover, there is evidence that positive lifestyle change in intervention studies focused on improving recurrence prevention behaviors [17], but it is not established if lifestyle changes can reduce stroke recurrence. Patients' medication adherence can be improved by providing information regarding the advantage of taking treatments, reminders, and (self)-monitoring [24]. Moreover, the (self)-management behavior of patients who had a stroke improved their self-efficacy, disease outcome, QoL, and self-satisfaction that could improve stroke recurrence [25]. It also increased patients' self-confidence and well-being [26].

Figure 1. Conceptual framwork.



To enhance the knowledge and awareness of modifiable risk factors, we provided health education on various topics: (1) diet (reducing salt intake, maintaining a balanced diet, and managing weight) (Multimedia Appendix 1), (2) physical activity (increasing exercise or rehabilitation if patients are bedridden) (Multimedia Appendix 2), (3) smoking cessation and reducing alcohol consumption (Multimedia Appendix 3), (4) medication compliance and regular clinical visits (Multimedia Appendix 4), and (5) (self)-monitoring of BP (caregivers monitor BP if patients are unable to do so themselves) (Multimedia Appendix 5). Additionally, patients are educated about the importance of taking medication as prescribed and recognizing stroke symptoms. In Bangladesh, where the illiteracy rate is still high [27], the investigators developed an easy-to-understand study book named "Preventing Recurrence of Stroke: Friendly Health Education Booklet," featuring illustrations and photos tailored to Bangladeshi culture and lifestyle. Based on the study book, videos were produced to ensure that even illiterate patients and caregivers could understand the content and watch them repeatedly. Furthermore, a 45-minute hands-on training session is provided for better comprehension. To ensure adherence to these (self)-management activities, the investigators provide patients with a digital BP machine, a salt-measuring spoon, and a medication box that divides the medicines for 1 week into morning, afternoon, evening, and bedtime doses. These tools are accompanied by a health education booklet and video, as well as a (self)-monitoring notebook for patients to utilize at home. The (self)-monitoring notebook is designed for patients or family caregivers to record daily monitoring data, including medication, BP readings, and any notable observations for a duration of 12 months. Nurses regularly contact patients to ensure they are measuring and recording data correctly, explaining how to interpret BP readings and their implications. The investigators recognize the critical importance of daily (self)-monitoring of BP to promote awareness of the patients' condition and foster a sense of (self)-management. In Bangladesh, where the practice of measuring BP at home or even in hospitals is rare, investigators teach patients and

XSL•FO
RenderX

caregivers how to measure BP, which is a new concept for the population who have never measured their BP levels before [28]. Another significant aspect is monitoring salt intake. The average daily salt consumption among Bangladeshi people ranges between 15 g/day and 21 g/day [29]. Due to the scarcity of processed and packaged foods in Bangladesh, where salt is the main seasoning, the concept of "measuring salt" is uncommon. Education on low-salt diets is virtually nonexistent in the country. Hence, it is crucial to teach individuals to comprehend and visualize "5 g of salt" by using a measuring spoon. Additionally, physical activities will be taught by a physical therapist.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) chart.

Methods

Study Design

This is an ongoing 12-month intervention study. This study follows a parallel (1:1), open-label, prospective, randomized controlled trial design, and adheres to the CONSORT (Consolidated Standards of Reporting Trials) guidelines [30]. The study flowchart is depicted in Figure 2. This study commenced in October 2022 and is expected to conclude in March 2024, with a total duration of 18 months. This trial is registered as ClinicalTrials.gov NCT05520034.

Study Site, Population, and Sample

This study was conducted at the National Institute of Neurosciences & Hospital (NINS&H) in Dhaka, Bangladesh. NINS&H is a state-run tertiary care hospital in Bangladesh that treats patients with neurological disorders. The inclusion criteria for enrollment encompassed individuals who experienced their first stroke attack, regardless of whether it was the ischemic or hemorrhagic subtype. In Bangladesh, ischemic stroke accounts for over three-quarters of cases [4], and health education can be effective for patients with ischemic stroke classified as modified Rankin Scale (mRS) scores 0-2. For hemorrhagic stroke, considering the impact of self-management, patients with an mRS score below 3 were included. However, in the context of Bangladesh, family caregivers often provide care, and if family education is considered, patients with an mRS score of 4 were also included. Additionally, we included patients who have an mRS score of 0-4, were 18 years of age or older, and of any gender. Moreover, due to the limited availability of emergency hospital beds in Bangladesh, patients with an mRS score of 0-2, particularly those with lacunar infarcts, are often treated as outpatients. Hence, we included outpatient care in

XSL•FO
RenderX

our study. In cases where patients were unable to care for themselves and relied on the support of family caregivers, consent was obtained from the caregivers. Primary caregivers, regardless of gender, who were 18 years of age or older, and resided with the patients were recruited. The exclusion criteria consisted of patients with a history of stroke recurrence, stroke caused by genetic factors or injury or accident, multiorgan failure, terminal illness, or previous participation in other clinical trials. Patients with an mRS score of 5, indicating severe disability requiring constant nursing care, were excluded [31]. In such cases, health education and follow-up may not have a significant impact. Additionally, individuals younger than 18 years, mentally unstable, cognitively impaired (diagnosed cases), and family caregivers who did not reside with their patients were also excluded from this study. When patients were admitted as inpatients or visited the outpatient department of the hospital, investigators and the research assistant (RA) nurses reviewed the participants' admission or visiting files, including their current medications. Subsequently, the RA nurses visited the inpatient wards and brought the outpatients to a designated research room within the hospital.

Patient Enrollment

A total of 760 patients were screened, and among them, 432 patients were enrolled. We randomly allocated 216 patients to the intervention group and 216 patients to the control group. After completion of 12 months follow-up, we will analyze the data.

Randomization Schedule

A randomization schedule was used following the stratified randomization technique on a computer-generated series of numbers. On the basis of studies conducted in China [32,33], we stratified the patients into <65 years group and ≥65 years group, as the study site had no statistics about the age of the patients with recurrent stroke and types of strokes (hemorrhagic stroke, large artery atherosclerosis, cardioembolic, small vessel occlusion, lacunar, transient ischemic attack) because recurrence rates differed by the stroke type [6]. An experienced investigator who was not involved in this study generated the random allocation number by sequences. She distributed them in sealed opaque envelopes with serial numbers, which were kept in locked file cabinets in the hospital.

Study Procedure

Enrollment occurred over a span of 6 consecutive days during morning hours, excluding government holidays, within a week. After determining eligibility and obtaining consent, the RA nurses opened the sealed randomization envelope in the presence of the participants. They collected demographic information, conducted physical examinations, and filled up questionnaires (Table 1).

Table 1. Study activities.

Schedule	Intervention group	Control group
At baseline	• Data collection by RA[a] nurses through structured questionnaires • RA nurses provide knowledge-related health education before discharge or after the hospital visit: health education (face-to-face, 45 min) by RA nurse and exercise session by the physiotherapist • RA nurses perform physical examination: BP[b] level (systolic and diastolic) • Blood tests: HbA_{1c}[c], total cholesterol, and HDL cholesterol (calculate non-HDL cholesterol)	• Data collection by RA nurses through structured questionnaires • Provide usual practice • RA nurses perform physical examination: BP level (systolic and diastolic) • Blood tests: HbA_{1c}, total cholesterol, and HDL[d]-cholesterol (calculate non-HDL cholesterol)
Middle of study (6 months)	• Data collection by RA nurses through structured questionnaires • RA nurses provide refresher health education same as baseline • RA nurses perform physical examination: BP level (systolic and diastolic) • Blood tests: HbA_{1c}, total cholesterol, and HDL cholesterol (calculate non-HDL cholesterol)	• Data collection by RA nurses through structured questionnaires • Provide usual practice • RA nurses perform physical examination: BP level (systolic and diastolic) • Blood tests: HbA_{1c}, total cholesterol, and HDL cholesterol (calculate non-HDL cholesterol)
End of study (12 months)	• Data will be collected by RA nurses through structured questionnaires • RA nurses will perform physical examination: BP level (systolic and diastolic) • Laboratory tests: HbA_{1c}, total cholesterol, and HDL cholesterol (calculate non-HDL cholesterol)	• Data will be collected by RA nurses through structured questionnaires • RA nurses will provide health education at the end of the study, and a health education booklet will be given to them • RA nurses will perform physical examination: BP value (systolic and diastolic) • Laboratory tests: HbA_{1c}, total cholesterol, and HDL cholesterol (calculate non-HDL cholesterol)

[a]RA: research assistant.

Intervention Group Study Plan

After obtaining informed consent and baseline data, RA nurses provide health education through a booklet to patients and family caregivers and give them the booklet to follow the instructions at home. Subsequently, a video containing the risk factors of stroke and their management and prevention is shown to the patients and family caregivers. Health education sessions on booklet contents take around 20 minutes, and video show sessions take around 15 minutes. We provide these health education sessions 2 times after enrollment of the patients and 6 months after the follow-up visit in the hospital. Health education booklets guide patients on how to read food labels accurately for the prevention of stroke-related risk factors. Booklets have a reminder for the schedule date of the next clinic visits. There is also a notebook for recording daily health monitoring charts such as BP, exercise, and medication intake by the patients or caregivers. The video presentation includes simulation training on essential tasks such as how to measure BP and organize the medication boxes prescribed by physicians. We recommended placing the medications in our provided medication boxes to increase the adherence to doctors' guidelines for consumption and using salt-measuring spoons. After that, an assigned physiotherapist provides about 15-minute exercise orientation sessions to show how to do physical exercises at home. A repeated session is conducted by the physicians and RA nurses at 6-month follow-ups for their memorization. RA nurses provide motivational SMS texts every month to the patients and caregivers to remind patients to measure their daily BP, reduce salt intake, avoid oily and fatty foods, consume more fruits and vegetables, exercise regularly, and adhere to their medication regimen. Additionally, RA nurses provide refresher health education twice a month in the first 3 months and then monthly in the next 9 months over a phone call to obtain information about the health condition of the patients and document in the questionnaires. Patients receive a reminder phone call on the fifth month to visit the hospital for the sixth month follow-up visit. At the 6-month follow-up visit (middle of study), if the patient and family caregiver are not able to come for any reason, RA nurses collect data and provide refresher health education over a phone call (Figure 3).

Figure 3. Follow-up and evaluation timeline (months) of the intervention and control groups.

Control Group Study Plan

The control group participants receive a monthly telephone call for 1 year from RA nurses solely to gather information about the patients' health conditions and document the information in the questionnaires. At the fifth month, patients are reminded to visit the hospital for their sixth month follow-up visit (Figure 3). To mitigate the disadvantage faced by participants in the control group, after completing the study at the end point, they will be given the same health education booklet. If requested by the participants, a brief health education session will be provided based on the information contained in the booklet for their easy understanding.

Outcomes and Data Collection Procedure

Primary Outcome

The primary end point is the recurrence rate of stroke at 12 months.

Secondary Outcomes

The secondary outcomes are (1) all adverse events (stroke and other events), (2) changes in the values of modifiable risk factors of BP, glycated hemoglobin, non–high-density lipoprotein cholesterol, and (3) changes in the scores of knowledge related to stroke in the investigator-developed questionnaire (this questionnaire consists of 10 items with "no/wrong answer," "yes/correct answer," and "don't know" answers; the score ranges from 0 to 20, and a higher score indicates having better knowledge), (4) changes in scores in lifestyle behavior related to stroke in the investigator-developed questionnaire (this questionnaire consists of 14 items with a Likert scale to assess the frequency of behavioral changes; the score ranges from 0 to 37, and a higher score indicates having better lifestyle behavior), (5) changes in behavior in medication adherence by using Morisky Green Levine Medication Adherence Scale [34] (this questionnaire consists of 4 items with "yes=0" and "no=1" answers; the score ranges from 0 to 4, and a higher score indicates better compliance), and (6) changes in scores of QoL by using the QoL questionnaire (WHOQoL-BREF Bangla version [35]; each item scores from 1 [very poor or very dissatisfied] to 5 [very good or very satisfied] and ranges [mean of 2 items] from 1 to 5—a higher mean indicates a better QoL).

Operational Definitions for This Study

Recurrence of Stroke

Recurrent stroke is defined as a new stroke event occurring at least 28 days after the stroke incident [32], which is confirmed by the physician who treats and diagnoses the patients in this study.

Adverse Events

All adverse events (all causes of death, cardiovascular events) refer to all cases that need to be diagnosed, for example, recurrence of stroke, new onset of acute myocardial infarction

XSL•FO
RenderX

and unstable angina, heart failure with hospitalization, and peripheral arterial disease with hospitalization—those that are confirmed by the physician who treats and diagnoses the patients in this study.

Sample Size

Stroke recurrence rate in Bangladesh was 20% within 1 year in 2019 [8]. A study that evaluated the effectiveness of health education in preventing the recurrence of stroke showed 50% reduction among the intervention group compared to the control group [13]. The expected proportion of outcomes from the intervention group was assumed as P1=0.10; P2 (proportion of outcome from control group)=0.20; α=.05 (2-tailed), 1-β=.80; Z1-α/2=Z, α=1.96; and Z1-β=Z, β=.84. We found that the estimated sample size was 196 for each arm (a total 392 for both arms). By considering 10% dropout, the total sample size was 432 (216 for each arm).

Study Preparation

Training of RA Nurses

Five RA nurses were recruited from NINS&H and another tertiary hospital, and 5 student nurses were recruited from 2 nursing schools for this study. Investigators provided protocol-specific theoretical and practical training to all RA nurses before the study initiation. They received training on physical measurements and were taught the motivational interviewing technique [36] to effectively encourage patients who had a stroke to adhere to instructions. We trained them how to educate patients to maintain daily activities and to send SMS text messages. Throughout the study, the RA nurses have been receiving monthly feedback sessions on the participants' health education materials.

Data Monitoring and Quality Assurance

The investigators (medical doctors) are directly involved in patient management. The investigators and the RA nurses have regular biweekly meetings for study purpose. Pretesting of the questionnaires was done among the patients (5% of the sample of 432) who did not participate in the main study. Additionally, for regular quality control purpose, investigators independently check 5% of the study participants' data on the same day by using field testing. The investigators check the process of taking consent, data collection, and physical examination by the RA nurses. The detected errors are corrected immediately at the field site. For any query, RA nurses consult with the investigators. RA nurses fill up the questionnaires and enter the data into a password-protected computer. Investigators check the data and resolve the queries.

Ethics Approval

This study was approved by the institutional review board and the ethics review board of the NINS&H (IRB/NINSH/2022/151). All participants were explicitly informed about the study goals, significance, risks, and benefits, and their rights to participate in the study prior to the requirement. To participate in this study was entirely voluntary, and participants can withdraw at any point from their participation.

Statistical Analysis

To compare the outcomes of the intervention group and the control group, we will conduct an intention-to-treat analysis and a full set analysis. A chi-square test will be performed for categorical data, and a 2-sided *t* test or Mann-Whitney *U* test will be employed for continuous variables, as appropriate, to compare the 2 groups. For the primary end point, the cumulative risk of recurrence and adverse events occurring in 12 months will be estimated using the Kaplan-Meier method and presented overall by age group and by stroke subtypes. For the secondary end points, an analysis of covariance will be conducted to assess the effect of the intervention on the outcomes by adjusting confounding variables. Changes in outcomes over time will be analyzed using repeated-measures analysis of variance as well as regression analysis. Friedman test will be performed to examine the changes within the groups. Associations between risk factors and outcomes will be tested using Cox proportional hazards models, adjusting for all baseline factors. Additionally, laboratory test and physical examination data will be analyzed using 2-sided *t* tests or 2-way repeated-measures analysis of variance, considering data normality. For the knowledge-related questionnaire, medication adherence–related questionnaire, and QoL, reliability checking will be performed, and total scores will be calculated. The significance level will be set at .05. Data analysis will be conducted using SPSS (version 26.0; IBM Corp).

Results

The enrollment of the participants was completed in February 2023, and the study follow-up and data collection will continue until February 2024. A total of 432 participants agreed to participate in this study, with 216 allocated to the intervention group and 216 to the control group. Data cleaning and analysis are expected to be completed in May 2024.

Discussion

Overview

This study describes the protocol for a randomized controlled trial that aims to develop awareness, enhance knowledge, and make behavioral changes through face-to-face health education and phone calls among individuals who had their first stroke and were discharged from hospitals admitted from different regions of Bangladesh. To the best of our knowledge, this is the first research study conducted in Bangladesh to measure the effectiveness of health education and monthly follow-ups over mobile phone in reducing the recurrence of stroke. One of the most significant barriers to the effective treatment of stroke is the lack of awareness and education about modifiable risk factors, its complications, and the optimal way to treat stroke, which can be addressed by providing health education and monthly follow-ups over mobile phone for knowledge generation. Further, creating an awareness and employing behavior change communications among patients with stroke can reduce the recurrence of stroke and increase their QoL. Although stroke management is a significant burden on health practitioners in low-resource settings, RA nurses can be an important and underutilized resource for patient education. RA

XSL•FO
RenderX

nurses have been shown to be effective in assisting people in improving their health habits. An RA nurse intervention among patients with modifiable risk factors such as hypertension and diabetes can increase patients' awareness and help them control their BP and blood glucose levels. Monthly follow-ups as well as health education show a lot of potential in raising patient awareness and understanding of stroke disease as well as improving stroke knowledge.

Strengths

We implemented various strategies to empower patients and caregivers, including training on BP measurement, medication box usage, salt intake measurement using spoons, and health education booklets. Self-monitoring of BP is facilitated by providing patients with a BP machine for daily measurements, which is generally not practiced in Bangladesh. Medication compliance is assessed using medication boxes, and accurate salt intake measurement will be facilitated by providing salt-measuring spoons. Most of the participants are not aware of the benefits of regular medication and low salt intake. Health education materials such as booklets and videos in Bengali are tailored to accommodate both literate and illiterate patients and their caregivers. Participants and even health care providers had no understanding to date about the advantage of health education in the health care system in Bangladesh. NINS&H is the only referral hospital in Bangladesh that patients attend from all over the country. Thus, our study findings can be generalized to all the patients who had a stroke in Bangladesh.

Limitations

Our study has certain limitations. Although we provide education to the patients and their caregivers for their disease (self)-management at home, the level of education and understanding of each patient and his or her caregiver about the importance of monitoring risk factors would be different. This might influence the study outcomes. There will be heterogeneity at baseline in the level of illness, including level of consciousness, among patients with different subtypes of stroke. This could be a cause of outcome bias.

Conclusions

Stroke recurrence can be caused by different modifiable risk factors. Thus, early detection and management of these risk factors are crucial for preventing subsequent stroke recurrences and for lowering morbidity and death. If our results show an enhancement in the study outcomes among patients with stroke (mRS score 0-4), health education can be integrated with monthly follow-ups as an effective tool for preventing stroke recurrence at the national level in Bangladesh. Further, we can improve patient knowledge and motivate patients with stroke regarding their health care practices to improve their QoL. If this health education program results in significant improvements in the QoL of patients who have had a stroke, then this program can be introduced and implemented in the health care system of Bangladesh.

Acknowledgments

We would like to express our sincere gratitude to the study participants for their generous support. We extend our thanks to the National Institute of Neurosciences & Hospital, specially Professors Dr Quazi Deen Mohammad, Dr Md Badrul Alam Mondal, and Dr MS Jahirul Haque Chowdhury for their tremendous support as well as the research assistant nurses and laboratory staff for their unwavering assistance. We thank the following clinical investigation team members. Mohammad Habibur Rahman Sarker, MBBS, MPH, PhD, from International Centre for Diarrheal Disease Research served as a Clinical Investigator. Md Moniruzzaman, MBBS, FCPS, and SK Jakaria Been Sayed, MBBS, FCPS, MRCP, from National Institute of Neurosciences & Hospital, Dhaka served as clinical physicians. The following people served as the clinical head nurse or clinical nurse or research assistant nurses or student nurses in this study: Israt Jahan Eti, RN, MPH, Naznin Nahar, RN, MPH, Shorifunnahar, RN, Shika Parven, RN, MPH, and Tarana Manju Joya, RN, MPH, from National Institute of Neurosciences & Hospital, Dhaka, Bangladesh; Salma Akhter, RN, MSN, and Sipra Mondal, RN, MPH, from Dhaka Medical College Hospital, Dhaka; Israt Jahan Rima, RN, Shakil Ahmed, RN, Md Kayes Azad Polok, Raisha Islam, Mostarina Shopna, Pronoy Bonik, and Suraiya Akter from Rufaida College of Nursing, Dhaka, Bangladesh; and Gita Roy, RN, MSS, from the 250-bed TB Hospital, Shyamoli, Dhaka, Bangladesh.

Abstract

Background: Alcohol use disorder (AUD) is characterized by problematic alcohol use accompanied by clinically substantial distress. Patients with AUD frequently experience high relapse rates, and only 1 in 5 remain abstinent 12 months post treatment. Traditional face-to-face relapse prevention therapy (RPT) is a form of cognitive behavioral therapy (CBT) that examines one's situational triggers, maladaptive thought processes, self-efficacy, and motivation. However, access to this treatment is frequently limited due to its high cost, long waitlists, and inaccessibility. A web-based adaptation of RPT (e-RPT) could address these limitations by providing a more cost-effective and accessible delivery method for mental health care in this population.

Objective: This study protocol aims to establish the first academic e-RPT program to address AUD in the general population. The primary objective of this study is to compare the efficacy of e-RPT to face-to-face RPT in decreasing relapse rates. The secondary objective is to assess the effects of e-RPT on quality of life, self-efficacy, resilience, and depressive symptomatology. The tertiary objective is to evaluate the cost-effectiveness of e-RPT compared to face-to-face RPT.

Methods: Adult participants (n=60) with a confirmed diagnosis of AUD will be randomly assigned to receive 10 sessions of e-RPT or face-to-face RPT. e-RPT will consist of 10 predesigned modules and homework with asynchronous, personalized feedback from a therapist. Face-to-face RPT will comprise 10 one-hour face-to-face sessions with a therapist. The predesigned modules and the face-to-face sessions will present the same content and structure. Self-efficacy, resilience, depressive symptomatology, and alcohol consumption will be measured through various questionnaires at baseline, amid treatment, and at the end of treatment.

Results: Participant recruitment is expected to begin in October 2022 through targeted advertisements and physician referrals. Completed data collection and analysis are expected to conclude by October 2023. Outcome data will be assessed using linear and binomial regression (for continuous and categorical outcomes, respectively). Qualitative data will be analyzed using thematic analysis methods.

Conclusions: This study will be the first to examine the effectiveness of e-RPT compared to face-to-face RPT. It is posited that web-based care can present benefits in terms of accessibility and affordability compared to traditional face-to-face psychotherapy.

Introduction

Alcohol use disorder (AUD) is a mental health disorder that affects approximately 3.6% of the global population aged 15 to 64 years [1]. The disorder is highly prevalent and a major contributor to illness and mortality worldwide [2,3]. AUD is characterized by impaired control over alcohol use, leading to physiological dependence and negative psychological, social, and physical consequences [3,4]. The disorder is associated with many physical and psychiatric comorbidities, such as major depressive disorder, generalized anxiety disorder, liver cancer, and hypertension [2,5-7].

The rise in mental health challenges during the COVID-19 pandemic resulted in growing concerns over the health behaviors of individuals with AUD [8]. Stay-at-home orders presented complex relationships between financial issues, low social interaction, and anxiety about the future [9]. Moreover, the disruption to clinical services is believed to have contributed to increased relapse and subsequent negative health outcomes for people with AUD [10]. Kim et al [11] demonstrated that out of 182 participants with previous AUD, 23% increased their consumption during the lockdown. Additionally, 17% of the subjects abstained for an average of 19.5 months before relapsing during lockdown [11].

AUD treatments typically involve abstinence from alcohol due to the high failure rates and risks associated with controlled drinking approaches [12,13]. However, AUD is known as a "relapsing condition," since patients often relapse following abstinence [14]. Within the AUD framework, a lapse is defined as a single episode of drinking, whereas a relapse involves a return to a pattern of problematic drinking [15]. Stillman et al [16] found that relapse rates in people with AUD are approximately 60% to 80% after 3 months of treatment and 70% to 80% after 12 months post treatment. These rates highlight the importance of integrating relapse prevention into AUD treatment programs. These programs identify personal factors that contribute to relapse and offer helpful strategies to improve coping with cravings, and mood fluctuations, and identify triggers to decrease the rate and severity of relapses [17].

Psychosocial interventions are commonly used to treat AUD, with cognitive behavioral therapy (CBT) being one of the most studied psychological approaches [18,19]. CBT for AUD encourages abstinence in the presence of triggers and cravings by targeting maladaptive thought processes and behaviors [20,21]. This therapeutic approach has demonstrated greater efficacy compared to no treatment or minimal treatment [22]. Relapse prevention therapy (RPT) is a validated CBT treatment for AUD that targets both interpersonal and intrapersonal factors such as motivation and trigger identification. RPT also equips patients with coping strategies to use in situations where alcohol may be available [23-25]. The efficacy of RPT can vary depending on the substance used, personal factors such as income, and comorbid disorders [26,27]. However, despite the effectiveness of this type of therapy, financial issues, accessibility problems, and logistical problems may make it challenging for individuals to receive face-to-face care [28]. Moreover, individuals with AUD frequently experience shame and stigma surrounding their diagnosis, which can reduce treatment seeking in this population [29].

To address some of the issues of accessibility and availability, web-based adaptations of traditional face-to-face psychotherapy, such as internet-based CBT (e-CBT) have flourished in recent years. Web-based psychotherapy offers several advantages, such as not requiring office space, placing lower demands on therapists' time, improving accessibility, etc [30]. Although the literature has shown comparable effectiveness between web-based psychotherapy and face-to-face psychotherapy in the management of AUD [31], and face-to-face RPT has demonstrated beneficial effects in relapse prevention [12,24], web-based RPT (e-RPT) remains an understudied option for the management of AUD [32].

Therefore, this study proposes the development, study, and implementation of an e-RPT program for the management of AUD. The proposed program could be a viable solution to address the potential accessibility, stigma, and financial issues presented by traditional in-person therapies [32]. Thus, the primary objective of this study is to compare the efficacy of a secure e-RPT program to face-to-face RPT to decrease relapse rates in patients with AUD. Based on the evidence comparing face-to-face and web-based psychotherapies in other disorders, we hypothesize that both face-to-face RPT and e-RPT will have similar effectiveness in AUD symptom management, reducing alcohol consumption, and lowering relapse rates [33,34]. The secondary objective is to assess the effects of online treatment on quality of life, self-efficacy, resilience, and depressive symptomatology. The tertiary objective is to evaluate cost-effectiveness by comparing the amount of time an e-RPT therapist spends with each patient to the therapists administering face-to-face RPT. The results of this study will supplement the available literature and aid in the development of clinical recommendations for the management of AUD.

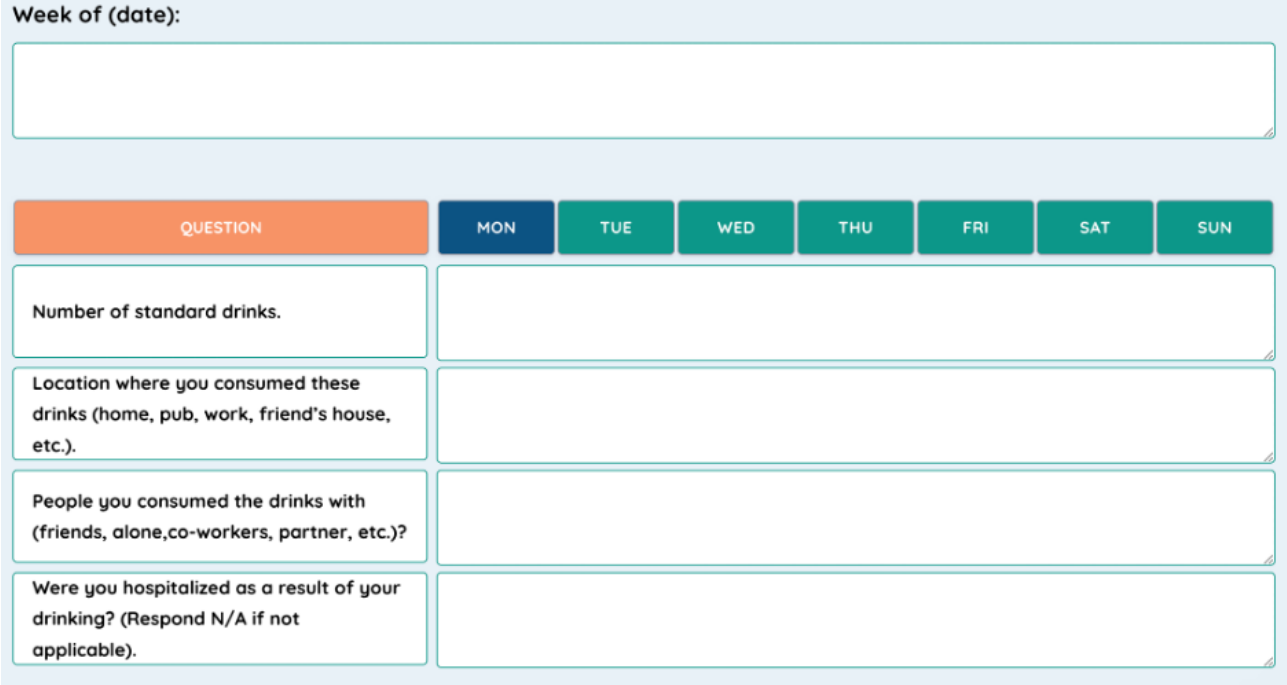
Methods

Study Design and Participants

This is the protocol for a randomized controlled trial studying the efficacy of a novel e-RPT program. Participants (n=60) diagnosed with AUD will be recruited through physician referrals from Kingston Health Sciences Centre, family physicians, other health care providers, and self-referrals within Kingston, Ontario. After providing consent to participate in the study, a Mini International Neuropsychiatric Interview 7.0.2 (MINI) will be conducted to confirm the diagnosis of mild to moderate AUD [35]. The MINI is a diagnostic interview that assesses 17 common mental disorders by following the diagnostic criteria of the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth edition [35]. After the MINI, the Readiness to Change Questionnaire (RCQ) will be administered in an interview format to investigate the individual's desire to change their alcohol consumption [33]. In addition to the RCQ, participants will be asked questions listed in Textbox 1 to capture their history with AUD. Answers to these questions, along with the intake MINI, will be reviewed with the principal investigator (PI) to ensure that the participant meets eligibility criteria and to confirm the AUD diagnosis.

Textbox 1. The 6 additional interview questions to establish eligibility.

1. Have you been diagnosed with alcohol use disorder (AUD)?
2. If applicable, when were you diagnosed with AUD?
3. Are you currently enrolled in another relapse prevention program?
4. In the past month, how many times have you had an alcoholic beverage?
5. If applicable, how many drinks did you have on average in those times?
6. If applicable, how many drinks did you have per week on average in the past month?



Participant inclusion criteria are being 18 years or older at the start of the study and having a diagnosis of mild to moderate AUD according to the MINI (2 to 5 MINI AUD symptom criteria) [20], competence to consent and participation, ability to speak and read English, and consistent and reliable access to the internet. Additionally, contemplation about stopping or having stopped consuming alcohol in the past 30 days is required. This will be assessed by the RCQ (participants should be in the contemplation or action stage according to the questionnaire) and by asking them about when they stopped drinking or began considering alcohol cessation [34,35]. Exclusion criteria are acute hypomanic or manic episodes, acute psychosis, other active substance use disorders classified as moderate or severe, active suicidal or homicidal ideation, untreated clinically substantial somatic symptoms or mental disorders, or current enrollment in another relapse prevention program. Additionally, men who consumed more than 4 drinks per day or 14 drinks per week and women who drank 3 drinks per day or 7 drinks per week in the past month will be excluded [36].

Procedure

Upon completion of the eligibility assessments, participants will be randomly assigned through a computerized system to one of the 2 groups: e-RPT or face-to-face RPT. Participants will be equally stratified (e-RPT n=30; face-to-face RPT n=30). These treatments will be delivered as an augmentation to treatment as usual (eg, medications, regular physician or clinician visits, referrals, or consultations that are conducted outside of this research study). The e-RPT program will be delivered through the Online Psychotherapy Tool (OPTT), a secure and interactive platform developed by the PI [37]. The face-to-face RPT program will be delivered through videoconference sessions using Microsoft Teams. Participants in the e-RPT and face-to-face groups will also have access to OPTT to access the triage module, the daily drinking diary (Figure 1), and assessment questionnaires.

XSL•FO
RenderX

Figure 1. Daily drinking diary.

Triage Module

The triage module is a short module intended to introduce clients to the RPT program and the drinking diary. All participants in the e-RPT and face-to-face groups will complete this module before starting their respective treatments.

e-RPT

Participants in the e-RPT group will receive 10 predesigned online modules per week on the OPTT platform. Each module consists of approximately 30 slides and should have an estimated completion time of 45 minutes. At the end of each module, participants will be assigned homework to be completed before their next module is assigned. The therapists will submit personalized feedback by using session-specific therapy feedback templates. These structured templates standardize the quality of feedback across different patients and therapists. In previous studies, therapists have been able to effectively use these templates to prepare feedback in approximately 15-20 minutes [30].

This e-RPT program will focus on teaching essential cognitive and behavioral skills such as identifying maladaptive thought processes, increasing engagement in day-to-day activities, and developing strategies to reduce alcohol consumption. The content of the sessions is outlined in Table 1.

XSL•FO
RenderX

Table 1. The program outline and session summary for the 10-week web-based and face-to-face relapse prevention program.

Session number	Session subject
1: Understanding addiction	• Introduces relapse prevention and what to expect from the course. The session explains what addiction is, including the symptoms, signs, consequences, and different types of addiction. Participants will create a SMART goal that they will try to achieve throughout the program. They will also share their personal experiences with addiction.
2: Exploring and strengthening your motivation	• Focuses on the 5 stages of motivation and the role of motivation in relapse prevention. Helpful techniques are discussed to help them reflect on and boost motivation throughout their recovery journey. Participants will create a pros and cons list about stopping alcohol use and reflect on different aspects of their ability to stop using alcohol.
3: Triggers	• Describes what triggers are and how to recognize them, including both internal and external triggers. This session also provides strategies to handle triggers through avoidance and careful planning. Participants will learn to identify their triggers and to be prepared for them if encountered.
4: Handling cravings and signs of relapse	• Presents skills for dealing with cravings as well as identifying and preventing a potential relapse. For instance, applying distraction methods during stressful situations decreases their urge to consume alcohol. Participants will also identify their warning signs by reflecting on previous relapse experiences.
5: The 5-Part Model	• The 5-Part Model will be explained, which highlights the importance of differentiating between our thoughts, feelings, physical reactions, and behaviors in stressful situations. Participants will complete the 5-Part Model using an example from their lives.
6: The Thought Record—Part 1	• Introduces the thought record and its relation to cognitive restructuration to highlight the connection between feelings, behaviors, and thoughts. This session focuses on the first 3 columns of the Thought Record (out of 7 columns). • The first 3 columns include the situation, followed by the feelings and automatic thoughts associated with the situation. Participants are asked to complete the first 3 columns of a thought record for a stressful situation they experienced within the past week.
7: The Thought Record—Part 2	• This session continues with the remaining 4 columns of the Thought Record, including gathering evidence in support of and against the identified automatic thoughts and finding alternative and balanced thoughts after examining the evidence. Participants will learn to challenge irrational thoughts using the thought record. They will also learn how to replace these irrational thoughts with more balanced and helpful ones. Participants have to complete a full thought record of a stressful situation related to their AUD within the past week.
8: Thinking errors and the Activity Record	• Explores irrational thinking and common thinking errors. This session also presents and highlights the importance of the Activity Record, a tool designed to record and plan weekly activities. Participants are asked to complete an activity record for an entire week.
9: Mindfulness and breathing techniques	• Presents mindfulness, breathing techniques, and other helpful skills to reduce urges and cravings associated with alcohol and to promote increased awareness. Participants are asked to incorporate one or more of these practices into their daily routines for a week and to reflect on how these practices made them feel. Participants will also identify which, if any, practices they found to be most effective.
10: Review	• This session is a review of the program. It summarizes all of the useful tools and techniques for relapse prevention that were described throughout the program. Participants are asked to reflect on the activities that they found to be the most effective throughout the sessions.

Face-to-Face RPT

Participants in the face-to-face intervention will meet with their therapist weekly through videoconferencing on Microsoft Teams [38]. During these 1-hour sessions, therapists will follow the same 10-week structure and content as e-RPT (Table 1). In contrast to e-RPT, where homework is written web-based by the therapist, the homework for the face-to-face sessions will be reviewed with the participant during the live session. At the end of each session, participants will receive the same homework and feedback as the e-RPT condition.

Training

Therapists for both e-RPT and face-to-face RPT will consist of research assistants who are trained in RPT and writing feedback. All therapists are trained by the PI, who is an expert in the electronic delivery of psychotherapy [30,39,40]. During training, the PI will closely guide the therapists through their first patient (assigning modules, reviewing homework, writing feedback, and conducting face-to-face sessions). All therapists will be supervised by the PI to ensure the quality and reliability of the treatment programs. To ensure the quality of the feedback, therapists will practice writing it using structured templates. All face-to-face sessions and feedback will be reviewed with the PI before being sent to the participants.

Outcome Measures

The primary objective of this study will be to determine if e-RPT has similar effectiveness to face-to-face RPT at reducing alcohol consumption and preventing relapses. This study defines relapse

XSL•FO
RenderX

as either the consumption of at least 2.5 oz. of pure ethanol, which is around 4 and a half standard drinks (Canadian guidelines for standard drinks: 12 oz of beer with 5% ethanol, 12 oz of cider with 5% ethanol, 5 oz of wine with 12% ethanol, and 1.5 oz of spirits with 40% ethanol) [41,42] on one occasion or hospitalization because of alcohol drinking [43]. Therefore, to determine the effectiveness of this program, daily alcohol consumption will be recorded in a drinking diary accessible through OPTT. This diary will ask the participants to report how many drinks they consumed on each day of the week, where they had those drinks, with whom, and if their alcohol consumption resulted in hospitalization (Figure 1).

The study will also determine whether e-RPT and face-to-face RPT have a beneficial effect on self-efficacy, quality of life, resiliency, coping behaviors, and depressive symptomatology. These metrics will be assessed through the following scales: Situational Confidence Questionnaire (SCQ-100) [44], 14-item Resilience Scale (RS-14) [45], Coping Behaviors Inventory (CBI) [46], Patient Health Questionnaire (PHQ-9) [47], and Quality of Life Enjoyment and Satisfaction Questionnaire—Short Form (Q-LES-Q-SF) [48]. These assessment scales will be completed at study entry (baseline), amid the program (week 5), and post treatment (week 10). After the treatment period, we will conduct follow-up assessments with all our outcome measures at 3, 6, and 12 months. The amount of time that e-RPT therapists spend writing feedback compared to the 1-hour face-to-face session will be used as a measure of therapists' time efficiency and will be tracked on the OPTT platform.

Ethical Considerations

All components of this study were reviewed for ethical compliance by the Queen's University Health Sciences and Affiliated Teaching Hospitals Research Ethics Board (File #: 6033212) in April 2022. Participants are only identifiable by an ID number, and all records are stored on a secure platform. Participant data is only accessible by the care providers, and anonymized data is provided to the analysis team. Participants can withdraw from the study at any point and request that their data be removed from the analysis. The research team will safeguard the privacy of the participants to the extent permitted by the applicable laws and their duty to report.

OPTT is compliant with the Health Insurance Portability and Accountability Act, Personal Information Protection and Electronic Documents Act, and Service Organization Control 2. All servers and databases are hosted in Amazon Web Service Canada cloud infrastructure to assure provincial and federal privacy and security regulations are met. OPTT does not collect identifiable personal information or IP addresses. OPTT collects anonymized metadata to improve service quality and provide advanced analytics to the clinician team.

Data Analysis

The data will be initially assessed for outliers, missing, and nonsensical variables. These variables will not be imputed, since they will be handled as missing. Similar studies that involved CBT and e-CBT demonstrated a dropout rate of up to 40% for both conditions once the study concluded [49]. Thus, this study will intentionally oversample the experimental and control groups to account for this dropout rate. Considering the effect size for face-to-face RPT reported by Harada et al [50] (2021) for CBI (effect size=0.65), a significance level of α=.05 and a power of 0.90, a sample size of 60 (30 per arm) would be sufficient to detect substantial changes from our interventions [51]. As this is the first study aiming to establish an e-RPT program for AUD, this sample size calculation relies on data from face-to-face RPT and takes into account the established effectiveness of online psychotherapy compared to face-to-face psychotherapy [30].

The analysis will begin by examining the data for missing, nonsensical, and outlying variables. The data will then be analyzed on a per-protocol basis, excluding missing data, and with intention-to-treat analysis to assess the clinical effects of the program on participants who dropped out prematurely. All calculations will be done using a 2-tailed significance level of α=.05, except for when a Bonferroni correction is needed. The demographic information of program completers and program dropouts will be compared using independent sample *t* tests to identify possible differences. A 2 by 3 repeated measures ANOVA of the primary (daily drinking and relapse) and secondary (SCQ-100, Q-LES-Q-SF, RS-14, CBI, and PHQ-9) outcomes will be conducted to test for the effects of the interventions (e-RPT or face-to-face RPT) throughout the 10-week treatment (0, 5, and 10-week assessment points). Linear regression (for continuous outcomes) and binomial regression analysis (for categorical outcomes) will be used to identify variables associated with outcome measures. Additionally, OPTT will collect usage statistics (ie, number of logins per day, amount of time spent logged in) and compare them to face-to-face metrics (ie, attendance to weekly 1-hour face-to-face sessions) to determine cost and time savings between the 2 programs. All statistical analyses will be conducted using IBM SPSS Statistics for Mac (version 24; IBM Corp).

Results

According to the literature on the efficacy of face-to-face psychotherapy compared to web-based psychotherapy in the management of AUD, we hypothesize that both e-RPT and face-to-face RPT will reduce alcohol consumption and relapse risk and improve secondary outcome measures (depressive symptomatology, self-efficacy, quality of life, and resilience) [44-47]. Recruitment and data collection are expected to end in October 2023. Data analysis will be concluded by December 2023, at which point the process of knowledge dissemination will begin, including but not limited to peer-reviewed publications, scientific presentations, grant proposals, and reports.

Discussion

This is a protocol for an RCT that aims to establish a novel e-RPT program to improve the mental health of patients with AUD. This program will teach effective coping techniques to maintain abstinence and reduce the risk of a relapse by applying the widely validated principles of CBT and relapse prevention [12,24,31,32,50]. Supporting the structure and design of this

XSL•FO
RenderX

program, this study will apply the evidence gathered by Alavi et al [30,39,40] on the efficacy of e-CBT in managing other psychiatric disorders. Thus, this study hypothesizes that this novel e-RPT program will have a similar effectiveness as face-to-face RPT at maintaining long-term abstinence and reducing the risk of experiencing a relapse.

Psychosocial interventions are one of the most commonly used methods for the treatment of mental health disorders [18]. CBT is one of the most-studied approaches for treating AUD and involves one-on-one sessions between the patient and therapist [19]. These sessions work on overcoming cravings for drinking alcohol by developing strategies that help people abstain from consuming alcohol when cravings occur. When targeted to prevent or reduce the risk of relapses after an initial alcohol reduction program, this CBT approach becomes RPT. RPT involves addressing coping skills to decrease the risk of relapse [21,50]. Additionally, both interpersonal and intrapersonal factors are addressed so that patients can develop the skills necessary to aid in preventing relapse. For instance, through the development of coping mechanisms to respond effectively to stressful situations that otherwise could have led to relapse [12,50]. However, despite these benefits, there are many obstacles to receiving face-to-face psychotherapy, such as financial issues and logistical problems.

The strengths of this program and this study include the use of asynchronous psychotherapy through predesigned web-based modules. These web-based modules have been shown to increase therapy efficiency by allowing a web-based therapist to deliver care to 3 to 4 patients at a time compared to 1 synchronous session [30,39,40]. The use of a web-based platform like OPTT allows for the automatic and reliable collection of user analytics, which can then be used to continuously improve and optimize the delivery of web-based psychotherapy programs. Given that face-to-face RPT has been previously validated in the literature, this study hypothesizes that e-RPT will be effective at maintaining abstinence, reducing the risk of relapse and depression symptomatology, and improving quality of life, resiliency, and coping behaviors [12,24,31,32,50]. Furthermore, comparing our proposed e-RPT program to a validated face-to-face therapeutic approach (RPT) strengthens the design of this RCT and the conclusions that will stem from this evidence.

Despite the strengths of this program, the web-based mode of delivery of this program may have some potential limitations. The main limitation is that participation requires a reliable internet connection and sufficient technology literacy. This limitation could introduce biases in participant demographic characteristics. Thus, this study will analyze demographic factors through multiple sample *t* tests to determine if these factors could impact treatment outcomes. Additionally, due to the delivery mode and design of the program, it is not possible to conceal client allocation. Moreover, web-based psychotherapy is often characterized by a dropout rate of up to 40% by the end of the treatment [49,50]. To account for this without compromising statistical power, this study is intentionally oversampled.

The knowledge dissemination plan for this study includes publishing the outcomes of this study in a peer-reviewed, academic journal. The research team will also attend academic meetings and conferences to present these findings and commit to continuing education in the relevant research areas. Furthermore, the dissemination and application of knowledge will be further enhanced through the collaboration of the Canadian enterprise, OPTT Inc. Additionally, by providing this service to clinicians, the care capacity for accessible, affordable, and high-quality mental health care could be more rapidly scaled across Canada.

To conclude, online psychotherapy has the potential to allow for more services to be provided at a lower cost and with increased capacity and accessibility, but research on its applications to relapse prevention is limited. Therefore, the results of this study aim to supplement the literature on the use of online psychotherapy for the management of AUD and to validate the implementation of this e-RPT program. Thus, the findings from this study can help provide the stepping stones for the large-scale implementation of programs like this one and may provide family medicine clinics, specialists, mental health professionals, and insurance companies with a new, more affordable, and accessible mental health resource.

Abstract

Background: The use of e-cigarettes, or vaping, has increased exponentially in the past decade, particularly among youth. Emerging evidence indicates growing nicotine dependence among youth, revealing historically higher rates of dependence among current e-cigarette users compared to rates seen in earlier research. Despite the urgent need for youth vaping cessation interventions, there is limited knowledge about the process of vaping cessation, and few evidence-based interventions are available to young people seeking support. A notable literature review on vaping cessation resources for young people recommended technology-based interventions, such as smartphone apps and SMS text messaging services, as a promising area of vaping cessation research and intervention development.

Objective: The primary aim of our study is to determine the effectiveness of the *Crush the Crave* app in supporting vaping cessation among youth recruited to the intervention arm via comparison with an assessment-only control group. The primary hypothesis is that participants in the intervention group—those using *Crush the Crave*—will be more likely to be abstinent at the 6-month follow-up point than participants in the assessment-only control arm.

Methods: A 2-arm, single-blind, parallel randomized controlled trial will be conducted over 12 months. Study invitations will be sent to 600 youth (age: 16-18 years) and young adult (age: 19-29 years) e-cigarette users and randomized between an intervention arm, which will be using *Crush the Crave* (n=300), and an assessment-only control arm (n=300) in a 1:1 ratio. The primary hypothesis is that participants in the intervention group—those using *Crush the Crave*—will be more likely to be abstinent at the 6-month follow-up point.

Results: Study recruitment began on March 4, 2022. Recruitment is anticipated to be completed in December 2022.

Conclusions: This protocol describes one of the first-ever randomized controlled trial studies to evaluate the effectiveness of an app-based intervention for supporting vaping cessation among youth aged 16 to 18 years and young adults aged 19 to 29 years. The findings from our trial will help increase our understanding of the process of vaping cessation among youth and provide evidence on the effectiveness of an app-based intervention in helping young people quit vaping. The trial results will also have implications in the development of current and future approaches to youth vaping cessation.

Introduction

The use of e-cigarettes, or vaping, has increased exponentially in the past decade, particularly among young people [1,2]. Emerging evidence indicates growing nicotine dependence among youth, revealing historically higher rates of dependence among current e-cigarette users compared to rates seen in earlier research [3-5]. Several studies have documented the growing need for vaping cessation support among youth [4-10]. In 2019, young people who did not smoke accounted for a greater number of regular vapers (as opposed to *ever-vapers*) when compared to those who smoked [11]. The COVID-19 pandemic may have exacerbated these conditions, with research suggesting an increase in substance use, including vaping, among young people [9,12,13].

Despite the urgent need for youth vaping cessation interventions, there is limited knowledge about the process of vaping cessation, and few evidence-based interventions are available to young people seeking support [6,14]. To date, much of the clinical and public health guidance on vaping cessation is adapted from the literature on smoking cessation [6,8,14]. However, while there are several commonalities between smoking and vaping, there are important differences that have received relatively little attention. A narrative review published in 2021 identified the following three key differences between vaping and smoking dependence: (1) greater variability in vaping products than in cigarettes, (2) the discreetness and convenience of vaping, and (3) greater social acceptability of vaping among youth [6,8,14]. Knowledge of these differences can inform the development of vaping cessation interventions that are effective and acceptable among young people.

Previous work in intervention research and development identified technology-based interventions as a promising area for promoting youth vaping cessation [6]. Smartphone technology and mobile software apps are highly accessible, easily scalable, and cost-effective platforms for mental health interventions [15]. Globally, young people born after the year 2000 are the top smartphone users [16,17]. Consequentially, vaping prevalence is also greatest among those aged 18 to 24 years and 15 to 17 years [11,18,19]. In fact, the use of apps for addressing mental health and substance use among youth is well documented in the literature [20-23], with apps for vaping cessation being among the latest additions [24]. However, there is currently no empirically tested smartphone app that specifically targets youth vaping cessation [24].

This protocol describes one of the first-ever randomized controlled trial (RCT) studies to evaluate the effectiveness of an app-based intervention for supporting vaping cessation among youth. The first-ever RCT of a vaping cessation intervention was designed to evaluate the effectiveness of an SMS text messaging program called *This is Quitting* in helping young adults in the United States aged 18 to 24 years to stop vaping [8]. The trial results showed that an SMS text messaging program that provided interactive and tailored messages was successful in promoting vaping cessation among young adults [8]. However, this trial did not include youth aged 14 to 17 years, for whom vaping cessation is urgently needed, as participants [1,4,18]. In our study, 600 youths (aged 16-18 years) and young adults (aged 19-29 years) who vape will be recruited. The intervention is called *Crush the Crave*—a comprehensive, full-featured app for supporting youth vaping cessation (Figure 1).

Crush the Crave for vaping cessation was developed based on an earlier version of the app for smoking cessation [25-27]. An RCT of 1599 young adult smokers assessed *Crush the Crave* for smoking cessation and found that the 30-day point prevalence abstinence (PPA) at 6 months for the intervention condition (118/820, 14.4%) was not significantly different (odds ratio 0.82, 95% CI 0.63-1.08) from that for the control condition (132/779, 16.9%). However, the rate of abstinence was favorable when compared with the unassisted 30-day quit rates of 11.5% of young adults [28]. In addition, it was determined that 61% of the young adult smokers in the RCT were vaping. The increasing nicotine dependence and use of vapes among youth have prompted interest in developing an app for vaping cessation based on people's experiences with *Crush the Crave* for smoking cessation. *Crush the Crave* is a tracker app that tracks the following information: the number of vape-free days and the amount of money saved since quitting vaping, as well as triggers and cravings. The app also provides the following functions: tailored supportive messages and inspirational graphic images for quitting vaping, personalized quit plans, graphic performance feedback, digital awards for achieving milestones, the reporting of vaping triggers, assistance for dealing with cravings, and links to other supportive resources that can aid in vaping cessation.

The primary aim of our study is to determine the effectiveness of the *Crush the Crave* app in supporting vaping cessation among youth recruited to the intervention arm via comparison with an assessment-only control group. The primary hypothesis is that participants in the intervention group—those using *Crush the Crave*—will be more likely to be abstinent at the 6-month follow-up point than participants in the assessment-only control arm. Our trial is currently open for recruitment. The anticipated completion date for our study is March 2024.

Figure 1. *Crush the Crave* app: comparison of the old version for young adult smoking cessation and the current version for youth vaping cessation.

Methods

Trial Design

A 2-arm, single-blind, parallel RCT will be conducted over 12 months. Study invitations will be sent to 600 youth and young adult e-cigarette users and randomized between an intervention arm, which will be using *Crush the Crave* (n=300), and an assessment-only control arm (n=300) in a 1:1 ratio. The trial protocol is registered with the Center for Open Science (registration digital object identifier: 10.17605/OSF.IO/HMD87). The trial protocol was developed in accordance with the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) 2013 checklist of recommended items for interventional trials [29].

Ethics Approval

The study is being conducted by the Ontario Tobacco Research Unit. Approval for the study protocol was obtained from the University of Toronto Office of Research Ethics (protocol number: 00038410).

Recruitment and Enrollment

Eligible participants are youth aged 16 to 29 years who live in Canada and have used nicotine e-cigarettes in the previous 30 days. Study participants will be recruited through the Vaping Dependence Cohort—an existing panel of youth enrolled in a prospective cohort study at the University of Toronto who provided consent for recontact in future studies at the Ontario Tobacco Research Unit. This panel is comprised of a broad sample of youth who self-reported current or past regular use of nicotine e-cigarettes. The use of nicotine e-cigarettes was assessed through a question that asked respondents if they had used e-cigarettes daily, in the past week, in the past month, in the past 3 months, or in the past year and if they had ever used an e-cigarette. This cohort was designed to balance recruitment by smoking status (*ever* or *never*), e-cigarette use (*ever* or *never*), and age (16-18 years or 19-25 years). Consequently, the prevalence of smoking, e-cigarette use, and younger participants was higher than what would be expected in a simple random sample of the population. An analysis controlling for the study design elements found that the within-group characteristics of the included youth were broadly consistent with expectations, which were based on a representative sample [9].

Informed Consent

After eligibility screening, participants must provide informed consent to proceed with study enrollment. The web-based consent form contains information about the study, the *Crush the Crave* app, participant eligibility, requirements and expectations for study participation, compensation, data collection, and plans for protecting participants and their privacy (ie, data deidentification), as well as the contact information of study staff and the University of Toronto Office of Research Ethics. Those who agree to participate in the study will receive an email containing a link to download the *Crush the Crave* app (sent to the email addresses they provided).

Compensation

Each participant in the intervention and control arms will receive compensation (CAD $10 [US $7.46] electronic gift card) upon completion of the baseline survey questionnaire and each time they complete a follow-up survey throughout the course of the study.

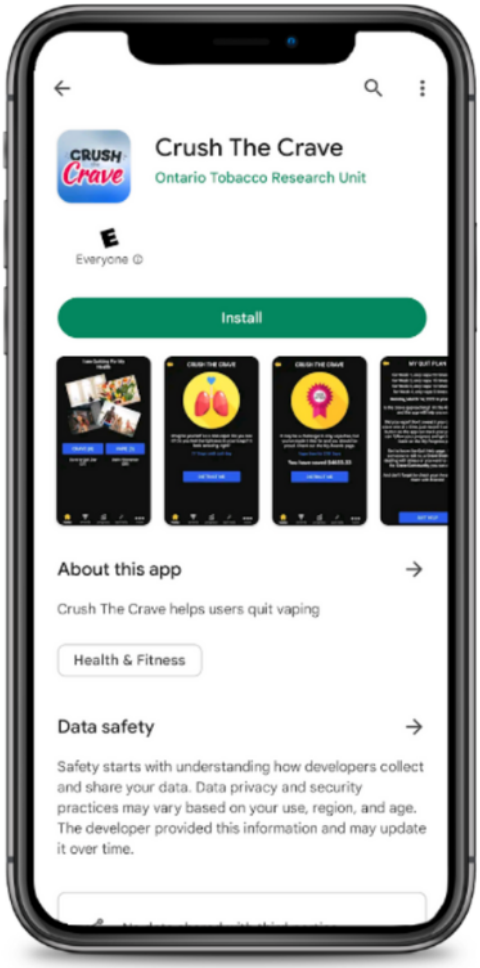
Randomization

Eligible participants will be identified from the Vaping Dependence Cohort. The *rand()* function in Excel (Microsoft Corporation) allowed for simple randomization; the top 50% highest numbers identified the participants that will receive invitations to use the *Crush the Crave* app. A research assistant from the Vaping Dependence Cohort will conduct the randomization and create a variable with a blinded key for the initial data analysis, which will allow the investigators and analyst to be blinded to the group allocation up until the data analysis is complete.

Interventions

Crush the Crave

An earlier version of the *Crush the Crave* app was developed for smoking cessation [22,25], incorporating fundamentals of persuasive technology [30] and recommended practices for addressing tobacco use and dependence [31]. This evidence



XSL•FO
RenderX

base formed the foundation for the current version of the *Crush the Crave* app for vaping cessation (Figure 2), which was redesigned (using principles of co-design [32]) by a multidisciplinary team of tobacco control researchers, design researchers, and software developers. Youth and young adults who vape were also engaged in the co-design process through a series of focus groups (January to February 2020) and an intensive design research workshop called *VapeHack* (May 2020).

Like the original app for young adult smoking cessation, *Crush the Crave* for vaping cessation enables users to customize a quit plan. As a tracker app, *Crush the Crave* monitors the amount of money saved and the number of vape-free days since the user's quit date. This savings calculator is one of the most significant changes in this version of *Crush the Crave*, which involved the conversion of the money saved based on the number of cigarettes smoked in a day to the money saved based on the number vape pods used in a week (calculated as the number of vape-free days multiplied by the product of the average number of vape pods used each day and the price of vape pods in Canada). The previous version of the app had a health calculator that monitored users and informed them of the health milestones achieved since quitting smoking. In the current version of the app, the health calculator feature was removed as a reflection of the lack of definitive evidence on the health effects of vaping. Further development of *Crush the Crave* for vaping cessation will be halted during the trial.

The app also tracks cravings and vaping habits through a diary of vaping triggers that records when, where, and why vaping occurs. The app displays supportive messages and graphic images of encouragement in response to cravings and relapse, as well as direct links to evidence-based resources, such as quitlines. A visual representation of quitting progress over time is provided to users on the main page, and users have the ability to upload personalized pictures and verbal affirmations. *Crush the Crave* also gives users the ability to geotag where vaping and cravings occur, and this information is only viewable to the user. Other features include reminders or push notifications regarding the money saved, health improvements, and the achievement of goals; digital awards for reaching milestones; and supportive messages tailored to where users are in the quitting process.

Figure 2. *Crush the Crave* app on the Google Play Store.

XSL•FO
RenderX

Assessment-Only Control

Based on an approach that is similar to the one used by Graham and colleagues [8], participants will be invited via email to complete the baseline assessment, and they will be invited to complete the follow-up assessment questionnaires asking about e-cigarette use and abstinence (as outlined in the following sections) at 3, 6, 9, and 12 months. At the end of the intervention period and following the last follow-up assessment, they will be invited to try the *Crush the Crave* app, if they are interested.

Data Collection

A baseline questionnaire will be sent to both the intervention group and the control group, using a self-administered web-based survey. This will collect comprehensive data on the history and characteristics of vaping (eg, vaping dependence, use of e-cigarettes, and self-confidence to quit), self-perceived addiction to vaping, health status (including mental health, mood, and perceived stress), and current and previous history of the use of other substances (combustible cigarettes, marijuana, alcohol, hookahs, and other tobacco products). The baseline survey will also ask questions on environmental factors and cessation goals. Self-reported demographic data (age, sex, gender and sexual orientation, province and country of residence, race and ethnicity, education, and marital status) will also be collected in the baseline survey.

A follow-up survey will be sent to the control and intervention groups at 3, 6, 9, and 12 months. Responses to the follow-up survey will be used to analyze any significant changes in vaping habits and differences between groups. The follow-up survey questionnaire includes items on cross-contamination and the use of cessation methods.

Outcome Measures

The primary outcome variable will be self-reported 30-day PPA at 3 months, operationalized as not having vaped, even a puff, in the last 30 days. The secondary measures include the intention to quit smoking in the next 6 months (*yes* or *no*), number of puffs per vaping session, number of vape sessions per day, and number of sessions in the past 30 days.

Process Measures

The mHealth (mobile health) App Usability Questionnaire [33] will be used to collect data on process measures from the intervention group. The mHealth App Usability Questionnaire collects data on the following three main constructs: ease of use and satisfaction (8 items), system information arrangement (6 items), and usefulness (7 items). Data from app analytics will also be used as process measures for the intervention group, including whether participants downloaded the intervention (*yes* or *no*), the frequency of use, the most frequently used features, and user reviews.

Qualitative interviews (n=25) will be conducted with participants in the intervention arm to gain insight on the usability and acceptability of the app. Interviews will be audio recorded and transcribed verbatim, and they will be analyzed in NVivo 12 (QSR International) by using a 6-step approach to thematic analysis, as proposed by Braun and Clarke [34].

Data Analysis Plan

Primary Outcome

Demographic and vaping characteristics (eg, vaping dependence, use of e-cigarettes, and self-confidence to quit) will be compared between groups at baseline. The intention-to-treat principle will be followed for statistical analyses, and all participants will be analyzed in the study arm to which they were randomized. Negative binomial regression with an identity function and robust SEs will be used to test between-group comparisons of the primary outcome variable—30-day PPA at follow-up. Multiple imputation via chained equations using the observed predictors of outcomes and the predictors of loss to follow-up will be performed to impute missing outcome data to correct for any potential bias caused by missing data. The imputation model will include age, sex and gender, education, marital status, province of residence, ethnicity, vaping dependence, self-confidence to quit, perceived stress, and the intervention group. The inverse of the adjusted risk difference will provide the number needed to treat.

The sample size of 600 (inclusive of both the control arm and the intervention arm) was selected to differentiate an effect size odds ratio of 1.60, assuming a base cessation rate of 5%, an α of .05, a power of 0.8, and a 75% (450/600) response rate.

Secondary Outcomes

For comparisons between secondary continuous outcomes and continuous outcomes, a linear regression with an identity function will be used. The secondary analysis of missing information will use the following two approaches to handle missingness: (1) imputation using the baseline observation carried forward or the classification of nonresponders as vapers in accordance with the Russell standard [35] and (2) imputation using the last observation of vaping status carried forward for nonresponders.

Process Analysis

For the process measures (whether participants downloaded the intervention, the frequency of use, satisfaction, and helpfulness), a chi-square test of association will be performed for binary and categorical variables, and for the ordinal variables approximating a normal distribution, a two-tailed *t* test for independent groups will be performed.

Results

Study recruitment began on March 4, 2022. Recruitment is anticipated to be completed in December 2022.

Discussion

Protocol Overview

This is the first-ever RCT study to evaluate the effectiveness of a smartphone app for supporting youth vaping cessation. The primary aim of our study is to determine the effectiveness of the *Crush the Crave* app in supporting vaping cessation among youth recruited to the intervention arm via comparison with an assessment-only control group. The primary hypothesis is that participants in the intervention group—those using *Crush the*

XSL•FO
RenderX

Crave—will be more likely to be abstinent at the 6-month follow-up point than participants in the assessment-only control arm.

The *Crush the Crave* app was developed based on the best available evidence on vaping cessation and an empirical investigation on the effectiveness of an earlier version of the app for smoking cessation [22]. At the time of writing, 4 other clinical trial protocols for evaluating vaping cessation interventions among youth and young adults were registered on ClinicalTrials.gov. Of these, only 1 has been completed; the results are accessible in the published scientific literature and show that the intervention was successful (abstinence success rates of 16% for the intervention group and 8% for the control group) in encouraging young adults to stop vaping through an SMS text messaging program [8]. This study was useful in providing a benchmark for intervention effectiveness [8]. Of the 3 remaining protocols that are actively recruiting participants, 2 aim to evaluate the effectiveness of nicotine replacement therapy for vaping cessation among youth and young adults, and 1 aims to determine the effectiveness of a smartphone app called *Goal2QuitVaping*. Compared to the target sample size in our study (N=600), that of the Goal2QuitVaping study is relatively small (N=45).

Limitations

It is important to note the potential limitations in some aspects of the design and implementation of our trial. First, most notably, our trial was designed to include an assessment-only control group. We recognize that other app-based interventions for health are typically compared against other active controls or even other app-based interventions. Our methodology was adopted from the methodology used in the only completed trial (at the time of writing) of a technology-based vaping cessation intervention [8]. Second, our study focuses on evaluating the effectiveness of the intervention among youth and young adults who vape nicotine e-cigarettes. Given the recent rise in cannabis vaping among youth, interventions that focus on cannabis vaping will need to be developed and studied rigorously. Finally, we recognize that the active intervention is publicly available on the Apple and Google app stores and that participants in both trial groups may become aware of this fact during the trial. Cross-contamination measures will be put in place to assess awareness of and engagement with the *Crush the Crave* app among control group participants.

Conclusions

The findings from our trial will help increase our understanding of the process of vaping cessation among youth and provide evidence on the effectiveness of an app-based intervention in helping young people quit vaping. The trial results will also have implications in the development of current and future approaches to youth vaping cessation.

Abstract

Background: People with spinal cord injury (SCI) report feeling unprepared to manage their disability upon discharge to the community. This situation is exacerbated when they return to settings where self-management support and resources are sparse, thus increasing the risk of costly secondary conditions and rehospitalizations. These factors make a compelling case for implementing innovative community-based SCI self-management programs that empower and engage individuals with SCI. Using a community-engaged research (CEnR) approach, we developed a peer-supported SCI self-management intervention, known as PHOENIX (Peer-supported Health Outreach, Education, and Information Exchange), which integrates online educational content and support from peer navigators (PNs) through telehealth, to promote health and community participation after SCI.

Objective: The objective of this pilot study is to evaluate the feasibility and acceptability of PHOENIX and the study design, and to obtain estimates of the variability of relevant outcome measures.

Methods: We conducted a pilot randomized waitlist-controlled trial (n=30) in collaboration with the South Carolina Spinal Cord Injury Association (SCSCIA), our long-standing community-based nonprofit organization research partner. We recruited 4 PNs through our SCSCIA collaboration using its existing network of trained peer mentors. Our study design supported comparison of the following 2 randomly assigned groups: PHOENIX intervention group and waitlist enhanced usual care (EUC) group. The PHOENIX intervention was administered online by PNs over 16 weeks through scheduled “video visits.” The EUC group participated in the study for 16 weeks with usual community services and no navigation, and received 4 monthly newsletters from the SCSCIA on a variety of SCI-relevant topics. At the end of the waitlist period, the waitlist EUC group received the full PHOENIX intervention. Measures of feasibility included PN and participant recruitment and retention, PN workload, protocol adherence, and incidence of technical issues. We conducted qualitative interviews with participants and PNs to evaluate the acceptability of PHOENIX and the study design. Outcome measures, including community participation, quality of life, and the occurrence and subjective impact of medically serious secondary conditions and rehospitalizations, were assessed at baseline after randomization and at subsequent time points to allow between-group comparisons.

Results: PN hiring and training were completed in August 2018. Recruitment began in November 2018. A total of 30 participants were recruited across South Carolina, and 28 participants completed follow-up by August 2020. An analysis of the results is being finalized, and the results are expected to be published in 2023.

Conclusions: This study will provide valuable information to guide future research seeking to address unmet self-management needs and improve outcomes in individuals with SCI. Feasibility findings of this study will provide evidence from CEnR guided

XSL•FO

by people with SCI and SCI service providers to inform further development, testing, and dissemination of effective and scalable self-management strategies for people with SCI.

Introduction

Background

Spinal cord injury (SCI) is a life-altering event that results in varying degrees of paralysis, depending on the level and completeness of injury. According to the National Spinal Cord Injury Statistical Center, there are about 17,900 new SCI cases each year and about 296,000 people with SCI in the United States [1]. Presently, 87% of all people with SCI return to private noninstitutional residences in the community [2]. Individuals with SCI are among the most complex and costly patients to manage in the health care system, with approximately 30% of people with SCI being rehospitalized one or more times during any given year following injury. While the prevalence of SCI is relatively low in comparison with the prevalence of other chronic conditions, the costs are staggering. Estimates suggest that first-year postinjury health care and living expense costs average US $567,000 for individuals with paraplegia and US $1.16 million for quadriplegia, with estimated lifetime costs of up to US $5.16 million [1]. The treatment of secondary complications, such as pressure injuries and urinary tract infections, requiring rehospitalization further increases the cost.

Self-management is both a goal and a lifetime task after a traumatic disabling event such as SCI [3]. Individuals with SCI must engage in proactive self-care (eg, pressure relief, skin checks, and bladder and bowel care) to reduce the occurrence and severity of costly potentially preventable secondary conditions that can detract from community participation and reduce quality of life (QOL). Medical rehabilitation is an essential component of recovery and adaptation to life with SCI. However, the median rehabilitation length of stay has declined over the last 40 years from 98 days in the 1970s to 30 days currently [1]. Unfortunately, shorter rehabilitation results in reduced opportunities, before discharge to home, for education and practice in self-management skills that are essential to prevent common, albeit serious, postinjury secondary conditions. Rehospitalization and medically serious secondary conditions create risks for increased isolation, and decreased community participation and QOL [4,5].

People with SCI report feeling unprepared to manage their disability and its effects in an environment outside of the clinical setting [6]. This situation is exacerbated when they return to settings where self-management support and resources are sparse, thus increasing the risk of costly secondary conditions and rehospitalizations [7,8]. These factors make a compelling case for implementing innovative community-based SCI self-management programs that empower and engage individuals with SCI.

Intervention Overview

Our strategy to promote SCI self-management has consistently involved specially trained peer navigators (PNs). In the context of our studies, PNs are people with SCI who are informed about their condition, take an active role in their self-care, are trained in key self-management components, and have a desire to help others learn to navigate life with a new disability [9,10]. As our pilot work and other studies demonstrate, learning from peers is vital in rehabilitation from a disabling injury and adjustment to living with SCI [11-14]. Our peer navigation model was initially pilot tested as an in-person intervention delivered in participants' homes. However, given the issues of scalability and sustainability, scattered regional distribution of participants, access problems, and travel time and costs, we determined that a telehealth innovation was needed.

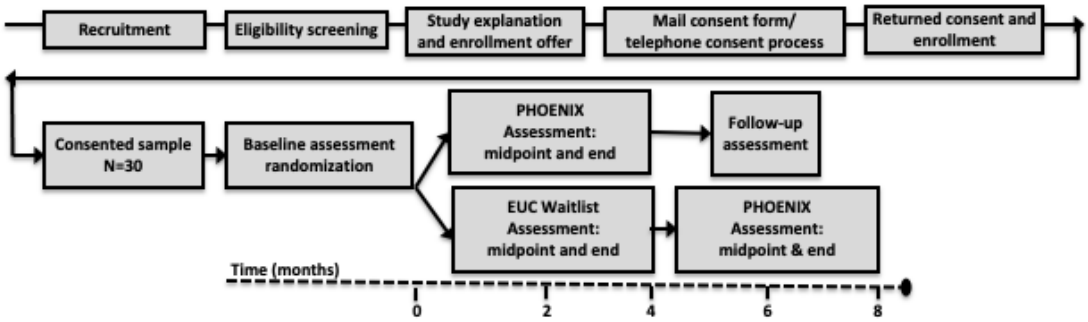
Our online PHOENIX (Peer-supported Health Outreach, Education, and Information Exchange) intervention evolved from lessons learned while piloting our in-person intervention. The primary goals of PHOENIX are to improve participants' community participation and QOL, and the secondary goals are to decrease the occurrence and subjective impact of medically serious secondary conditions and rehospitalizations. The 16-week PHOENIX intervention consists of 3 key components: (1) education on post-SCI self-care, and community resource navigation and use; (2) skill optimization through role modeling by the PN, tailored participant-centered behavioral goal setting, and action planning; and (3) information exchange through shared problem solving and decision support with the PN. The primary modalities to support the telehealth delivery of PHOENIX include (1) web-based multimedia educational content and (2) scheduled televideo interactions, using a telehealth platform, for knowledge and skill building and information exchange between participants and PNs with SCI.

The purpose of this study was to pilot test, in collaboration with our long-standing community partner, the South Carolina Spinal Cord Injury Association (SCSCIA), a structured, sustainable, technology-enhanced SCI PN intervention (ie, "PHOENIX") for statewide implementation across South Carolina. In congruence with the purpose of feasibility studies, the objective of this study was not to test the efficacy of the PHOENIX intervention but to determine whether the novel telehealth intervention and the study design could be feasibly implemented, and to obtain estimates of the variability of relevant outcome measures [15]. We designed a randomized pilot trial, using a waitlisted control group, to identify the potential logistical and methodological issues of both intervention implementation and study procedures in preparation for conducting a future full-scale randomized controlled trial [15]. We also sought to evaluate the PHOENIX intervention to obtain estimates of the variability

XSL•FO
RenderX

of community participation and QOL (primary outcomes), and the occurrence and subjective impact of medically serious secondary conditions and rehospitalizations (secondary outcomes) to inform the design of an adequately powered future trial.

Methods



Community Engagement

Our approach reflected the Guidelines and Criteria for the Implementation of Community-based Health Promotion Programs for Individuals with Disabilities, including (1) use of an underlying theoretical framework; (2) implementation of process evaluation; (3) use of disability-appropriate outcome measures; (4) active involvement of people with disabilities in intervention development and implementation; (5) support of the personal beliefs, practices, and values of people with disabilities; (6) consideration of accessibility and barriers to program participation; and (7) sensitivity to financial constraints often experienced by people with disabilities [16]. A long-standing community-engaged research partnership between the principal investigator (SDN) and the SCSCIA supported this line of research. Over the course of our partnership, research activities have been guided by an active and empowered community advisory board comprised of community members with SCI, and representatives from agencies providing services to people with SCI. The advisory board participated in the conceptualization of PHOENIX and the development of multimedia content for the intervention to assure relevance and accessibility of the material. They also provided feedback on the structuring and layout of the online educational curriculum. The SCSCIA collaborated with the study team on (1) expansion and formalization of the PN training curriculum; (2) identification and recruitment of individuals who would serve well as PNs; (3) facilitation of PN training workshops; (4) periodic monitoring of PN performance; (5) assistance with participant recruitment; and (6) support to the principal investigator in addressing additional navigator training needs over the course of the study. It is also engaged in assisting with the dissemination of study results to nonacademic audiences in the community.

Study Design

Advisory board guidance was sought to address scientific rigor and logistics, as well as ethical concerns about condition assignment. We addressed these concerns through a randomized waitlist study design, so all participants received the intervention. Our study design supported the conduct of a pilot randomized (individual level) waitlist-controlled trial with 30 adults with SCI, comparing 2 groups: a waitlist enhanced usual care (EUC) group and a PHOENIX intervention group. At the end of the waitlist period, the EUC group received the full intervention (Figure 1).

Figure 1. Study design and flow. EUC: enhanced usual care; PHOENIX: Peer-supported Health Outreach, Education, and Information Exchange.

PN Recruitment, Training, and Retention

We recruited 4 PNs through our SCSCIA collaboration using its existing network of trained peer mentors. The PNs completed 2 full days of training on implementation of the PHOENIX intervention and working on a research team, which included completion of training in protecting human subjects, research ethics and compliance, and maintaining participant privacy and study data confidentiality. An additional full-day training was provided approximately 6 months after study initiation. To promote retention, all PNs were hired and paid as university employees. Additional retention strategies included scheduled weekly meetings with the team over the course of the study to address issues that arose in the navigation process and to provide ongoing support to PNs.

Ethics Approval

Institutional Review Board (IRB) approval (Medical University of South Carolina; number: Pro00071526) was obtained prior to the initiation of study participant recruitment. As the SCSCIA was determined to be engaged in research, a certificate of Federal Wide Assurance was obtained with a reliance agreement in place with the university IRB.

Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) South Carolina resident; (2) ≥18 years old; (3) chronic paralysis due to traumatic SCI; (4) level and severity of paralysis requiring locomotion with a wheelchair for >6 hours/day; (5) living in a private residence; (6) accessible by mail, phone, or email; and (7) able to speak English. The exclusion criteria were as follows: (1) cognitive or mental impairment that would prevent informed consent; (2) level of injury requiring use of a ventilator; (3) unhealed stage III or IV pressure ulcer requiring bed rest; (4) acute serious medical illness at the time of screening that would inhibit participation in the intervention; and (5) plans to move out of South Carolina in the next 8 months.

XSL•FO
RenderX

Number of Subjects

Our targeted sample was 30 adults with SCI from urban and rural regions across South Carolina. Consistent with guidance provided by Leon et al and Tickle-Degnen, our intent with this pilot study was not to estimate effect size, and our sample size was determined primarily by pragmatic reasons [15,17,18]. Sample size determination was based on estimates of workload for PNs. We expected that PNs could work with 2 study participants at a time during the first 8 weeks of the intervention that required weekly contact. For a sample size of 15 participants per group (intervention and waitlist control), the between-group difference in change scores for the relevant outcome measures for the intervention group versus waitlist control group was estimated with precision to range from ±7.6 to ±15.1 for SDs of difference scores ranging from 15.0 to 30.0 SD units.

Recruitment and Consent

Established collaborations, including the SCSCIA's network of peer support groups and relationships with SCI-related service providers and rehabilitation hospitals, supported recruitment of 30 adults with SCI from urban and rural regions across South Carolina. We announced the study through flyers, SCSCIA staff word of mouth, the SCSCIA Facebook page and other social media, and the SCSCIA website. Study announcements provided study team contact information to individuals interested in participating.

Once an individual responded to the call for participants, we conducted screening procedures to determine eligibility, thus following CONSORT (Consolidated Standards of Reporting Trials) guidelines to determine detailed information on recruitment flow. Eligible individuals were then provided with a brief study description, including randomization, and a general schedule of procedures to assess continued interest prior to conducting the informed consent process.

We offered 2 options for completing the informed consent process, by telephone or eConsent through REDCap (Research Electronic Data Capture). For telephone consent, eligible and interested individuals provided their full name and contact information. We then mailed 2 copies of the informed consent to the interested individuals and scheduled a time to complete the consenting process by phone, after which the participants signed and returned 1 signed copy of the consent. For eConsent, individuals interested in study participation provided their full name and contact information, including an email address, to which we sent a REDCap survey link containing the informed consent document. Study staff scheduled a time to complete the consenting process by phone, after which the participants signed the eConsent in REDCap. Upon submitting the eConsent, a REDCap trigger immediately notified the person obtaining consent, who then signed the document. Participants could download a copy of their executed informed consent directly to their own computer or request a copy be emailed or mailed to them.

Randomization

Once signed consent was received, participants were randomized and placed in the appropriate group in the REDCap database. Randomization was at the participant level, using the REDCap automated randomization feature. Following the completion of baseline measures, staff informed participants of their group assignment.

Intervention Delivery Platform

iTunes U

The iTunes U environment provided a private 1-way (ie, study participants did not enter any personal information into iTunes U) platform for the dissemination of multimedia educational content, including web links, documents, and videos, addressing topics in the PHOENIX curriculum (the educational videos are available online [19]). The educational content served as a source of information, as well as provided topics/themes for PN and participant discussions during the video visits. The educational content in iTunes U provided a library of resources available to PNs and participants, which was used to tailor the information provided, and an approach to address the relative learning needs of each participant.

Doxy.me

The low bandwidth televideo solution Doxy.me was used to facilitate the video visits between PNs and participants. Doxy.me is a Health Insurance Portability and Accountability Act–compliant, free, and secure telehealth solution that does not require downloads, plugins, or specialized hardware, and works natively on iPads through the Doxy.me app.

iPads

Once participants were assigned to PHOENIX, either at randomization or the end of waitlist, we assessed assistive technology needs, and participants were sent a kit by certified mail, which contained an iPad preloaded with PHOENIX educational materials, any required assistive technologies, and instructions on operation of the iPad. After we received confirmation that the iPad was received, study staff placed an initial call to assist iPad set up and provide information on the assigned PN who contacted the participant and initiated PHOENIX. The iPad provided a means for participants to access educational materials in iTunes U and engage in video visits using the Doxy.me app with PNs. In return for participants' time and effort for participating in the study, the study team transferred ownership of the iPad to the study participants, and they retained any additional assistive technologies provided to them at the end of the study. At the end of the study, the cellular data plan provided by the study was terminated, and participants were provided with suggestions for free Wi-Fi access in their community (eg, public library).

Intervention Implementation

PHOENIX was administered by the PN over 16 weeks. The first 8 weeks consisted of 6 educational modules (Table 1) and weekly televideo contact (ie, "video visits") via Doxy.me with the PN, followed by (weeks 9-16) biweekly scheduled video visits with the PN to address progress to goals; barriers encountered; skin, bladder, or bowel issues; or hospitalization since last contact. PHOENIX integrated the key skills of self-management as defined by Lorig et al: problem solving, decision making, resource utilization, formation of partnerships, action planning, and self-tailoring [3]. Developing participant

XSL•FO
RenderX

self-efficacy in these essential skills through construction of action plans and facilitated goal setting supported a participant-centered approach to self-management. PNs facilitated and modeled methods to access community services and resources, as well as incorporated aspects of peer mentoring by helping the individual establish goals, served as a resource for advice and guidance, and modeled strategies to meet goals [20]. The intervention was designed to promote participant efficacy in achieving a desirable level of community participation and QOL through knowledge and skill building related to self-management, guided by motivation and support from PNs.

Table 1. PHOENIX[a] curriculum.

Week	Content/activity	PN role[b]
Week 1: Introduction to PHOENIX and SCI[c] 101	• What is PHOENIX? • Relationship building exercise • Brief PN video bios • Understanding your SCI • Initial personal goal setting	• Describe role of the PN • Share personal story • Engage peer in story sharing • Use action planning strategies to identify goals • Facilitate realistic goal setting and identifying potential barriers
Week 2: Getting what you need: Being an empowered consumer	• Self-advocacy skills • Knowing your rights • Active versus passive communication	• Role play • Facilitate discussion of a video • Assess progress to personal goal (PTPG) • Facilitate problem solving barriers
Week 3: Getting out there: Engaging community resources	• Identifying resources to support personal goal attainment • Initiate contact with a resource	• Assist with locating relevant resources • Support peer in engaging a resource • Assess PTPG • Facilitate problem solving barriers
Week 4: Staying healthy: Skin care and preventing pressure injury	• Skin care after SCI • Pressure injury prevention • Identifying a problem and taking action	• Evaluate knowledge/address gaps • Share personal experiences and strategies • Assess PTPG • Facilitate problem solving barriers
Week 5: Staying healthy: Preventing urinary tract infection (UTI)	• Bladder management after SCI • UTI prevention • Identifying a problem and taking action	• Evaluate knowledge/address gaps • Share personal experiences and strategies • Assess PTPG • Facilitate problem solving barriers
Week 6: Staying healthy: Bowel management	• Bowel management after SCI • Identifying a problem and taking action	• Evaluate knowledge/address gaps • Share personal experiences and strategies • Assess PTPG • Facilitate problem solving barriers
Weeks 7, 8, 10, 12, 14, and 16: Follow-up	• Video visit for action planning and goal support	• Share personal experiences and strategies • Assess PTPG • Facilitate problem solving barriers

[a]PHOENIX: Peer-supported Health Outreach, Education, and Information Exchange.

[b]PN: peer navigator.

[c]SCI: spinal cord injury.

Comparison Condition

The EUC waitlist group participated in the study for 16 weeks with usual community services and no navigation. Waitlist participants received 4 monthly newsletters from the SCSCIA on a variety of SCI-relevant topics. The newsletters contained contact information should participants need information or assistance. Following the end of waitlist assessment, waitlist participants crossed over to the PHOENIX intervention group. To compensate the waitlist participants for the completion of additional measures before crossover to PHOENIX and receiving the iPad, we provided US $50 payment for completing baseline and week 8 study measures.

Data Collection and Analysis: Feasibility

Assessment of feasibility was guided by Leon et al and Tickle-Degnen [15,18]. We assessed the feasibility of both the intervention and the study design and research procedures. Specific intervention and study components that were assessed, and their relevant quantifications are mentioned in Table 2.

XSL•FO
RenderX

Table 2. Feasibility components and quantification.

Component	Feasibility quantification
Intervention component	
Navigator workload	Time logs (minutes per activity)
Retention	PN[a] attrition rate
Fidelity	Rates of adherence to intervention protocol by PNs
Adherence	Rates of adherence to intervention protocol by participants
Online module access (dosage)	Use statistics – number and duration of educational module access
Televideo access (dosage)	Use statistics – number and duration of televideo meetings
Technology	Rates of device and connectivity issues
Safety	Rate of adverse events
Study component	
Screening	Number screened per month
Recruitment	Number enrolled per month
Enrollment and consenting	Duration of enrollment and consenting process
Randomization	Proportion of screen eligible individuals who enrolled
Retention	Intervention versus waitlist attrition rates
Outcome assessments	Proportion of planned assessments completed; time to complete measures

[a]PN: peer navigator.

In addition to standard measures of feasibility, expanding the reach of PHOENIX across South Carolina using a telehealth approach removed the in-person procedures used in the original PN pilot, thus creating the need for study procedures that could be completed at a distance. We also evaluated the feasibility and logistics of our proposed screening, enrollment, and consenting procedures for use in a future larger trial with broader reach.

Part of our feasibility evaluation included determining the time required by PNs to complete navigation tasks through a telehealth platform. We closely monitored navigator workload and effectiveness. To support PN retention and closely monitor the PN experience, we held weekly team meetings, including the investigators, SCSCIA executive director, SCSCIA community outreach coordinator, and PNs, to assess and discuss issues uncovered by PNs in interactions with study participants and to provide support and guidance for addressing these issues. The proceedings of these meetings were audio recorded for later analysis and use in quality and process evaluation.

Intervention Fidelity

Standardized training of PNs and use of intervention manuals that listed session objectives and format, instructional resources, session content, and monitoring criteria supported fidelity in intervention delivery. Tracking logs in REDCap were completed by PNs at each study visit (Multimedia Appendix 1) and were used to monitor the dosage/fidelity of PNs' contacts, including frequency, length of contact, predominant interaction content, and participant progress. Feasibility will be evaluated by reporting 95% CIs on proportions and differences in proportions between the 2 groups for categorical feasibility measures, such as recruitment, retention, and adherence, and via 95% CIs for means and differences in means for continuous feasibility outcomes, including number of modules accessed, number of video visits completed, duration of video visits, etc.

Acceptability

We conducted postintervention evaluation surveys (Table 3) and interviews (Textbox 1) with participants, and a summative debriefing session with PNs to assess the usefulness, acceptance, and satisfaction regarding the waitlist study design and intervention components, as well as participant response burden for completing measures. Participants were asked about feedback regarding their experiences with engaging PNs, the use of the iPads and any other technology, the presence of any safety or comfort-related concerns about the study, and problems with the navigation process. The interviews and debriefing session were audio recorded, transcribed, and analyzed for process evaluation purposes, using the methods of qualitative content analysis.

XSL•FO
RenderX

Table 3. Postintervention evaluation survey items.

Item	Response options
Please select the answer that best describes your feeling about each statement	
The length of partnership with my peer navigator was…	Too short, too long, or just right
The number of times I met with the peer navigator was…	Not enough, too often, or just right
How satisfied were you with the peer navigator?	Not, somewhat, or very
How satisfied were you with the educational materials?	Not, somewhat, or very
How satisfied were you with using iTunes U?	Not, somewhat, or very
How satisfied were you with using the iPad?	Not, somewhat, or very
How comfortable were you with video visits with the peer navigator?	Not, somewhat, or very
Please indicate how much the PHOENIX[a] program helped you in the following areas...	
My ability to speak up and advocate for my needs	No help, some help, or great deal of help
My knowledge about community resources & services	No help, some help, or great deal of help
My ability to access resources & services that I need	No help, some help, or great deal of help
My ability to make decisions that affect my health	No help, some help, or great deal of help
My ability to solve problems that arise	No help, some help, or great deal of help
Building a support system	No help, some help, or great deal of help
My ability to participate in activities that interest me	No help, some help, or great deal of help
Feeling I'm in control over my life	No help, some help, or great deal of help
My knowledge about spinal cord injury	No help, some help, or great deal of help
My ability to prevent pressure ulcers	No help, some help, or great deal of help
My ability to prevent urinary tract infections	No help, some help, or great deal of help
My ability to prevent bowel problems	No help, some help, or great deal of help

Textbox 1. Evaluation interview questions.

Questions

- What were your expectations for the PHOENIX (Peer-supported Health Outreach, Education, and Information Exchange) program before you began?
- What are the most helpful parts of the PHOENIX program in general?
- What are the least helpful parts of the PHOENIX program in general?

Now let's talk about using technology in PHOENIX.

First let's discuss the educational materials that were provided through iTunes U.

- Did you find these materials helpful?
- What did you like about them?
- What would make them better?
- Was any information missing?
- Describe your experience in using the iPad to video chat with the peer navigator.
- Describe any technology problems or challenges you experienced.
- Did you use the iPad to access other SCI (spinal cord injury) information on the internet? If yes, tell me more about this.

Now let's talk about your experience in working with the peer navigator.

- How would you describe the nature of your relationship with your peer navigator?
- What did you like about working with a peer navigator?
- What would make this experience better?
- Goal setting and following up on your goals with your peer navigator is an important part of the program. Tell me a little bit about your experiences with setting goals while you were in PHOENIX.
- Tell me about what you learned about self-advocacy while you were involved with this program.
- Describe any changes in your life with SCI that resulted from participating in PHOENIX.
- What suggestions do you have to make this program better?
- Do you have any other last thoughts that you would like to share?

Data Collection and Analysis: Outcomes

Baseline data collection occurred after randomization (week 0). In the intervention group, we collected outcome measures at the intervention midpoint (week 8) and end (week 16), and at follow-up (week 24). In the waitlist control group, we collected outcome measures at the same time points to allow preliminary between-group comparisons, including at baseline (week 0), waitlist midpoint (week 8), end of waitlist/preintervention (week 16), intervention midpoint (week 24), and intervention end (week 32) (Figure 1). We used REDCap for data collection and management. Participants were provided with a link to access the REDCap survey using their iPads. Contact information was provided to allow the option of phone administration for participants who were not able to complete the REDCap survey.

Measures

We used established instruments with reported validity and reliability in populations with SCI (measures and timing are detailed in Table 4). We used relevant item banks from the Spinal Cord Injury-Quality of Life (SCI-QOL) instrument developed for use with SCI populations, which builds on the Patient-Reported Outcomes Measurement Information System (PROMIS) and the Quality of Life in Neurological Disorders (Neuro-QOL) initiative [21]. We used short-form instrument options when available to minimize participant response burden.

XSL•FO

[d]UTI: urinary tract infection.

[e]SCI: spinal cord injury.

Data Analyses

As this pilot study was intended to assess feasibility and was not a hypothesis testing study, no inferential statistical tests were proposed [15]. Descriptive statistics were calculated, as appropriate, for all variables for the total sample and within the PHOENIX and control groups. The primary purpose of this data analysis was to generate estimates of variability in the primary and secondary outcomes. The primary continuous outcome measures to be used to evaluate peer navigation efficacy in a future larger adequately powered trial are community participation (Craig Handicap Assessment & Reporting Technique [CHART], Reintegration to Normal Living Index [RNL], and SCI-QOL Ability to Participate [ATP] & Satisfaction with Social Roles [SRS]) and QOL (SCI-QOL Positive Affect & Wellbeing [PAWB]) scores, and the secondary outcome measures are occurrence and subjective impact of secondary conditions (SCI-QOL Pressure Ulcers Scale [PUS] & Bladder Complications Scale [BCS]) obtained at baseline and 2 and 4 months. In addition, within the PHOENIX group, the change from baseline to 6-month follow-up was assessed for community participation and QOL. We obtained 95% CIs for the unadjusted as well as adjusted mean change from pretreatment to posttreatment (baseline to 2 and 4 months) for primary and secondary outcome measures within each group and for differences in the change from pretreatment to posttreatment between the 2 groups (PHOENIX and EUC). Though CIs obtained as estimates of variability for the relevant outcome measures were wide, as expected from a feasibility study, they provided reasonable estimates as input for the determination of effect sizes in future trials. Given that estimates from small studies carry uncertainties for the calculation of sample size for future studies, we plan to carry out sensitivity analyses to assess deviations from variability assumptions, as suggested by Julious and Owen [36]. Future investigations will explore the effects of demographic (age, race/ethnicity, gender, education, income, and living situation) and clinical (injury level, injury severity, time since injury, stigma, anxiety, and depression) characteristics, as well as potential mediating (self-efficacy, social support, and patient activation) variables on community participation and QOL through inclusion as

XSL•FO
RenderX

adjustment variables; thus, we piloted the collection of these variables in this study.

Results

PN training was completed and IRB approval for the study was obtained in August 2018. The first participant was enrolled in early November 2018. Due to the pattern generated by the automated randomization feature in REDCap, 8 out of 12 participants in the first wave of the study were randomized to the active intervention, and 4 were randomized to the waitlist arm. By the end of November, our PNs had reached their maximum capacity of 2 participants each; thus, we paused enrollment and placed interested individuals on a study enrollment waitlist. As consented participants completed the active intervention, additional participants were consented and enrolled. The final participant postintervention interview was completed in August 2020, and a debriefing focus group with PNs was completed in November 2020. Initial analysis of feasibility and outcome data was completed in September 2021. The study results have been disseminated to community partners involved in the development of the PHOENIX intervention, and the multimedia educational content (Figures 2 and 3) is available on the SCSCIA website via Vimeo [19] since the discontinuation of the iTunes U platform by Apple in 2021. The findings will be submitted to peer-reviewed journals and presented at academic conferences [37]. An analysis of the results is being finalized, and the results are expected to be published in 2023.

Discussion

Principal Findings

Our research addresses an innovative combination of self-management and rehabilitation science, that is, the integration of peer-support, navigation, and telehealth to create an internet-based self-management intervention that is accessible, has extensive reach potential, and is designed to address the chronic consequences of an often permanently disabling injury with great individual and community burden. Use of a community-engaged research approach helps to ensure that the PHOENIX intervention is designed to be highly relevant to the unique needs of individuals with SCI, and that the study design and procedures are acceptable to the participant population. In congruence with the purpose of feasibility studies, the objective of this study is not to test for efficacy but to determine whether the PHOENIX intervention and the study design can be feasibly implemented, and to obtain estimates of the variability of relevant outcome measures. The field testing of the PHOENIX intervention through a randomized pilot trial using a waitlisted control group will facilitate the identification of potential logistical and methodological issues of both intervention implementation and study procedures. Specifically, our pilot trial is designed to evaluate aspects of feasibility and acceptability systematically, inform refinement of intervention components and delivery, and strengthen study procedures and processes required to conduct a robust future large-scale trial. Subsequent rigorous testing of the intervention will ultimately contribute to the scientific knowledge base regarding effective community-based self-management following a traumatic disabling injury, particularly those for which paralysis is central. This line of research will provide valuable information to support our long-term goal of developing an intervention that integrates online educational content and support from PNs through telehealth in order to promote effective self-management after SCI and ultimately increase the capacity of individuals with SCI to maintain health and participate in the community as desired.

Possible Challenges, Limitations, and Solutions

Designing and implementing a community-based trial using participatory methods with a historically vulnerable population while maintaining scientific rigor are quite challenging. We will attempt to maintain internal validity and minimize selection bias through randomization and by inviting all potentially eligible participants to join the study. We will report the demographic characteristics of our study participants and will compare these with published characteristics of the target group. We did not identify a specific time since injury in our recruitment criteria, as we did not want to eliminate the possibility of recognizing potentially unique needs related to SCI of a long duration. Regarding external validity, we recognize that the results of this pilot study cannot be generalized to the entire population with SCI but may be representative of the target population of people with SCI residing in the study area to the extent that those who volunteer to participate in our study sample are representative of this target population. We will monitor issues related to intervention fidelity and feasibility that can inform strategies to minimize threats to internal and external validity.

Conclusion

The results of this study will provide evidence from community-engaged research guided by people with SCI and SCI service providers to inform future development, refinement, testing, and dissemination of effective and scalable self-management strategies for people with SCI.

Abstract

Background: Colombia is a middle-income country in South America, which has historically had high rates of mental health problems, coupled with a scarcity of mental health care. There is growing concern for the mental health of the adolescent population within this region. There is a significant treatment gap for young people, especially those living in the most vulnerable areas. DIALOG+ is a low-cost patient-centered intervention that can potentially improve the delivery of care and quality of life for adolescents with mental health problems.

Objective: This exploratory randomized controlled trial aims to evaluate the effectiveness, acceptability, and feasibility of an adapted version of the DIALOG+ intervention (DIALOG-A) in the community treatment of Colombian adolescents with depression and anxiety.

Methods: In total, 18 clinicians and 108 adolescents will be recruited from primary health care services in Bogota and Duitama, Colombia. Clinicians will be randomized 2:1 to either the intervention (12 clinicians:72 adolescents) or control group (6 clinicians:36 adolescents). In the intervention arm, clinicians will use DIALOG-A with adolescents once per month over 6 months. The control arm will continue to receive routine care. Outcomes will be measured at baseline, 6 months, and 9 months following randomization. Semistructured interviews with all clinicians and a subset of adolescents in the intervention arm will be conducted at the end of the intervention period. Quantitative and qualitative analysis of the data will be conducted.

Results: Trial recruitment was completed toward the end of October 2022, and follow-up is anticipated to last through to October 2023.

Conclusions: This is the first study to test an adapted resource-orientated intervention (DIALOG-A) in the treatment of adolescents with depression and anxiety attending primary care services. If the results are positive, DIALOG-A can be implemented in the routine care of adolescents with these mental health problems and provide valuable insight to other middle-income countries.

Introduction

Background

Currently, an estimated 5.2 million adolescents are living in Colombia. During adolescence, physical, emotional, and social changes make individuals more vulnerable to mental health problems. Worldwide, and in Columbia, adolescence also marks the beginning of relationships and the emergence of sexuality, with a mature body capable of exercising it [1,2]. All these circumstances are intensified when adolescents live in an area with a history of conflict, displacement, inequality, poverty, violence, and lack of opportunities.

The internal conflict and violence experienced in Colombia for more than 50 years has led to the forcible displacement of 8.2 million individuals since 1985 [3], and a high proportion of the population is living in extreme poverty, which is currently estimated to be 12.2% (per the National Administrative Department of Statistics) [4]. This has contributed to fragile neighborhoods, particularly within urbanized inner-city areas, and deprived rural communities [3,4]. This complex picture has led to an increase in mental health illness among adolescents, including a rise in the prevalence of depression and anxiety, with a 1-year estimate of 4%-5% [5,6].

In Colombia, anxiety disorders are the most frequent, with an estimated prevalence of 15%-20%, and with rates reported to be as high as 31.9% among individuals aged between 13 and 18 years [7]. Similarly, rates of anxiety and depression are also commonly high among people aged 12 to 17 years. Using the Self-Reporting Questionnaire to assess this population, 13% of adolescents screened positive for depression [8,9].

Despite the high prevalence rates and long-term impacts of depression and anxiety, only half of the adolescents diagnosed with anxiety and depression in low- and middle-income countries (LMICs) access treatment, with a smaller percentage (20.5%) receiving at least the minimum standard of care. Consequently, less than 12% of adolescents in LMICs such as Colombia receive even minimally adequate treatment, pointing to an issue of both access and quality [10,11]. In Colombia, one of the most relevant barriers to mental health services delivery is a lack of sufficiently trained professionals [12,13]. Where resources are available, they tend to be distributed unevenly, concentrated in large cities, and fail to reach low-income or rural areas. Hence, low-cost, generic interventions that can be delivered by a range of staff (including those beyond the mental health system) are urgently needed to tackle depression and anxiety and ultimately improve adolescent health [14-16].

DIALOG+ is a technology-assisted and resource-orientated intervention based on quality-of-life research, patient-centered communication, and solution-focused therapy. Within DIALOG+, patients use a tablet to rate their satisfaction with 8 life domains (*mental health*, *physical health*, *job situation*, *accommodation*, *leisure activities*, *friendships*, *relationship with family/partner*, and *personal safety*) and 3 treatment aspects (*medication*, *practical help*, and *meetings with professionals*). This is followed by a 4-step solution-focused approach to identify and harness the existing resources available to the patient to address these concerns and improve their quality of life. This tool was established as an effective intervention for adults with mental health problems following a sustained program of research including multiple clinical trials [17-19].

Within a cluster randomized controlled trial (RCT) conducted across 6 European countries, regular use of the initial form of DIALOG+ over a year led to a better quality of life, fewer unmet needs, and higher treatment satisfaction for patients with psychosis. Following further modifications, DIALOG+, delivered once per month over 6 months, was compared to an active control in a pragmatic RCT involving 49 clinicians and 178 patients diagnosed with psychosis. Patients in the experimental group had a significant improvement in quality of life and lower general psychopathological symptoms after 3, 6, and 12 months. They also had fewer unmet needs and a better objective social situation. The effect size for improvements in quality of life ranged from 0.30 (95% CI 0.02-0.58) at 3 months to 0.32 (95% CI 0.06-0.58) at 12 months. Furthermore, DIALOG+ saved the National Health Service £1345 (US $1610.16) per patient, mainly due to fewer inpatient days required by the experimental group [17-19]. However, research has not assessed whether the intervention may also be effective for adolescents with common mental disorders.

Study Aims and Objectives

This planned exploratory cluster RCT sits within the context of a larger research program called “Building resilience in adolescence - improving quality of life for adolescents with mental health problems in Colombia (BRiCs).” This is a collaborative project between Queen Mary University of London (London, the United Kingdom) and the Pontificia Universidad Javeriana of Bogota (Bogota, Colombia), which aims to improve health outcomes and quality of life for the adolescent population with depression and anxiety in Colombia. During the initial phase of the project, semistructured interviews and focus groups were conducted alongside a pilot study to adapt the existing intervention (DIALOG+) for use with adolescents [20]. The new intervention is called DIALOG-A.

Given this background, the overall aim of this study is to evaluate the effectiveness of DIALOG-A in the community treatment of adolescents with anxiety and depression in Colombia.

Methods

Study Design and Setting

A multisite, exploratory cluster RCT will be conducted to assess the effectiveness, acceptability, and feasibility of DIALOG-A for adolescents with anxiety or depression. In total, 18 clinicians and 108 adolescents will be recruited from primary health care services in Colombia and outcomes measured at baseline, 6 months, and 9 months following randomization.

XSL•FO
RenderX

The 3 sites included in this RCT in are based in 2 cities: Bogota and Duitama. Bogota is the capital city of Colombia, with 7.9 million inhabitants. Duitama, in contrast, is a small city of approximately 128,400 inhabitants in a rural location. Community mental health care is provided by primary health centers, which include an adolescent-friendly service. The population within Duitama is traditionally rural where poverty, alcohol intake, adult illiteracy, and family violence are common. Almost all the adolescents that use health services on this site belong to low socioeconomic status [21,22].

Participants

Inclusion Criteria

The inclusion criteria for clinicians will be as follows: (1) being aged 18 years or older, (2) having a medical qualification as a general practitioner or pediatrician, (3) having regular contact with adolescent patients with anxiety and depression, (4) having at least 3 months of experience in working with adolescents, and (5) having no plans to leave their current position within the next 6 months.

The inclusion criteria for adolescents will be as follows: (1) being aged 13 to 16 years; (2) currently experiencing anxiety and depression, which is defined as a cutoff score of ≥7 on the Self-Reporting Questionnaire [23]; and (3) having the capacity to provide informed assent.

Exclusion Criteria

The exclusion criteria for adolescents will be as follows: (1) having severe mental illness (psychosis, bipolar disorder, or schizophrenia), (2) having cognitive impairment or severe learning disability, and (3) being unable to speak and understand Spanish.

Recruitment and Informed Consent

Each study site will include a coordinator who will recruit the clinicians for the study. A research assistant will recruit the adolescents, guide all participants through the informed consent process, and assess the outcomes at 3 defined time points (baseline, 6 months, and 9 months post randomization). A wider administrative staff member will schedule the follow-ups and provide the clinicians' caseload to the research assistant to identify potential adolescent participants.

Clinicians

Each clinical site was identified from the national network of public and private primary care centers that provide care to the adolescent population of Colombia. An in-person meeting was arranged between the potential clinicians and study coordinators of each study site.

Eligible clinicians will provide their informed consent by signing and dating an electronic informed consent form via the Research Electronic Data Capture (REDCap) data management platform.

Adolescents

With the support of the administrative staff, research assistants will check each physician's caseload to identify adolescent patients who meet the inclusion criteria. Potentially eligible adolescents will be then invited to a one-on-one meeting with the local site's research assistant to discuss the study in more detail and answer any questions. This meeting will also be used to verify whether the inclusion criteria are met and to obtain informed assent and consent from the adolescents and their parents or guardians, respectively. During the study period, new referrals to the clinics will be screened for eligibility, and potentially eligible adolescents will be contacted by a research assistant.

Both the research team and the participants will keep a copy of the signed informed consent or assent form via REDCap. The researcher's contact details will be provided on the informed consent form to allow participants to raise any questions or concerns they may have throughout the study. This process will take place before any data collection begins.

Intervention

The enrolled clinicians will be contacted and invited to a web-based meeting on a free videoconferencing platform such as Zoom or Microsoft Teams with a researcher who will re-explain the objectives of the RCT and answer any questions or concerns that are raised.

Clinicians randomized to the intervention arm will use DIALOG-A with the adolescents once per month for 6 months. Clinicians allocated in this arm will receive a tablet, with the DIALOG-A app already preloaded. Each DIALOG-A session will last approximately 20 minutes and will take place face to face with the clinician. Where it is not possible for a face-to-face consultation to occur, a web-based consultation will be conducted in line with standard care procedures within the health care service. In each session, the clinician will ask the patient to rate all the domains on the DIALOG scale, which will then be followed by the 4-step solution-focused approach. After completing the 6-month intervention with the DIALOG-A app, clinicians and adolescents can continue using the intervention depending on their needs, and this will be documented and considered in the analysis.

Treatment-as-Usual Control

The intervention group will be compared to treatment-as-usual control. Clinicians in the control arm will follow the routine care provided for adolescents accessing primary care services. The frequency of the consultations during the duration of the RCT will vary depending on the clinical criteria of the respective clinician and the adolescent; however, this will be, on average, once per month.

Training and Supervision

All clinicians in the intervention arm will receive training in DIALOG-A through one-to-one web-based sessions with a researcher, which will take between 45 and 60 minutes. During these training sessions, clinicians are provided with reading material, instructions, and examples on how to use the DIALOG-A app with adolescents [24]. Clinicians can contact any member of the local research team for further sessions and for advice or support at any time of the RCT. Refresher training will be provided to clinicians in the intervention arm depending on their needs, with a minimum of 2 refresher sessions provided throughout the RCT.

XSL•FO
RenderX

All clinicians allocated to either the intervention or control arms will receive training in the diagnosis and treatment of adolescent depression and anxiety through an asynchronous web-based course. These training sessions include academic passages on anxiety disorders, mental health disorders related to trauma and stress, and mood disorders, which are developed by adolescent mental health specialists from Pontificia Universidad Javeriana. Clinical cases and discussion forums will be available as well. A final quiz with a minimum passing score of 80% must be completed by participating clinicians.

Randomization

To reduce the potential for contamination, the unit for randomization will be the clinician. Clinicians will be randomized 2:1 to either the intervention (12 clinicians:72 adolescents; to have DIALOG-A sessions once per month for 6 months) or to the treatment-as-usual control group (6 clinicians:36 adolescents; appointments scheduled as and when needed, without DIALOG-A or specific assessments). For existing patients, who are already on the caseload, adolescent participants will be recruited and baseline assessments conducted prior to their clinician being randomized. Individuals who are new to the service and are not on the existing caseload of a clinician will be randomly assigned to either the intervention or control arm and then to an appropriate clinician, following completion of the baseline measures. We will record the number of adolescent participants who are recruited and individually randomized.

Clinicians and adolescents will not be blinded to allocation due to the nature of the intervention. However, to reduce bias, randomization will be carried out by a blinded independent statistician at the Unit for Social and Community Psychiatry, Wolfson Institute of Population Health, Queen Mary University of London. Baseline data collection will occur before randomization, and all research assistants involved in outcome data collection will be blinded to allocation. We will additionally record the number of postrandomization recruits; for example, individuals who were recruited after their clinician has been randomized.

Proposed Sample Size

A formal sample size calculation was not conducted as the primary objective is to collect data required for a full trial protocol, including the information needed for sample size calculation. Estimates for adequate sample sizes for exploratory trials range from 24 to 50 per arm, with at least 30 individuals required to estimate the SD of the outcomes. This exploratory trial will include 108 patients to provide usable estimates from each site. Unbalanced 2:1 randomization favoring the intervention will ensure sufficient data about the experience with the DIALOG-A intervention. Randomization will be stratified by the site to include 12 clinicians at the 3 study sites in Bogota and 6 at the study site in Duitama to reflect differences in population size and available resources.

Quantitative Data

All participants (clinicians and adolescents) will be asked to complete a sociodemographic questionnaire at baseline. Clinicians will be asked to rate the Clinical Global Impression questionnaire after every appointment.

The primary outcomes will be collected at 6 months, with a further follow up of 9 months post randomization—these include symptoms of depression measured using the 8-item Patient Health Questionnaire [25] and symptoms of anxiety measured using the 7-item Generalized Anxiety Disorder scale [26].

All secondary outcomes will be collected at baseline, 6 months, and 9 months (unless otherwise stated)—these include quality of life measured using the Manchester Short Assessment of Quality of Life [27], mental health symptom levels measured using YP-CORE [28], social support measured using the Multidimensional Scale of Perceived Social Support [29], empowerment measured using the Youth Efficacy/Empowerment scale [30], self-esteem measured using the Rosenberg Self-Esteem Scale [31], and economic outcomes measured using a modified Client Service Receipt Inventory [32].

In addition to the outcome data described above, we will collect process measures, including the number of DIALOG-A interventions performed, the date and duration of those sessions, the scores obtained on the DIALOG scale within each session, key topics discussed during the 4-step approach, and what actions were agreed upon. The DIALOG-A app on the tablet is able to capture the data required. This information will be synchronized to a server that the research team can access.

Qualitative Data

A subset of adolescent participants (n=20) and all clinicians (n=12) randomized to the intervention arm will be invited to complete an in-depth qualitative interview after the 6-month assessments (time point at the end of the intervention period) to capture and discuss their experience of delivering or receiving DIALOG-A. Interviews will focus on the barriers and facilitators of attending intervention sessions, suggested adaptations, trial procedures, practical implementation in the study sites, and potential processes of change. These interviews will be audio-recorded, transcribed verbatim, and further analyzed.

Statistical Analysis

The analysis of data will be discussed and agreed upon with the local and international research teams, with a statistical analysis plan developed by the statistician and signed off by trial steering committee. The local research team will take a leading role in the management and analysis of the data. Data analysis will not be conducted prior to signing off and blinding of the members of the research team, including the statistician responsible for the analysis, who will remain blinded throughout.

Quantitative Data Analysis

The number of approached and screened participants, those who refused participation, and those who could not be contacted will be recorded. The analysis will assess the number of intervention sessions received by participants and will collect data on dropouts (including reasons for dropping out, if available) from treatment, which will inform the assessment of the acceptability of the DIALOG-A intervention.

XSL•FO
RenderX

Descriptive statistics will be reported for sociodemographic data for all participants. Nominal and ordinal data will be presented as proportions (frequencies), whereas continuous variables will be described using measures of central tendency and those of variability. The latter will be selected in accordance with observed data distributions (parametric or nonparametric), which will be evaluated through normality tests and histograms (probability functions). To assess the effectiveness of the intervention, means and SDs (or median and IQR values) over the 3 time points (baseline, 6 months, and 9 months) will be calculated, and analysis will test the significance of the differences between the means (or other parameters) of outcomes measured. The primary outcome will be the scores on the 8-item Patient Health Questionnaire and the 7-item Generalized Anxiety Disorder scale at 6 months. Mixed effects multivariable logistic regression analysis will be conducted to assess the effect of the intervention on the primary outcome, while controlling for clustering. A full analysis plan will be developed prior to data analysis, which will consider which covariates should be adjusted for in the model, along with methods for dealing with missing data. Quantitative data analysis will be conducted using Stata (version 17; StataCorp).

Qualitative Data Analysis

Qualitative data will be analyzed using thematic analysis following the guidance of Miles and Huberman and will be conducted using NVivo qualitative analysis software [33]. All interviews will be audio-recorded and transcribed verbatim. A researcher will remove all identifying information from the transcripts, including any references to patients, clinicians, or local services.

An inductive approach will be used to provide new insights and a richer understanding of the data without using preconceived categories. Two members of the research team will first familiarize themselves with the transcripts. Open coding will be used (making notes and headings in the text to describe the content). Similar codes will be grouped under themes, and the identified themes and subthemes will then be checked and refined. Interrater reliability in applying second-level codes (or categories) will be calculated for 20% of the data.

Reporting of Adverse Events

For this RCT, we will adopt the World Health Organization's definition for an adverse event: "Any untoward medical occurrence in a patient or clinical investigation subject administered a pharmaceutical product and which does not necessarily have to have a causal relationship with this treatment" [34]. Adverse events and the need for urgent safety measures are not anticipated.

Adverse Events

Any adverse events will be recorded in the main research file and in the participant's clinical records, if appropriate, and the participant will be followed up by the research team. We will establish an adverse event registration form based on REDCap in which research assistants can make a report of any adverse event for the RCT.

Serious Adverse Events

Serious adverse events are those that are "unexpected" and will be reported in accordance with the regulations of the research ethics committee (REC) and other relevant regulations in Colombia.

Urgent Safety Measures

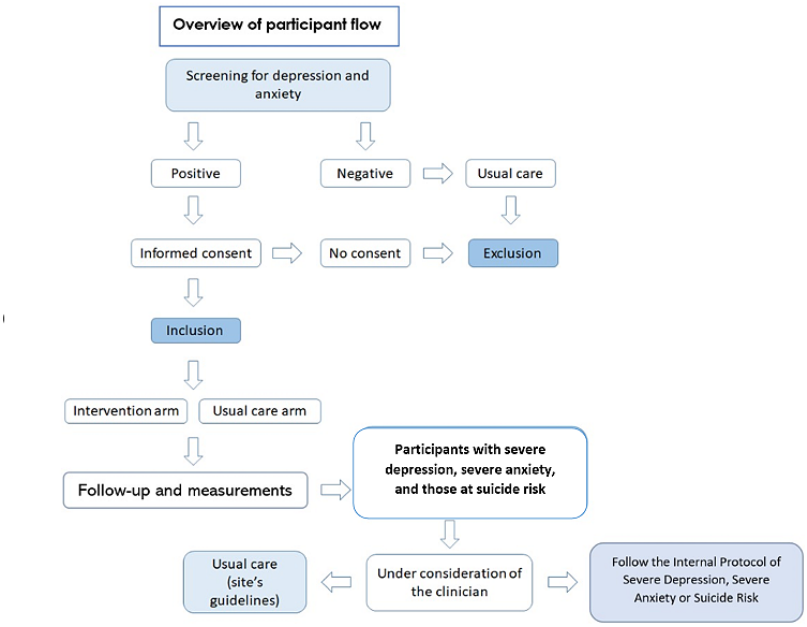
In the case of urgent safety measures being required, the local principal investigator (PI) will inform the UK PI and the REC of the event per the REC and other relevant requirements and guidelines.

Quarterly Safety Reporting

The local PI will send over quarterly reports as required by the REC, using their existing templates and guidelines. These will be additionally monitored by the international trial steering committee, who will assume the role of a data monitoring and ethics committee.

Overview of the Safety Reporting Responsibilities

The local PI will ensure that safety monitoring and reporting are conducted in accordance with the requirements of the REC and any other relevant organizations or institutions that are involved in overseeing and monitoring research activities in Colombia.



Safety and Suicide Risk Reduction

Participants who decline to participate but may have severe depression, severe anxiety, or are at a risk of suicide will be treated in accordance with each clinical site's procedures. For participants enrolled in the study who have been identified as having severe depression, severe anxiety, or being at a risk of suicide, the primary care physician will review and monitor the results of the screening. The participant will be managed in accordance with the primary care site's usual protocols and guidelines.

Additionally, if the participant meets the criteria for severe depression or anxiety, or is identified as being at risk of suicide, treatment may be either administered by or coordinated with a psychiatrist (in accordance with the Colombian clinical guidelines of best practices). According to the primary care physician, an optional case review could be performed by the academic psychiatrists involved in this study. Figure 1 summarizes the participant flow chart during the RCT.

XSL•FO
RenderX

Figure 1. Withdrawal from the study.

Withdrawing From the Study

During the consent process, researchers will ensure that participants are aware of their right to decline participation at any stage of the research and that withdrawing participation will not affect their treatment or rights. Participants who withdraw will be able to ask that their data be destroyed and removed from the database if their withdrawal occurs before the start of data analysis.

If participants withdraw from the study, the research team will ask permission to contact them to take part in the postintervention qualitative interview to capture valuable information regarding reasons for withdrawal, which might be associated with the intervention. This will be explained to participants during the consent process, and participants' decisions to not be contacted for the postintervention interview will be respected. Participants who wish to withdraw from the intervention will also be asked if they wish to attend the follow-up research assessments, and their decisions to not participate will be respected.

If a participant wishes to withdraw from the study, researchers will record the date of withdrawal and reasons for withdrawal (if provided).

Ethics Approval

This study received approval from the local REC at Pontificia Universidad Javeriana in Bogota (approval number FM-CIE-0084-20). Consent forms from the parents or guardians and clinicians and assent forms from the adolescents will be obtained prior to the start of the study. Any changes to the protocol will be communicated to and approved by the local institutional review board and patients as appropriate.

Dissemination

The aims and impact of the program will be achieved through a comprehensive communication plan, which will inform the different stakeholders of the research findings as well as provide information relating to each of the program outputs. This will ensure that the new knowledge obtained translates into improved health outcomes. Target audiences include (but are not restricted to) adolescents and young people, policy makers, service managers, nongovernmental organizations, education, health and youth organizations, charities, and the public. To promote broader capacity building and initiate wider collaborations, we aim to disseminate findings across Colombia and the wider network with which Javeriana University is linked, the Latin American Clinical Epidemiology Network (LatinClen); and an additional network that Javeriana University is linked with, which trains young researchers in community mental health care across South America (RedMaristan).

International Trial Steering committee

An international trial steering committee has been set up, and the final protocol was approved by this committee. Lead investigators (CG and VB) are nonindependent members, alongside 6 independent members from the United Kingdom and Colombia. CG is the principal investigator in Colombia and VB is the principal investigator in the United Kingdom. The trial steering committee will periodically review the progress of the study and have agreed to take on the role of the data monitoring and ethics committee.

Results

Trial recruitment was completed toward the end of October 2022, and follow-up is expected to last through October 2023. We anticipate the outcomes of the trial will be reported by mid-2023 and the follow-ups by early 2024. The primary outcomes will be changes in depression [25] and anxiety [26] symptoms and the secondary outcomes will include changes in quality of life [27], mental health symptom levels [28], perceived social support [29], empowerment [30], self-esteem [31], and economic outcomes [32]. Furthermore, we will report on dropout rates and adverse events which take place during the trial.

Discussion

Background

Depression and anxiety are leading causes of youth disability worldwide. This exploratory RCT will aim to repurpose an effective, low-cost intervention for the treatment of depression and anxiety in adolescence (DIALOG-A). The research focuses on Colombia where adolescents experience multiple stress factors such as internal displacement, violence, conflict, and deprivation. Improving the health outcomes of adolescents not only is a priority in its own right but also can aid the transferability of the intervention to other LMICs, where adolescents experience similar situations.

Strengths and Limitations

This study is the first to test the effect of DIALOG-A as a tool for use in primary care services for adolescents with depression and anxiety. One strength is the pragmatic design, which will enable us to adapt to the different logistics in the centers included in this RCT. One limitation, however, is that due to the characteristics of the intervention, blinding of the adolescent participants and clinicians will not be possible, which may result in the introduction of bias and a placebo effect. Additionally, the study is an exploratory study with unequal randomization (2:1 favoring the intervention). Although this will enable us to estimate potential interventions effects, a definitive trial will be needed to establish efficacy.

A potential benefit is that overall, the study has the potential to adapt a low-cost resource-orientated intervention for use in a vulnerable adolescent population. Additionally, for adolescents who will be involved in the testing of the modified intervention (DIALOG-A), this might lead to improved quality of life, social functioning, and symptoms. The RCT will also benefit the clinicians involved as they will be provided with training and supervision to enable them to implement the intervention. If results are successful, DIALOG-A can be implemented in the routine care of these adolescents in Colombia as it does not need the setting of new services or restructuring of preexisting organizations and is of low cost.

Acknowledgments

This study is funded by the Medical Research Council of the United Kingdom, the National Institute for Health Research of the United Kingdom, and UK aid (grant MR/S023674/1). These funding sources had no role in the design of the study and will not have any role in its conduction, interpretation, or dissemination.

Data Availability

Data will be available upon reasonable request. The approved consent forms did not specify that the data would be deposited in a public repository; hence, we will be unable to deposit the data. The deidentified participant data set will be made available from the corresponding author (VB, v.j.bird@qmul.ac.uk) upon reasonable request and subject to a data sharing agreement.

Authors' Contributions

VB, LO, and CG conceptualized the study. VB, DS, JR, and MR drafted the paper. All authors contributed to the refinement of the study protocol and approved the final version. All authors share responsibility for the submitted and published version. VB and CG obtained the funding for the study.

Conflicts of Interest

None declared.

Abstract

Background: Nondaily smoking is a widespread, increasingly prevalent pattern of smoking, particularly in ethnic minority and vulnerable populations. To date, no effective treatment approach for this type of smokers has been identified.

Objective: This study aims to use a randomized controlled trial to evaluate proof-of-concept markers of the Smiling instead of Smoking (SiS) app, a smoking cessation smartphone app designed specifically for nondaily smokers. This app was developed iteratively and is now in its third version. Previous studies have demonstrated acceptability and feasibility when participants were onboarded in person (study 1) and remotely (study 2) and showed within-person changes in line with hypothesized mechanisms of change. This is the first randomized test of this app.

Methods: In total, 225 adult nondaily smokers will be asked to undertake a quit attempt while using smoking cessation support materials for a period of 7 weeks. Participants will be randomized to use the SiS smartphone app, the National Cancer Institute smartphone app QuitGuide, or the National Cancer Institute smoking cessation brochure "Clearing the Air." Participants will take part in a 15-minute scripted onboarding phone call during which study staff will introduce participants to their support materials. Survey links will be sent 2, 6, 12, and 24 weeks after the participants' initially chosen quit date. The primary outcome is self-efficacy to remain abstinent from smoking at treatment end, measured using the Smoking Self-Efficacy Questionnaire. Secondary outcomes cover several domains relevant to treatment development and implementation: treatment acceptability (eg, satisfaction with smoking cessation support, measured using the Client Satisfaction Questionnaire, and app usability, measured using the System Usability Scale); treatment feasibility (eg, measured using the number of days participants used the SiS or QuitGuide app during the prescribed treatment period); and, in an exploratory way, treatment efficacy assessed using self-reported 30-day point prevalence abstinence.

Results: Recruitment began in January 2021 and ended June 2022. The final 24-week follow-up was completed in January 2023. This trial is funded by the American Cancer Society.

Conclusions: This study is designed to test whether the prescribed use of the SiS app results in greater self-efficacy to abstain from smoking in nondaily smokers than commonly recommended alternative treatments and whether the SiS app treatment is

XSL•FO
RenderX

acceptable and feasible. Positive results will mean that the SiS app warrants testing in a large-scale randomized controlled trial to test its effectiveness in supporting smoking cessation in nondaily smokers. The design of this study also provides insights into issues pertinent to smoking cessation smartphone app treatment development and implementation by measuring, in a randomized design, markers of treatment satisfaction, engagement with the technology and content of the treatment, and adherence to the treatment plan.

Introduction

Background

Cigarette smoking remains the number 1 cause of preventable disease and death in the United States, responsible for 16 million current cases of smoking-related diseases [1]. Although the prevalence of smoking has steadily declined over the past few decades, in part because of expansive public health efforts, taxation and indoor smoking policies, and accessibility to evidence-based cessation tools, the prevalence of nondaily smoking is steadily increasing. Currently, 25.4% of all adult smokers are nondaily smokers, a jump from 20.2% in 2008 [2]. Nondaily smoking has been a recognized public health issue for >10 years [3], yet the knowledge gap about treating nondaily smokers has remained largely unchanged, presenting a significant barrier to supporting this growing population of smokers in their cessation efforts [4]. However, knowledge has been gained that underscores the urgency of addressing nondaily smoking.

First, the detrimental health impact of nondaily smoking has now been clearly demonstrated. Nationally representative data have shown that, despite smoking a low number of cigarettes per month, nondaily smokers are exposed to substantial concentrations of carcinogenic nitrosamines [5]. Individuals who smoke as little as 6 to 10 cigarettes per month have a higher all-cause mortality risk than never smokers [6]. For individuals who smoke 11 to 30 cigarettes per month, the mortality risk compared with never smokers increases by 72%, and the median life expectancy decreases by 5 years [7]. Nondaily smokers are also at greater risk of cancer, heart disease, and respiratory disease [6].

Second, nondaily smoking is disproportionally prevalent in disadvantaged and vulnerable groups. Nondaily smoking is consistently highest among non-Hispanic Black individuals [8,9]. Nondaily smoking is also increasingly prevalent among adults with mental health and substance use problems [10], 2 groups with substantially higher smoking prevalence rates (35.8% in adults with serious psychological distress [11] and 65%-87% in individuals with substance use disorders [12]) than the general population (15.5%) [11]. Thus, failure to address nondaily smoking contributes to and further widens existing health disparities.

A promising method of engaging and meeting the needs of nondaily smokers are smartphone apps. Nondaily smokers are motivated to quit smoking, more so than daily smokers [13-15], with more recent and planned cessation efforts [14,16-18]. However, similar to daily smokers, nondaily smokers frequently fail in their quit attempts [19], demonstrating their need for smoking cessation support. Traditional treatment options fail to appeal to nondaily smokers, as evidenced by their lower rates of seeking or receiving formal smoking cessation treatment [13,14,20,21]. For nondaily smokers, many of whom resist labeling themselves as *smokers* [22-24], smartphone apps represent a low-barrier method for receiving smoking cessation support that invokes less treatment resistance than more traditional smoking cessation treatments [20].

Smartphone apps for smoking cessation have been increasingly prolific in recent years. Currently, there are an estimated 490 English-language smoking cessation apps on the market, downloaded an estimated 33 million times [25]. Despite this high number, a systematic review conducted in Australia found only 6 “high quality” smoking cessation smartphone apps [26]. None of these 6 identified apps specifically addressed nondaily smoking. A recent Cochrane review identified 5 randomized controlled trials (RCTs) on smoking cessation smartphone apps [27]. None of these tested apps addressed nondaily smoking.

To address this need, our team developed a smoking cessation smartphone app specifically for nondaily smokers, the “Smiling instead of Smoking” (SiS) app. Building on research that found that nondaily smokers did not view nicotine addiction as relevant to their efforts to quit but instead viewed themes related to a positive self-identity and wellness as more important [28], we built an app that focused on fostering the experience of positive emotions. This treatment approach was inspired by the development of positive psychotherapy for smoking cessation [29,30]. The app’s overall conceptual model, as described elsewhere [31,32], is based on Social Cognitive Theory [33], in which goal setting, self-efficacy, and knowledge are leveraged to support behavior change.

Our app development plan entailed a staged process consisting of 3 studies. In study 1, we tested feasibility and acceptability in a local sample of nondaily smokers [31]. In this study, nondaily smokers interacted with study staff in in-person meetings, both during onboarding to the app and 3 weeks after the prescribed app use period ended. The feedback gained from

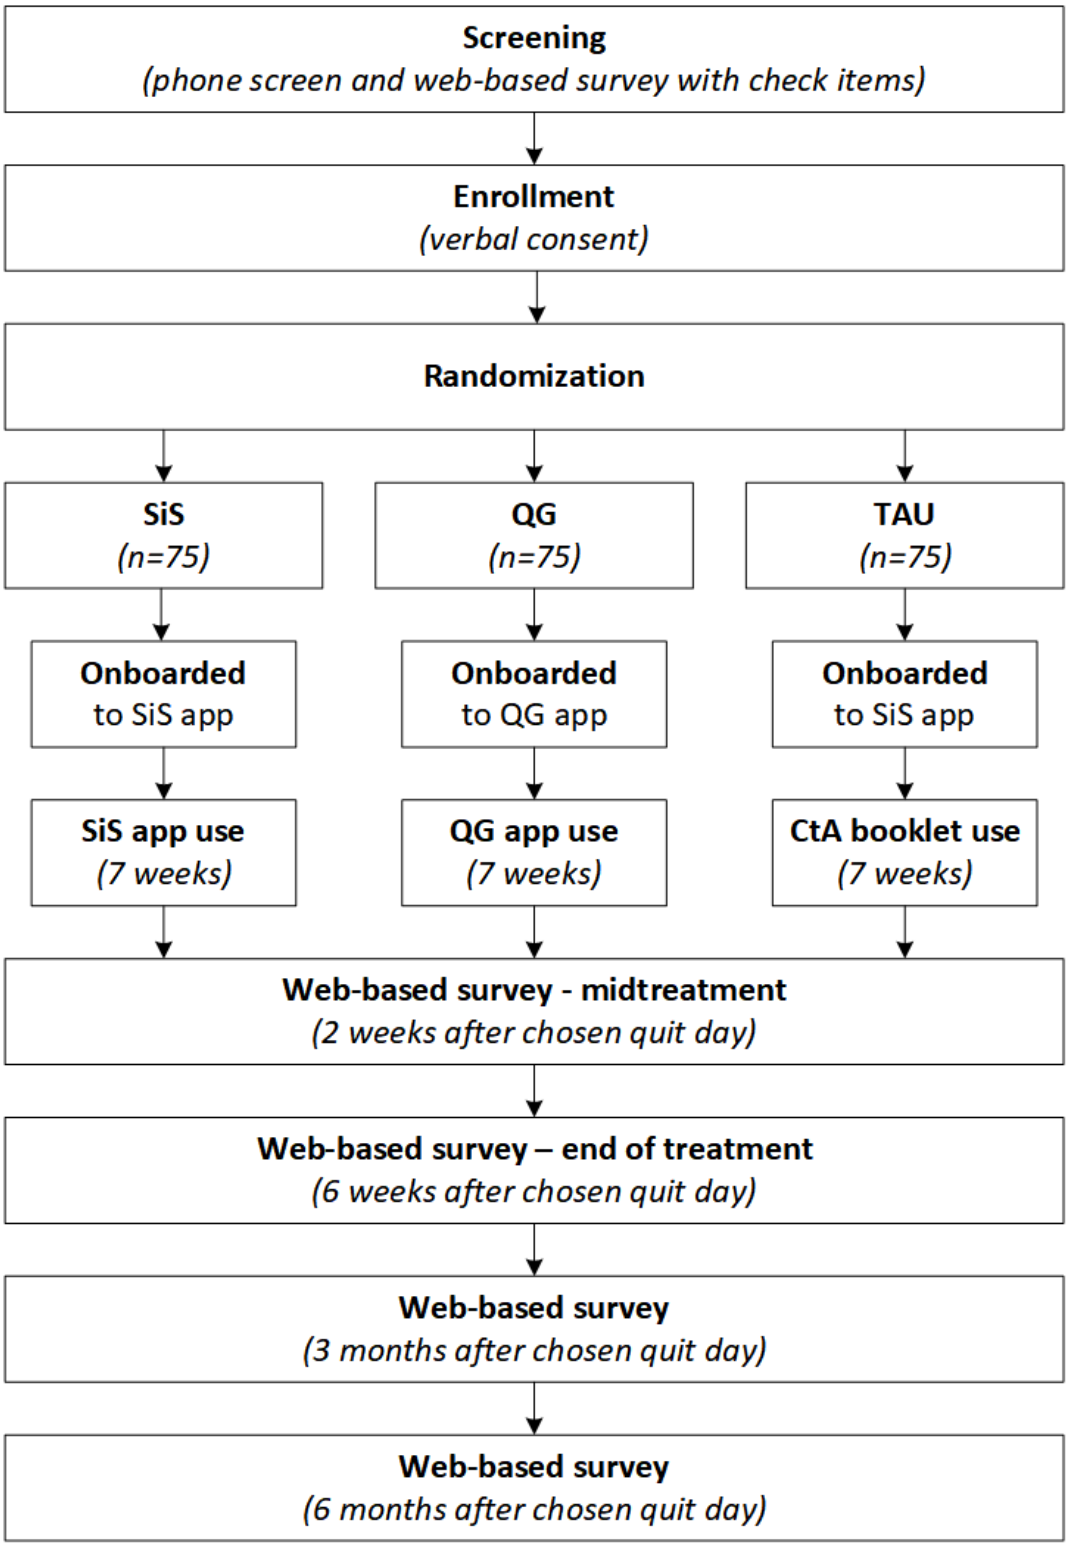
XSL•FO
RenderX

the study participants was used to make modifications to the app. In study 2, the feasibility and acceptability of version 2 of the app were tested, this time in a completely remote setting with nondaily smokers recruited nationwide [34]. Again, insights gained during this study were used to modify the app. In both studies, app use was high and sustained throughout the treatment period. Participants rated the app favorably in terms of its ease of use and usefulness. Longitudinal surveys demonstrated increases in the hypothesized direction for the underlying mechanisms of behavior change (ie, increased confidence, decreased urge to smoke, and less positive perceptions of smoking). Long-term self-reported abstinence rates were high (ie, 53% and 56% of the participants reported 30-day point prevalence abstinence at the 6-month follow-up in studies 1 and 2, respectively) [31,34]. These data supported the investment in a randomized trial.

Objectives

This study is study 3, which is a proof-of-concept RCT designed to test whether the SiS app successfully affects an early marker of smoking cessation success, namely, self-efficacy to abstain from smoking. We chose self-efficacy as our primary outcome variable as it is a causal component in many health behavior change theories and has been shown to be the primary mediator of conferring benefit in another mobile health (mHealth) intervention for smoking cessation, an SMS text messaging intervention [35]. The primary aim is to test for differences between randomized groups on the primary outcome, self-efficacy to remain abstinent, as measured at the end of treatment using the Smoking Self-Efficacy Questionnaire (SEQ-12) [36]. Self-efficacy to remain abstinent is hypothesized to be greater among participants in the SiS condition compared with 2 different but clinically relevant control conditions: the National Cancer Institute (NCI) smartphone app QuitGuide and the NCI smoking cessation brochure "Clearing the Air." The QuitGuide app was chosen as a comparator as it is a widely used, publicly available smoking cessation app that is part of the best-practice recommendations for treating smokers in the health care setting. Thus, it is a credible control for using a smoking cessation smartphone app. It controls for time, attention, and modality of delivery of smoking cessation support. Clearing the Air was chosen as an additional comparator as, to date, there is no evidence to demonstrate that QuitGuide confers smoking cessation benefits. Although widely used and endorsed, QuitGuide has never been tested against a treatment-as-usual (TAU) control condition. Thus, by including the Clearing the Air group in the design, this RCT tests whether app support provides better smoking cessation support than the standard of care and, if so, whether the SiS app does so more effectively than the QuitGuide app. The secondary aim is to test for differences between randomized groups on secondary outcomes pertaining to treatment acceptability; treatment feasibility; and, in an exploratory way, treatment effectiveness in terms of smoking cessation outcomes. Also measured were the impacts on secondary proof-of-concept efficacy markers: positive affect, desire to smoke, and attitudes toward smoking.

Methods



Overall Trial Design

Figure 1 shows the flowchart of this trial. This trial is a 3-group, randomized, fully remote, nationwide study. The trial aims to assess the efficacy of the SiS app version 3 in increasing smoking cessation self-efficacy in nondaily smokers compared with 2 control conditions representing current standards of care for providing low-barrier smoking cessation support. Participants in all treatment conditions will be asked to undertake a quit attempt while using smoking cessation support materials for a period of 7 weeks—1 week before and 6 weeks following their chosen quit date. Participants will be randomized to be onboarded to 1 of 3 conditions: the SiS smartphone app version 3, the NCI smartphone app QuitGuide, or the NCI brochure "Clearing the Air." The onboarding process is an approximately 15-minute–long scripted phone call during which study staff will guide participants through how to use SiS, QuitGuide, or Clearing the Air. The script is time-matched across conditions. In all 3 groups, the script covers setting the quit date, logging cigarettes, identifying triggers and strategies for those triggers, and managing challenging times. The onboarding process will conclude with study staff instructing participants to use SiS, QuitGuide, or Clearing the Air for the next 7 weeks.

Follow-up assessments are conducted via web-based surveys administered via REDCap (Research Electronic Data Capture; Vanderbilt University) [37] 2, 6, 12, and 24 weeks after the chosen quit date. Survey completion is remunerated at up to US $25 for the 2-, 12-, and 24-week survey (US $10 if check items are responded to incorrectly; these items are interspersed throughout the survey and ask participants to use the survey interface to indicate specific answers, eg, "Please set the slider to '0' to indicate 'not at all confident'") and US $50 for the 6-week survey, which is longer than the other surveys. The primary end point for this proof-of-concept RCT is end of treatment (ie, 6-week follow-up). The primary outcome is self-efficacy to remain abstinent from smoking, as measured by the SEQ-12 [36]. Secondary outcomes are shown in Table 1.

Ethics Approval

This protocol is consistent with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist [38]. This study was registered with ClinicalTrials.gov (NCT04672239) and approved by the Mass General Brigham Institutional Review Board (protocol 2020P003466).

Trial Participants

Participants who meet all inclusion criteria and pass the screening process will be included in the trial. The eligibility criteria are (1) age of ≥18 years, (2) smartphone ownership

XSL•FO
RenderX

(Android or iPhone only), (3) current nondaily smokers who smoke at least weekly and no more than 25 out of the past 30 days, (4) lifetime history of having smoked ≥100 cigarettes, (5) willingness to make a smoking quit attempt as part of this study, and (6) currently residing in the United States. The screening process entails a screening phone call with study staff during which the eligibility criteria are assessed, followed by a web-based survey containing check items that test that screening participants are able to complete web-based surveys. Incorrectly completed check items render a participant ineligible for the study. Under unusual circumstances (eg, a participant reports a technical glitch to the study team), the study team will review the survey to evaluate the time spent on the survey and consistency of survey responses across phone-screen answers and the survey and across measures and, if consistent, may proceed with enrollment of the participant. Participants will also be required to provide contact information for 1 to 2 contacts who can assist study staff in locating participants for follow-up surveys. After screening, study staff will ask screening participants to choose their smoking cessation quit date. Study staff will then schedule the study enrollment call to occur 8 days before this date. Consent is obtained verbally during the enrollment phone call after nondaily smoking status is once again confirmed. A total of 225 nondaily smokers will be enrolled and randomized. To ensure adequate representation of racial and ethnic minorities, we will close enrollment to non-Hispanic White participants when 54.2% (122/225) of the planned total sample size have been enrolled as, nationwide, 54% of nondaily smokers are non-Hispanic White as per the 2014 National Health Interview Survey [39].

Randomization

Eligible participants will be randomly allocated in a 1:1:1 ratio to the 3 treatment conditions: SiS, QuitGuide, and Clearing the Air. Randomization is done using the PROC PLAN procedure in the SAS statistical software package (SAS Institute) with a block size of 4.

Treatment and Control Conditions

Participants in all treatment conditions are instructed to use the provided smoking cessation materials (ie, SiS, QuitGuide, or Clearing the Air) for 7 weeks starting on the day of their onboarding. They are also informed that they may use any additional smoking cessation support that they would like to use during this time.

Treatment Condition: SiS Smartphone App

Participants randomized to the treatment condition will use version 3 of the SiS smartphone app. We will first describe the app in its current form and then describe the ways in which version 3 differs from version 2. Adjustments that were made in transitioning from versions 1 to 2 are detailed in the study 2 outcome paper [34].

The SiS app is a smartphone app that engages participants in positive psychology exercises (Figure 2) and smoking cessation activities (Figure 3). It is part of an emerging generation of smoking cessation smartphone apps that provide smoking cessation tools within a specific therapeutic approach (eg, acceptance and commitment therapy [25,40]). In our case, the focus is on maintaining positive affect. Reduced positive affect during smoking cessation is a common experience of substantial magnitude [41]. The use of the SiS app seeks to offset this effect as experiencing positive affect during the process of smoking cessation is related to increased self-efficacy to abstain from smoking [42], decreased desire to smoke [43,44], and greater readiness to process self-relevant health information [45]. Engaging in positive psychology exercises is also pleasurable and, thus, may be a particularly effective way to keep users engaged with the app [31,34].

Each day, participants are asked to complete a positive psychology habit-building exercise. The goal of completing these exercises is for participants to develop a habit of noticing and savoring the positive experiences they encounter in everyday life. The app selects 1 of 3 exercises each day at random (ie, "3 Good Things," "Rose, Thorn and Bud," and "Savoring," as tested in prior work) [46]. If they have not completed this exercise by 7 PM, the app sends a push notification with a reminder to do so. App users are also encouraged to engage in a happiness-boost activity throughout the day as needed. The goal of the boost activity is to serve as a "rescue" activity during moments of craving or particularly low positive affect. Completing these activities is meant to provide a momentary boost in positive affect. To provide variety, the app randomly selects 1 of 11 possible happiness-boost activities each day as derived from the positive psychology literature. This differentiation between habit-building and boost activities was introduced in version 3. In version 2, there was a total of 5 happiness exercises. In study 2, participants commented that they would like to have more variety. Thus, in version 3, we limited the daily exercises to the 3 activities most suitable for habit-building and offered more variety through the introduction of boost activities. Throughout the app, information is provided to explain why participants are asked to complete positive psychology activities while quitting smoking, including through a feature called "Owl Wisdoms," which are push notifications that provide participants with relevant findings from the literature.

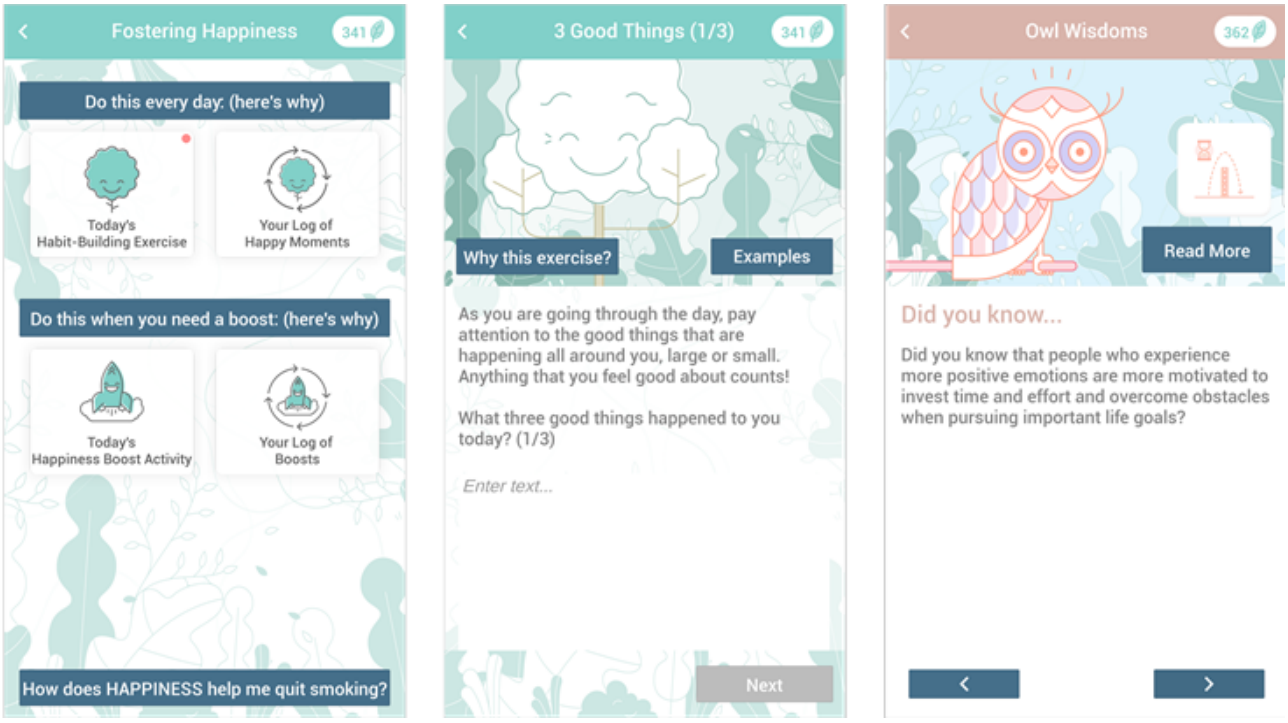
The smoking cessation content of the app is presented through the use of a number of app tools (Figure 3). The tools and information are in line with clinical practice guidelines for smoking cessation (ie, United States Clinical Practice Guidelines) [47] and are presented in a way that conforms to published recommendations for smoking cessation apps [48]. Each day, participants are asked to log their cigarettes or confirm that they were smoke-free. When participants log cigarettes, they are asked to indicate their reason for smoking by choosing from a list of common triggers or writing in their own response. After participants log cigarettes, they have access to a pie chart that offers personalized strategies matching their smoking triggers. Every 2 to 3 days, participants receive a push notification to complete a specific activity within the app that focuses on smoking cessation, called a "Behavioral Challenge." The timing of the "Behavioral Challenges" is anchored on the resettable quit date that participants specify in the app so as to provide participants with temporally appropriate smoking cessation activities as they progress. These "Behavioral Challenges" guide participants through the app's smoking

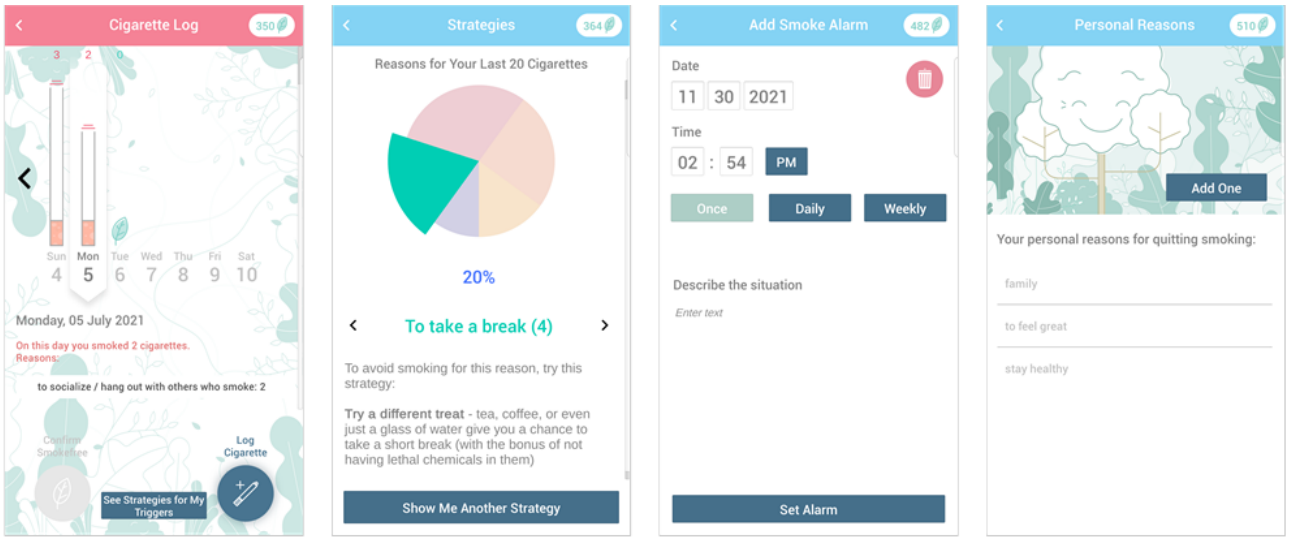
XSL•FO
RenderX

cessation tools, which enable setting reminders, note keeping (ie, personal reasons for quitting), and using distractions to get through moments of craving (ie, a game called "Magma Bear") and provide information on the benefits of quitting smoking. For example, 5 days before their chosen quit date, participants receive a push notification to write down their personal reasons for quitting smoking; 2 days before the chosen quit date, they are asked to look at the pie chart of their triggers for smoking.

To make it easy for participants to remember what they should do on a given day, the SiS app version 3 provides an overview of all tasks required that day in a feature called "Today's Tasks" (Figure 4). This feature was added based on secondary data analyses of app use data collected during the SiS study 2 [49]. Results indicated that participants completed the assigned tasks with a relatively high completion rate (57% of behavioral challenges and 45% of daily happiness exercises). Tasks that were offered but not required were rarely completed (on <7 days). These findings suggested to us that prescriptive clarity may enhance app engagement and, thus, in SiS version 3, we incorporated a tool that enhances prescriptive clarity.

Figure 2. Screenshots of Smiling instead of Smoking version 3. The app prompts users to complete 1 happiness habit-building exercise every day and try out a happiness-boost activity, as needed. Information is provided throughout the app to explain the relevance of the positive psychology activities, including through a science-oriented feature called "Owl Wisdoms".





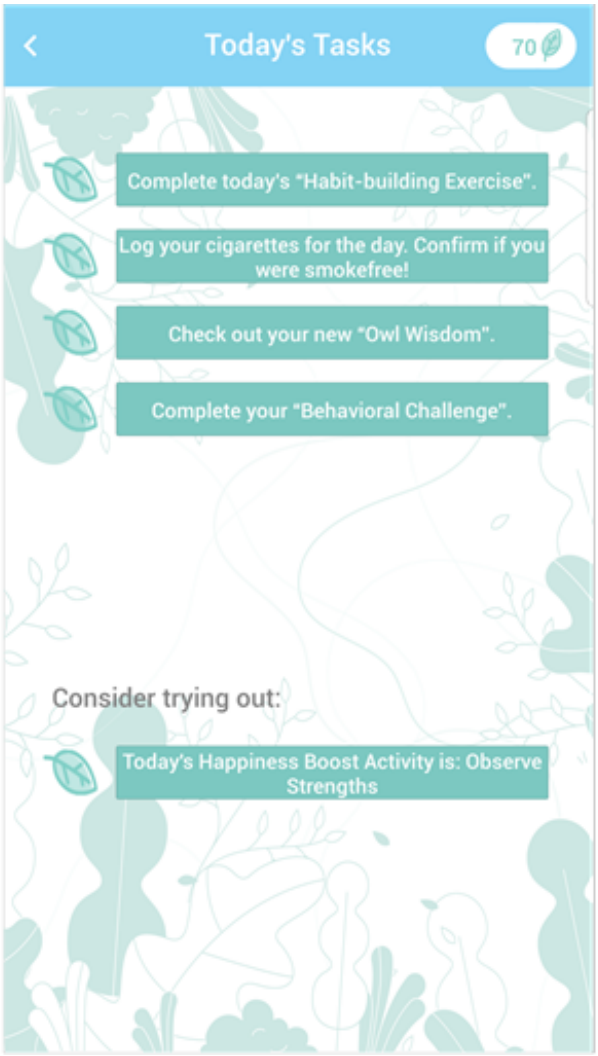


Figure 3. Screenshots from Smiling instead of Smoking version 3. While engaging in positive psychology content, app users are also prompted to complete smoking cessation activities within the app, including logging their cigarettes, which generates feedback on strategies for their triggers, and setting reminders to stay smoke-free, which reminds participants of their own personal reasons for quitting smoking.

Control Condition 1: NCI "QuitGuide" Smartphone App

Participants randomized to this control condition will use the NCI "QuitGuide" smartphone app. This smartphone app is 1 of 2 smartphone apps that the NCI currently has publicly available for use on their Smokefree.gov website. Referral to this website is recommended for treating smokers in health care settings [50]. QuitGuide is frequently used as a comparison app in smartphone app smoking cessation studies [40,51-55]. Although QuitGuide was not developed specifically for nondaily smokers, it targets both nondaily and daily smokers (ie, when downloading the app, users are asked to specify their smoking pattern, which includes both nondaily and daily patterns of smoking). Some SiS features have direct analogs in QuitGuide; others do not. The onboarding script leads QuitGuide users through the QuitGuide content in the same order as for SiS to the degree possible—setting the quit date (SiS and QuitGuide), happiness-promoting activities versus tracking mood and craving (SiS vs QuitGuide, respectively), guidance on quitting (via behavioral challenges in SiS vs "Learn to Quit" information in QuitGuide), logging cigarettes (SiS and QuitGuide), strategies for smoking triggers (pie chart in SiS and various graphs in QuitGuide), setting reminders (time-based in SiS and time- and location-based in QuitGuide), and as-needed tools (happiness-boost activities and suggested strategies in SiS vs tips in response to reporting craving or negative affect in QuitGuide). This control condition controls for time, attention, and modality of delivery of smoking cessation support.

Control Condition 2: NCI "Clearing the Air" Brochure

Participants randomized to this control condition will use the NCI booklet "Clearing the Air" [56]. This booklet has been used as a "treatment as usual" comparison condition in past RCTs evaluating phone-based mHealth smoking cessation technologies (ie, SMS text messaging). It remains a standard-of-care smoking cessation treatment today. Similar to SiS and QuitGuide, it is a low-barrier option for offering smoking cessation support. Unlike SiS and QuitGuide, it offers this support in a widely accepted booklet format rather than via mobile technology. During the scripted onboarding call, study staff will lead participants through the booklet's content in the same order as implemented in the SiS behavioral challenges (ie, reflecting on reasons to quit, informing about the benefits of quitting, logging smoking and its triggers, and formulating strategies for dealing with triggers). By comparing with this control group, it can be tested whether the SiS app provides an advantage over the currently existing standard of care. This is an important question for implementation.

XSL•FO
RenderX

Measures

Primary Outcome Measure

Although, ultimately, the goal of engaging with a smoking cessation smartphone app is smoking cessation, we chose a process indicator toward that goal as the primary outcome of this proof-of-concept RCT. Namely, we selected self-efficacy to abstain from smoking as a process indicator of subsequent smoking cessation. Self-efficacy has been identified as the primary mediator through which an SMS text messaging intervention conferred smoking cessation benefits. Similar to our study, the latter trial used the "Clearing the Air" booklet as the control condition and showed that self-efficacy observed 1 month after the chosen quit date mediated group differences in smoking cessation at the 6-month follow-up [35]. In this study, self-efficacy to abstain from smoking will be measured using the SEQ-12 [36], a 2D 12-item self-report scale measuring a person's confidence in their ability to abstain from smoking when facing internal stimuli (eg, feeling depressed) and external stimuli (eg, being with smokers) on a 0 to 100 slider scale (ie, 0=*not at all confident that I can refrain* to 100=*extremely confident that I can refrain*). Scale scores are created by averaging across items and range from 0 to 100. Higher scores indicate greater self-efficacy to abstain from smoking.

Secondary Outcome Measures

This is the first randomized trial to evaluate the SiS app. As this is a proof-of-concept trial, our secondary aims cover several domains: treatment acceptability; treatment feasibility; and, in an exploratory way, treatment efficacy in terms of smoking cessation outcomes.

Treatment Acceptability

As an overall measure of treatment acceptability, we will assess participants' satisfaction with the smoking cessation support they will receive as part of the study. To this end, we will use the widely used Client Satisfaction Questionnaire. [57]. For this study, and with permission, we adjusted the wording of the introduction to this scale to clarify that the items refer to the smoking cessation support received as part of participating in this study. The wording of the 8 items will be used verbatim (eg, "How satisfied are you with the amount of help you received?"). Scores are summed across items and range from 8 to 32, with higher scores indicating greater satisfaction. For the 2 randomized groups using an app (SiS and QuitGuide), we will also assess the satisfaction with the apps from a technical standpoint. To this end, we will use the 10-item System Usability Scale, [58], as used in other studies on smoking cessation smartphone apps [59,60]. This 10-item scale provides a global view of subjective assessments of usability. To make clear that we are seeking feedback on the app and not on other aspects of the study, we have replaced the phrase "this system" (original scale) with "app" (modified scale; eg, "I found the app unnecessarily complex" 5-point Likert scale: 1=*strongly disagree* to 5=*strongly agree*). Scale scores range from 0 to 100, with greater scores indicating a more favorable perception of the usability of the app. To obtain an overall summary impression combining technical issues and smoking cessation support satisfaction, the survey will also include 2 stand-alone items: "How satisfied are you with the smoking cessation support this app provided you with?" (5-point Likert scale: 1=*very unsatisfied*, 2=*somewhat dissatisfied*, 3=*neither satisfied nor dissatisfied*, 4=*somewhat satisfied*, and 5=*very satisfied*) and "How much did you like using the smoking cessation app we asked you to use?" (5-point Likert scale: 1=*I strongly disliked using the app*, 2=*I somewhat disliked using the app*, 3=*I neither liked nor disliked using the app*, 4=*I somewhat liked using the app*, and 5=*I strongly liked using the app*). These scales and items will be assessed only once, at end of treatment (week 6).

Treatment Feasibility

To assess treatment feasibility, we will assess processes that are relevant across all 3 randomized groups and issues that are specific to app use. For all 3 groups, the end-of-treatment survey (week 6) will include scales to assess the degree to which participants applied the smoking cessation content delivered during treatment and the degree to which they practiced the type of positive psychology habits taught in the SiS app. Our hypothesis is that participants randomized to SiS will use taught smoking cessation strategies at least comparably with those in the QuitGuide and Clearing the Air groups and will use positive psychology strategies more frequently than QuitGuide and Clearing the Air participants, who are not taught these skills. We will assess the use of smoking cessation strategies using a list of 19 items developed for another randomized trial on smoking cessation [30]. Participants rate their agreement with statements about the support they received (eg, "I used the Smiling Instead of Smoking app/QuitGuide app/Clearing the Air pamphlet [logic-branched by treatment group] the way I was supposed to (in the days leading up to and following my quit attempt)") and the things they did while quitting (eg, "I avoided situations that would make me want to smoke"). Items are rated on a 5-point Likert scale (1=*strongly disagree* to 5=*strongly agree*). Higher scores indicate greater use of smoking cessation strategies. This scale also included items that referred to the positive psychology content of the intervention (eg, "I told myself that quitting smoking would eventually improve my moods, not make them worse" and "I focused on the good things that happened each day"). To assess the use of positive psychology techniques more directly, we will also use the Appreciation Scale [61]. This 18-item scale assesses the frequency with which one engages in thoughts and actions to heighten awareness of the blessings in one's life (eg, "I enjoy the little things around me like the trees, the wind, animals, sounds, light, etc.," rated on a 7-point frequency scale: 1=never to 7=more than once a day) and the degree to which one feels appreciative (eg, "I recognize and acknowledge the positive value and meaning of events in my life," rated on a 7-point agreement scale: 1=strongly disagree to 7=strongly agree). The score is created by sum scoring, with higher scores indicating a more appreciative mindset. As a subjective evaluation of the received treatment, participants will be administered 17 items to assess the impact of the treatment they received. The stem of the items is "The 'Smiling Instead of Smoking app, QuitGuide app, or Clearing the Air pamphlet [logic-branched by treatment group]..." which is followed by possible impacts (eg, "...gave me confidence that I can quit smoking," "...made me think it

XSL•FO
RenderX

was worthwhile for me to quit," and "...helped me stay positive while quitting"). The same items were used to evaluate version 2 of the SiS app [34]. These scales and items will be assessed only once, at end of treatment (week 6). Finally, 1 treatment feasibility item will be administered in multiple surveys (weeks 6, 12, and 24). This item seeks to assess the degree to which participants engaged with the provided smoking cessation materials: "*During this past week, how much time did you spend applying or contemplating the content of the SiS app, QG app, or 'Clearing the Air'*?" (in minutes).

Regarding app use (SiS and QuitGuide groups only), passive data recording will be used that time-stamps each action participants take in the app. For QuitGuide, we will receive these data from the Smokefree.gov team. From these data, we will calculate the number of days the participants used the app during the treatment period. As objective reality and subjective experience can differ, the surveys will also ask participants to self-report app use. At week 2, they will be asked to report the number of days they used the app during weeks 0, 1, and 2. At week 6, they will be asked to report the number of days they used the app during weeks 3, 4, 5, and 6. In addition, they will be asked to self-report how many minutes per day they used the app.

Exploratory Treatment Effectiveness Outcomes

All surveys will include items to assess self-reported 30-day point prevalence abstinence. Participants will be asked the following—"what is your current smoking status?"—with the following options: "I smoke daily," "*I smoke non-daily (and have smoked in the past 7 days),*" "*I smoke non-daily (but have NOT smoked in the past 7 days),*" and "*I do not smoke at all.*" If a participant reports abstinence, they will then be asked, "have you been abstinent during the past 30 days?" (yes or no). If a participant does not report abstinence, they will be asked to indicate how many cigarettes they smoked over the past 7 days. From these data, we will code a binary indicator for self-reported 30-day point prevalence abstinence (yes or no) and calculate an indicator of cigarette reduction by subtracting the total number of cigarettes smoked in the week before baseline from the total number of cigarettes smoked in the past week.

Exploratory Outcomes (ie, Secondary Proof-of-concept Efficacy Outcomes)

Overview

As our secondary outcomes spanned several domains, including acceptability, feasibility, and exploratory estimates of gold-standard effectiveness markers, we designated secondary proof-of-concept efficacy outcomes as exploratory outcomes. Similar to our primary outcome, these outcomes measure constructs that, according to our conceptual model, should be affected by treatment and, in turn, should affect long-term smoking cessation. All these measures are self-report measures and are included in every survey. As proof-of-concept process markers, the primary end point of interest is the end of treatment. Treatment effects are hypothesized to have occurred at that point, with the hope that these impacts translate into subsequent smoking cessation success.

Positive Affect

The SiS app is designed to offset expected decreases in positive affect as smokers undertake a quit attempt [41]. Thus, if successful, positive affect should be higher among participants randomized to the SiS group by treatment end. To measure positive affect, we will use the 20-item Positive and Negative Affect Schedule [62]. Participants are given a list of 20 adjectives (eg, interested or distressed) and asked to rate to what extent they have experienced these states over the past week. Rating options range from 1 to 5 (1=*very slightly or not at all* to 5=*extremely*). A total of 10 items measure positive affect (ie, attentive, interested, alert, excited, enthusiastic, inspired, proud, determined, strong, and active), and the other 10 items measure negative affect. Positive affect items are sum scored to create the positive affect score, with a higher number reflecting a more frequent experience of positive affect.

Desire to Smoke

Previous research has indicated that experiencing positive affect during the process of smoking cessation is related to a decreased desire to smoke [43,44]. Although nondaily smokers are not nicotine-dependent, craving, or, rather, the desire to smoke, is the most common reason why nondaily smokers attempting to quit relapse to smoking during the 2 weeks after their chosen quit date [63]. Thus, reducing the desire to smoke is a meaningful outcome in supporting nondaily smokers with quitting. To measure the desire to smoke, we will use the 10-item Brief Questionnaire of Smoking Urges [64]. Participants rate items about their desire to smoke (eg, "A cigarette would taste good now" and "*I could control things better right now if I could smoke*") on a 7-point Likert scale (1=*strongly disagree* to 7=*strongly agree*). Items are sum scored to create the total score, with higher scores indicating a greater desire to smoke.

Attitudes Toward Smoking

Experiencing positive affect during the process of smoking cessation is related to greater readiness to process self-relevant health information, particularly information about the negative health effects of smoking [45]. In our previous studies on the SiS app, we conceptualized that this readiness would entail shifts in the appraisals of the pros and cons of smoking [31,34]. In these single-group studies, we found that positive appraisals of smoking decreased, as expected, but that negative appraisals stayed largely the same. In this study, we will measure these constructs in the same way, assessing both the participants' expectations of the effect of smoking on them using the Attitudes Toward Smoking Scale (ATS-18) [65] and the importance of these expectations on their decision to smoke using the Decisional Balance Inventory for Smoking (DCB)-Short Form [66]. The ATS-18 consists of 18 items that participants rate on a 5-point Likert scale (*1=strongly disagree* to *5=strongly agree*). These items address the adverse effects (eg, "Smoking is extremely dangerous to my health"), psychoactive benefits (eg, "A cigarette calms me down when I am stressed"), and pleasures (eg, "It feels so good to smoke") of smoking. The DCB consists of 6 items rated on a 0 to 100 slider anchored at 0=*not at all important* and 100=*extremely important* and asks participants the following: "HOW IMPORTANT is each statement to your decision to smoke

XSL•FO
RenderX

RIGHT NOW?" Both the pros (eg, "Smoking cigarettes relieves tension") and cons (eg, "I'm embarrassed to have to smoke") of smoking are represented. For both the ATS-18 and DCB, items are sum scored to create subscale scores, with higher scores indicating greater endorsement.

Contextual Variables

At baseline, participants will be asked if they have ever tried to quit smoking (yes or no). If yes, they will be asked to indicate the number of previous quit attempts and what type of support they have used to quit smoking before (ie, group counseling, one-on-one counseling, quitline, web-based chat with a tobacco cessation specialist, website, social networking site for smoking cessation, SMS text message program, smoking cessation app, and medications). If they have previously used an app, they will be asked to indicate which one. In subsequent surveys, they will be asked which of these methods they have used since their onboarding call.

For descriptive purposes, the baseline survey will also include items on participants' demographics, past mental health diagnoses, smoking history, nicotine dependence (Fagerström Test for Nicotine Dependence), previous quit attempts, generalized self-efficacy (Generalized Self-Efficacy Scale), and personality (Single-Item Measures of Personality). Across time, also for descriptive purposes, participants will answer questions about their e-cigarette use, alcohol use, depression (Center for Epidemiological Studies Depression-10), generalized anxiety (Generalized Anxiety Disorder-7), capacity to experience pleasure (Snaith-Hamilton Pleasure Scale), optimism (Life Orientation Test-Revised, State Optimism Measure, and Brief State Optimism Measure), and coping style (Brief Coping Orientation to Problems Experienced).

Masking or Blinding

This proof-of-concept trial is not blinded. The same staff member who onboards participants to their smoking cessation materials may be the staff member reaching out via phone and email to remind participants to complete the surveys. However, contact with study staff is minimal and scripted. The initial survey invitations are automated using REDCap. Only surveys that are not completed within 3 days of the automated survey invitation will trigger a reminder email from the study staff, using an email template, and a phone call.

Sample Size

To select the sample size for this proof-of-concept trial, we were guided by one of the few mHealth smoking cessation studies that examined processes of smoking cessation over time. That study tested the effectiveness of an SMS text messaging intervention and, similarly to our study, used the "Clearing the Air" booklet as the control condition [67]. The study identified self-efficacy as the primary mediator of the observed salutary effect of the intervention on smoking cessation. Specifically, self-efficacy observed 1 month after the chosen quit date mediated group differences in smoking cessation at the 6-month follow-up [35]. The observed group difference between treatment and control at 1 month after the quit date on self-efficacy was Cohen d=0.66. Thus, we conservatively powered our proof-of-concept RCT to detect an effect size of Cohen d=0.50. As no trials have been published that test the effectiveness of QuitGuide, we assumed that QuitGuide would be as effective as Clearing the Air and that SiS would be more effective than either of them. Using SAS PROC POWER, we calculated that we would need a sample size of 64 per group to detect an effect of Cohen d≥0.50. Assuming a retention rate of 85%, we would need to enroll 75 participants per group to retain 64 by end of treatment. Thus, the total number of participants to be enrolled in this trial is 225 (3 randomized groups×75 participants to be enrolled in each group=225).

Analysis Plan

All successfully enrolled participants (ie, those who passed the screening process and were successfully onboarded to the assigned smoking cessation materials) will be included in the outcome analyses. Each follow-up survey will include 5 check items randomly interspersed throughout the survey. If a participant incorrectly responds to more than one of the 5 check items, this participant's entire survey for this time point will be considered unreliable and excluded from the analyses. If a participant incorrectly responds to only 1 of the 5 check items, the participant's data for the scale in which the error occurred will be considered unreliable and excluded from the analyses. All analyses will be conducted using SAS (version 9.4).

In this proof-of-concept RCT, the primary outcome is self-efficacy to abstain from smoking, as measured by the SEQ-12. The primary end point is end of treatment, which occurs 6 weeks after the originally chosen quit date. To test for differences between randomized groups, we will fit a fixed-effects repeated-measure model using PROC MIXED where observations are modeled as nested within persons. The predictors included in the model will be group (ie, SiS vs QuitGuide vs TAU), time (ie, baseline, week 2, week 6, week 12, and week 24), and the group×time interaction effect. A contrast statement will be used to derive the test statistic for the group comparison at week 6, our primary end point, given the overall longitudinal model. This contrast statement will test the null hypothesis that SiS=QuitGuide=TAU. If this null hypothesis is rejected (P<.05), we will conduct pairwise follow-up tests that compare the 3 possible pairwise comparisons (ie, SiS vs QuitGuide, SiS vs TAU, and QuitGuide vs TAU). Subscale scores can be computed for the SEQ-12 (ie, confidence to abstain from smoking in response to internal vs external triggers). For this trial, we consider the total SEQ-12 score as the primary outcome. We will also report outcomes on subscale scores.

The secondary outcomes of this proof-of-concept RCT are exploratory. Thus, we will not correct for multiple testing. We will fit 1 model per secondary outcome using an α of .05 for all analyses. To test for differences between randomized groups for outcomes that are assessed multiple times (ie, time spent applying content, app use, self-reported 30-day point prevalence abstinence, and cigarette reduction), our overall modeling approach will be the same as that for the primary outcome variable. That is, for each outcome, we will fit a fixed-effects repeated-measures model where observations are modeled as nested within persons. The predictors included in the model will be group, time, and the group×time interaction effect.

XSL•FO
RenderX

However, the definition of the time effect varies across these secondary outcomes based on their assessment schedule. The distribution of the outcome variables also varies across these variables. Thus, we will implement this overall modeling approach for these variables but adjust the model to match the assessment schedule and distribution of the variable. To test for differences between randomized groups for outcomes that are only assessed at end of treatment (ie, satisfaction with smoking cessation support, system usability, app likeability and satisfaction, use of smoking cessation strategies, use of positive psychology strategies, and perceived impact of treatment), for each outcome, we will use a fixed-effects model where group is the only predictor and the score at end of treatment is the dependent variable. Histograms will be used to guide the selection of the most appropriate distribution. If the group effect is statistically significant (P<.05), we will conduct pairwise follow-up tests that compare the 3 possible pairwise comparisons (ie, SiS vs QuitGuide, SiS vs TAU, and QuitGuide vs TAU) using the Tukey adjustment. These follow-up analyses will not be necessary for secondary outcomes that are only assessed for the SiS and QuitGuide conditions.

For exploratory outcomes (ie, secondary proof-of-concept efficacy outcomes), we will use the same statistical approach as for the primary outcome but will match the analysis to the distribution of the variable under examination. For example, 30-day point prevalence abstinence will be a binary variable. Thus, we will use a binomial distribution with a logit link function.

Results

Recruitment began in January 2021 and ended June 2022 at this time. The final follow-up occured in January 2023. Specifically, the last partial follow-up response was collected on January 4, 2023, and efforts to obtain the rest of these participants' data ceased on January 6, 2023. We expect to publish the main outcomes of this study in summer 2023.

Discussion

This RCT will provide the first test of the SiS app versus relevant comparison conditions—the NCI smoking cessation brochure “Clearing the Air” and the NCI smoking cessation smartphone app QuitGuide. The primary outcome will be self-efficacy to remain abstinent, as measured using the SEQ-12. Secondary outcomes include treatment acceptability; treatment feasibility; proof-of-concept efficacy markers such as positive affect, desire to smoke, and attitudes toward smoking; and, in an exploratory way, treatment effectiveness in terms of smoking cessation outcomes. We hypothesize that participants using the SiS app will have higher self-efficacy to abstain from smoking than participants in either of the control conditions as the SiS app is specifically designed for nondaily smokers, whereas the other 2 comparison conditions are geared more generally toward daily smokers. In terms of acceptability and feasibility, we anticipate that participants using the SiS app will find the treatment at least as acceptable and feasible as the comparison conditions (ie, not worse). We further hypothesize that we may be able to detect differences in proof-of-concept efficacy markers as well as smoking cessation outcomes such that participants using the SiS app will have higher levels of positive affect, a lower desire to smoke, reduced prosmoking attitudes (eg, lower ratings of the psychoactive benefits of smoking, lower ratings of the pleasures of smoking, and lower ratings of the pros of smoking), and a greater self-reported 30-day point prevalence abstinence proportion at the end of treatment compared with both comparison conditions.

This study is innovative in several ways. First, the study results will indicate whether a fully powered test of the effectiveness of the SiS app is warranted. This is a vital contribution to future clinical trials. Currently, nondaily smoking is not addressed by clinical practice guidelines for smoking cessation and, thus, treatment recommendations for this increasingly prevalent pattern of smoking are not clear. Therefore, testing whether this novel treatment may warrant a larger, fully powered trial moves the field forward toward the critically important goal of providing empirically based smoking cessation support for nondaily smokers. This is especially important as other efforts to identify effective treatments for this group of smokers have so far been unsuccessful. Specifically, in recent years, nicotine replacement therapies have been tested, but studies have failed to show efficacy [68,69]. The SiS app uses a different treatment modality (mHealth rather than medication) and targets a different mechanism (bolstering positive affect rather than ameliorating withdrawal) and, thus, is a novel, promising treatment approach. If our study provides evidence that the SiS app promotes greater self-efficacy to abstain from smoking than the comparison treatments and if the study gives a positive indication of treatment acceptability and feasibility, we plan to submit a proposal for a fully powered RCT to test the efficacy of the SiS app in promoting smoking abstinence in nondaily smokers.

The results of this study will also be useful more generally to understand how people who smoke interact with smoking cessation self-help materials and how a smartphone app may confer benefits. This study includes numerous measures that provide insights into treatment acceptability and feasibility, both from the point of view of the user and based on observed behaviors that are passively recorded. The chosen measures address a diversity of aspects that are relevant to treatment development (eg, does the app successfully teach or prompt the use of smoking cessation behaviors? Does the app successfully engage users in positive affect–supporting behaviors?) and implementation (eg, do people like the treatment? Will they adhere to the treatment instructions? Do they perceive the treatment to be impactful?). To date, only a handful of studies have looked at these important indexes, and even fewer have done so in a randomized design.

A limitation of this study is the lack of biochemical verification of smoking status for entry into the study and to verify smoking abstinence at the end of treatment. At study entry, we will use several check items and consistency checks to evaluate whether interested participants are providing attentive, consistent, and detailed information about their current smoking behavior. This will increase the likelihood that participants entering the study are nondaily smokers. The lack of biochemical verification of smoking abstinence at end of treatment may inflate our estimates

XSL•FO
RenderX

of smoking abstinence overall, but we do not expect that it will bias the comparison between treatment groups. In total, 2 strengths of the study are the efforts to recruit a diverse, representative sample of nondaily smokers and the use of 2 clinically relevant control groups that allow for the answering of different but equally important questions. With respect to recruitment, our efforts to ensure that we enroll a proportion of ethnic and racial minority participants that is representative of nationwide estimates will strengthen the generalizability of our results. With respect to the comparison groups we chose, in most health care settings, referral to smoking cessation apps is not provided. Although many such apps exist, only a handful have been tested empirically and, thus, the evidence base to support such a standard-of-care referral is slim. In these settings, providing written materials to support smoking cessation, such as the NCI booklet "Clearing the Air," remains a standard of care. Thus, comparing the SiS app with that control group answers the following question: would it be useful to change the standard of care to include referral to an app? This is an important practical question that can guide decision-making in health care settings. The other control group addresses the following scientifically relevant question: is the SiS app better than existing smartphone apps for smoking cessation? Although the NCI QuitGuide app has never been tested in a randomized trial designed to test its effectiveness, it is a widely used smartphone app and a recommended resource. Thus, it is an important benchmark that can help tease apart the effects of using a credible, well-designed app from the treatment mechanisms targeted and implemented in the SiS app. Note that this design also represents the first true test of QuitGuide against an established standard of care (ie, referral to "Clearing the Air"). Comparing QuitGuide to Clearing the Air provides insight into whether referral to this publicly available and widely used app is indeed beneficial to nondaily smokers.

Thus, we believe that this study will provide data to inform the next steps toward providing smoking cessation support for nondaily smokers while also providing important, multifaceted insights into smoking cessation smartphone app treatment development and implementation.

Abstract

Background: Despite substantial investments in ending the HIV epidemic, disparities in HIV care persist, and there is an urgent need to evaluate novel and scalable approaches to improving HIV care engagement and viral suppression in real-world settings.

Objective: This paper aims to describe a study protocol for a pragmatic type II hybrid effectiveness-implementation randomized controlled trial comparing existing standard of care clinic HIV linkage, adherence, and retention (LAR) protocols to a mobile health (mHealth)–enhanced linkage, adherence, and retention (mLAR) intervention.

Methods: The study will enroll 450 participants from clinics in Baltimore City. Eligibility criteria include being ≥18 years of age, having a new HIV diagnosis or being HIV-positive and out of care, or being HIV-positive and deemed by clinic staff as someone who could benefit from linkage and retention services. Participants randomized to the intervention receive mHealth-supported patient navigation for 12 months. Participants in the control group receive the referring clinic's standard of care patient support. The primary outcome is HIV virologic suppression at 12 months. A subset of participants will be interviewed at 12 months to learn about their HIV care experiences and, for those in the intervention arm, their experiences with the mLAR intervention. This protocol was developed in collaboration with the Baltimore City Health Department (BCHD) and the Maryland Department of Health (MDH) and with input from a community advisory board.

Results: Enrollment began on February 25, 2020. As of August 11, 2022, 411 of the 450 target participants had been enrolled.

Conclusions: Pragmatic implementation science trials designed with input from key stakeholders, including health departments and community members, can help evaluate the evidence for mHealth interventions to reduce HIV health disparities.

Introduction

Advances in HIV treatment have markedly improved clinical outcomes among people living with HIV [1]. The United States has an ambitious strategy to end the HIV epidemic by 2030, but persistent racial and ethnic disparities in HIV outcomes must be addressed to achieve this goal [2]. African American people represent 13% of the population but account for 42% of people living with HIV and are less likely to receive antiretroviral therapy (ART) or achieve virologic suppression compared to White people [3]. Latinx people have higher HIV rates than non-Hispanic White people and are at high risk for delays in diagnosis and linkage to care [3,4]. Delayed initiation of ART is associated with increased morbidity and mortality, and high viral load is the main predictor of HIV transmission [5-8].

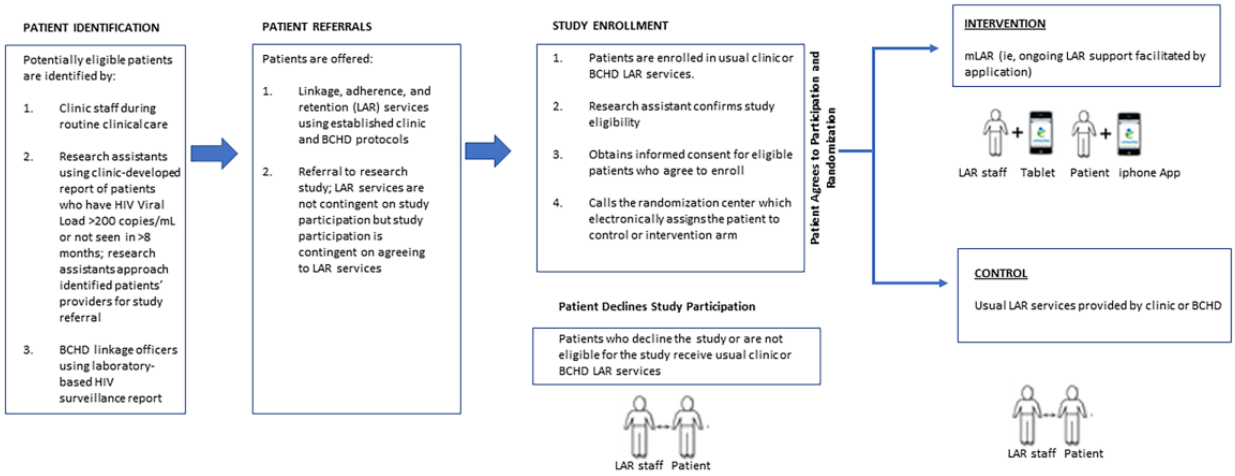
Modeling studies suggest that reengaging people living with HIV into care and suppressing their viral load is one of the most important interventions to reduce HIV incidence in the United States [9,10]. HIV retention in care and virologic suppression rates above 80% are needed to sharply reduce HIV transmission, but in 2021, only 66% of people living with HIV in the United States were suppressed [3]. HIV clinics have implemented various strategies to improve retention in care and adherence to treatment, such as automatic reminder calls for upcoming appointments, intensive case management, or systematic reviews of patients to identify those who have fallen out of care [11]. Evidence suggests that increased contact with the clinic can improve retention in care but may not be enough for people with substance use disorders and other unmet needs [12]. Several personal and structural barriers to care have been identified, including difficulty with transportation to the clinic, lack of information and practical support in navigating the system, and cost [13,14].

HIV retention and adherence strategies could be enhanced with the use of evidence-based mobile health (mHealth) strategies that leverage mobile phones to improve health outcomes. Systematic reviews have found that mHealth interventions can promote engagement in care, adherence to ART, and virologic suppression [15-17]. These platforms can be programmed to send tailored messages, reminders, and alerts to patients and providers using algorithms that leverage existing data. A distinct potential advantage of mHealth platforms is the ability to securely facilitate patient-centered approaches to retention in care efficiently and without overburdening providers, with alerts for action designed to focus on areas that truly require provider input. Studies from Baltimore demonstrate the feasibility and acceptability of using mHealth approaches with diverse populations, including African American men who have sex with men, people who inject drugs, and foreign-born Latinx people [18-20]. However, additional evidence is needed on the relative benefit of mHealth interventions in real-world settings to justify routine investments in mHealth resources and technology.

This manuscript describes the Leveraging mHealth and Patient Supporters for African Americans and Latinxs in HIV Care (LEAN) study protocol for a pragmatic type II hybrid effectiveness-implementation randomized controlled trial. This trial will compare existing standard-of-care clinic HIV linkage, adherence, and retention (LAR) protocols to an mHealth-enhanced linkage, adherence, and retention (mLAR) intervention with the hypothesized finding of improved virologic suppression and engagement in care in the mLAR study arm. This protocol was developed in collaboration with the Baltimore City Health Department (BCHD) and the Maryland Department of Health (MDH) and with input from a community advisory board. The study will evaluate the effectiveness of an mHealth intervention integrated into clinical and public health operations and examine implementation mechanisms and outcomes to inform broader scalability and sustainability.

Methods

Study Setting



This is a collaborative study between the BCHD, MDH, and Johns Hopkins University conducted in Baltimore City. The HIV prevalence rate in Baltimore is among the highest in US metropolitan areas, and it is a city that faces profound health disparities. In Baltimore, African American people have an HIV prevalence that is 5 times higher than among White people and account for more than 80% of all HIV cases; Latinx people have a higher prevalence of HIV than White people and are at the highest risk for late HIV diagnosis among all racial and ethnic groups [21].

Study Design

This study is a pragmatic type II hybrid effectiveness-implementation [22,23] randomized trial comparing standard LAR services to mLAR services (Figure 1). The study was conceptualized through discussions with patients, providers, linkage officers, and health officials regarding barriers and facilitators to engagement in HIV care and ways to leverage technology into existing services and systems to facilitate provider-patient communication. Study activities were reviewed and approved by the Institutional Review Board at the Johns Hopkins School of Medicine (IRB00195120). The study was registered at ClinicalTrials.gov (NCT03934437).

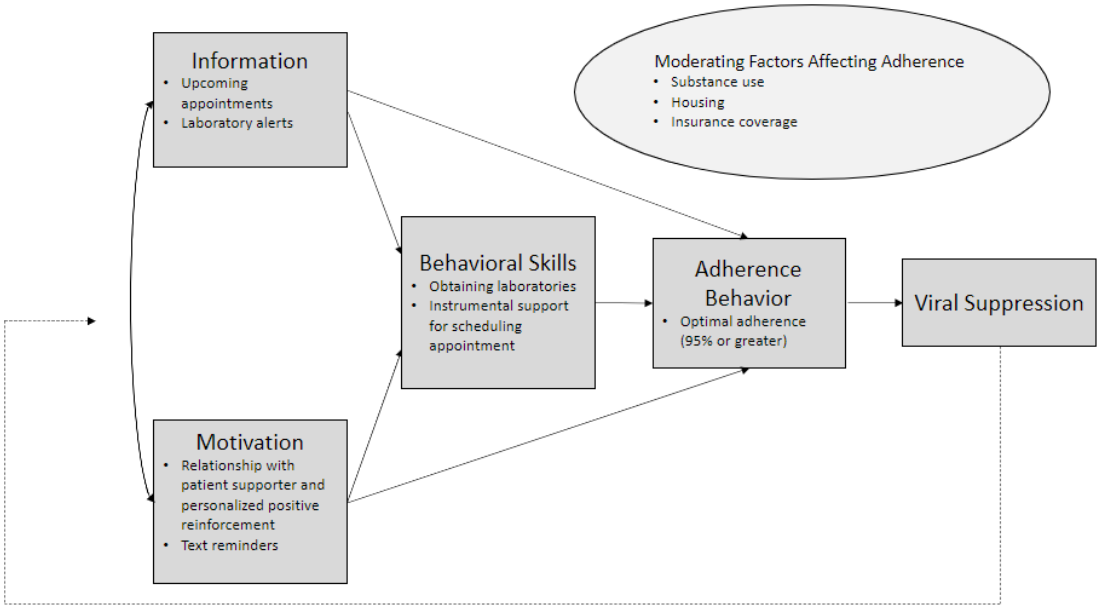

Figure 1. LEAN (Leveraging mHealth and Patient Supporters for African Americans and Latinxs in HIV Care) study design. BCHD: Baltimore City Health Department; LAR: linkage, adherence, and retention; mLAR: mobile health–enhanced linkage, adherence, and retention.

Conceptual Framework

The mLAR intervention was informed by the situated Information-Motivation-Behavioral Skills (IMB) Model of Adherence, an evidence-based and theory-driven approach to understanding ART adherence and engagement in care (Figure 2). The situated IMB model focuses comprehensively on the information, motivation, and behavioral skills factors that are conceptually and empirically linked to ART adherence and specifies individual and social factors that may moderate the relationship between the IMB model constructs and ART adherence. At its most general level, the IMB model asserts that someone who is informed about medication adherence (ie, appointment reminders and lab alerts), is motivated to act, and has the behavioral skills necessary to act effectively (ie, objective and perceived abilities, facilitated by patient supporters) is more likely to adhere to ART over time [24,25]. Social determinants of health, such as housing, and individual factors, such as depression and substance use, moderate adherence and can create barriers to gaining information, being motivated, and acquiring or adhering to ART. Figure 2 highlights examples of specific components of how the mLAR intervention provides information, motivation, and behavioral skills to promote ART adherence. Patient supporters try to address moderating factors, such as depression and substance use, by facilitating referrals to appropriate resources and maintaining close communication with the patient's case manager, as needed.

Figure 2. The situated Information-Motivation-Behavioral Skills (sIMB) Model of Adherence conceptual framework.

Formative Work and Community Engagement

Extensive discussions with stakeholders informed the study's implementation and app design. The BCHD and MHD expressed a strong preference for a pragmatic "real life" study so that results could be generalizable to public health practice. A steering committee of old and new partners included African American and Latinx individuals affected by HIV, HIV clinicians, clinic-based staff (ie, patient supporters), BCHD linkage team leaders, public health officials, and members of

XSL•FO
RenderX

the nonprofit sector. The SC met monthly during the planning phase and then quarterly once data collection started. The SC provides guidance on all patient-facing aspects of the study, including app characteristics and use (ie, app name, app logo, materials to assist participants with using the app), participant referral and recruitment processes, study closeout for participants, and the in-depth interview guide. Ongoing SC meetings provide an opportunity to discuss challenges and brainstorm solutions. The app development team included JH researchers, members of the health department, and emocha Mobile Health software engineers who helped develop a Health Insurance Portability and Accountability Act (HIPAA)–compliant mHealth app to facilitate engagement in care. Adaptations to the app were also made in response to feedback from the community advisory board and in-depth interviews with participants and patient supporters. Based on community advisory board feedback, the app was named NxtSTEP.

Study Participants

Study Enrollment Criteria

Enrollment criteria include (1) being ≥18 years of age, (2) having the ability to provide consent, (3) having a new HIV diagnosis or being HIV-positive and "out of care" or being deemed by clinic staff as someone who could benefit from LAR services, and (4) living in Baltimore (within BCHD and Baltimore clinics' catchment areas).

Participating Clinic and Program Selection Criteria

Criteria for LAR program participation are (1) BCHD or other Baltimore-based HIV program, (2) has an existing HIV-focused LAR program, (3) has existing patient supporters as part of the LAR program, (4) does not use any formal mHealth component for patient supporters to communicate with patients (beyond basic telephone calls and texting), and (5) the leadership and staff of the LAR program must be willing to participate.

Recruitment

Study participants are recruited from participating programs in 1 of 3 ways (Figure 1): (1) participating clinics identify newly diagnosed patients with HIV, those who are out of care and those who clinic staff determine could benefit from LAR services, offer LAR services to these patients, and refer interested patients to the study; (2) research assistants use clinic-developed reports to identify patients who could benefit from LAR services and approach these patients' care providers during their regularly scheduled clinic visits or during hospitalization to refer interested individuals to the study; and (3) BCHD linkage officers use a laboratory-based HIV surveillance report from the state's enhanced HIV/AIDS Reporting System (eHARS) that identifies newly diagnosed patients with HIV or those who are out of care, and when these patients are offered linkage services, the linkage officer offers study referral.

LAR services are provided regardless of study interest, but individuals who would like to enroll must agree to LAR support. Individuals interested in study enrollment are referred to a research assistant, who confirms eligibility, describes study participant responsibilities, and obtains informed consent.

Randomization

After obtaining consent, the research assistant enters the participant's information into a Research Electronic Data Capture (REDCap) database [26,27], which has been programmed to randomly assign the patient to the control or intervention arm in a 1:1 ratio. The randomization schedule was generated by the study statistician, uses permuted blocks of varying sizes, and is stratified by whether the patient identified as Black or African American to ensure equal distribution of race in each study arm. Due to practical considerations, participants, clinic staff, and the study team are not blinded to arm assignment. Data analysis related to HIV clinical outcomes will be conducted in a blinded fashion.

Study Assessments

This is a pragmatic implementation trial with outcomes (eg, retention in care) that could be influenced by frequent study-related interactions, so study contact is minimized to a baseline visit where the research assistant obtains basic demographic and contact information and the reasons for referral to LAR services (ie, newly diagnosed, previously diagnosed but out of care, etc). A brief client satisfaction survey is conducted at the end of the 12-month follow-up period. Participants who agree to be contacted for an in-depth interview are randomly selected, aiming to capture both male and female participants in the control and intervention arms, including participants who did not use the app.

Participant Remuneration

All participants receive a US $50 incentive at initial enrollment in the study. Participants also receive US $20 for the completion of a client satisfaction survey and US $50 if they participate in an in-depth interview.

Study Arms

Overview

Patients are randomized to the control arm or the intervention arm. Participants randomized to the control arm will receive the usual LAR services as per clinic. Participants randomized to the intervention arm will download the NxtStep app to their personal phones (or the study phone if the participant does not own a compatible phone) and be onboarded for using the app with the research assistant. Subsequently, the intervention arm participants will use the app to communicate with their patient supporter at the clinic or BCHD and receive algorithm-driven alerts (Table 1).

Standard LAR Services

Below are descriptions of the standard LTCR services at each site.

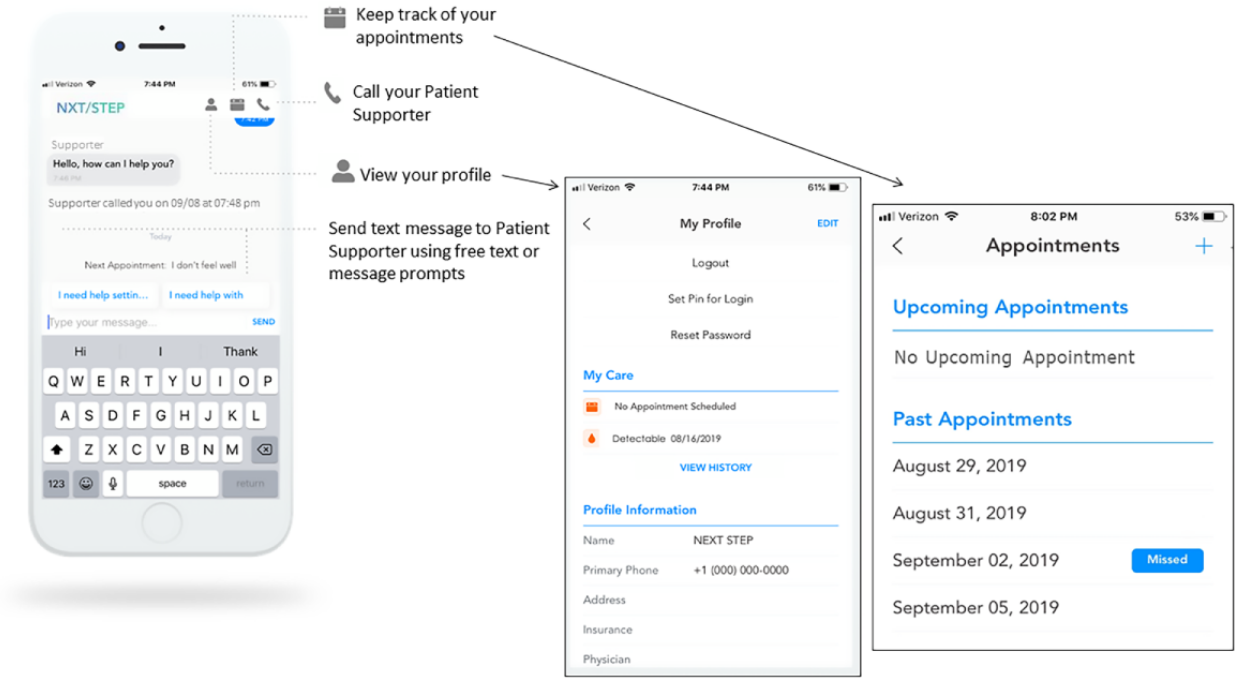
BCHD Linkage to Care Program

BCHD has patient supporters called linkage officers who attempt to contact and provide linkage services to all Baltimore residents newly diagnosed with HIV or who are presumed to be out of care [28]. These patients are identified using the state's eHARS,

XSL•FO
RenderX

which includes results for all HIV tests (including HIV viral load) conducted in Maryland, DC, and Virginia. An MDH algorithm generates weekly reports for the BCHD linkage team of new HIV diagnoses or out-of-care patients in Baltimore (defined as patients with a viral load >50,000 or no HIV labs for >12 months). The linkage officers attempt to contact patients on this list, and those who agree to be linked to HIV care by linkage officers are provided a same-day appointment and a warm handoff to clinical care (ie, the outreach worker drives the patient to the clinic of his or her choice).

Clinic-Based LAR Programs



The Ryan White–funded HIV clinics currently participating in our study (Johns Hopkins Bartlett Clinic, BCHD Sexual Health Clinic, University of Maryland THRIVE Clinic, University of Maryland JACQUES Initiative) have patient supporters (called patient supporters, advocates, navigators, or health workers) who remind patients of upcoming appointments and act as a point of contact to help patients navigate their care. They help patients schedule appointments, lab visits, and medication refills. They also provide counseling and education to help patients self-advocate and connect to necessary services (eg, mental health services, substance use disorder treatment, or social services). Except for appointment reminders, which are intended to reach all patients, other services are delivered in response to patient or provider requests, not systematically to all patients. All clinics have rapid ART programs, and the patient supporters assist newly diagnosed patients through this process (quick appointment and introduction to the clinic). None of the programs provide home visits or services outside the clinic.

Intervention (mLAR)

This approach leverages existing LAR services at each study site and adds a novel mHealth component. The mHealth enhancement consists of 2 smartphone apps (NxtSTEP app), 1 for patients and 1 for existing patient supporters, to help facilitate communication on issues related to HIV care (eg, appointment scheduling, laboratory reminders, transportation), as well as patient-directed requests. The NxtSTEP app is designed to facilitate secure communication between the patient and patient supporters and to automate certain tasks, alerts, and reminders so that patient supporters can focus their efforts on patients at high risk of falling out of care (eg, calling a patient with a high viral load) rather than on time-consuming tasks not specifically targeted to high-risk patients (eg, general appointment reminders).

The NxtSTEP app has a viral load–driven algorithm using MDH HIV surveillance data that automatically alerts patient supporters and patients if the viral load is not suppressed (>200 copies/ml) or if more than 4 months have passed since the last viral load. This interval is consistent with HIV guidelines to monitor viral load at least every 3 to 4 months, or more frequently as clinically indicated, in patients who have not had sustained virologic suppression for more than 2 years [29]. In addition, patients are prompted to enter upcoming appointment dates in an app calendar, which allows for automatic reminders. Patient supporters are alerted if a patient does not have an upcoming appointment or if the patient missed their appointment. Patient supporters are trained to contact the patient alerted (lab alert, appointment alert, or patient message alert). Figures 3 and 4 show the patient and patient supporter's NxtSTEP views, respectively. Tasks, alerts, and action prompts are outlined in Table 1 for the patient app and in Table 2 for the patient supporter app.

Figure 3. Patient view of NxtSTEP app.

XSL•FO
RenderX

Figure 4. Patient supporter view of NxtSTEP app.

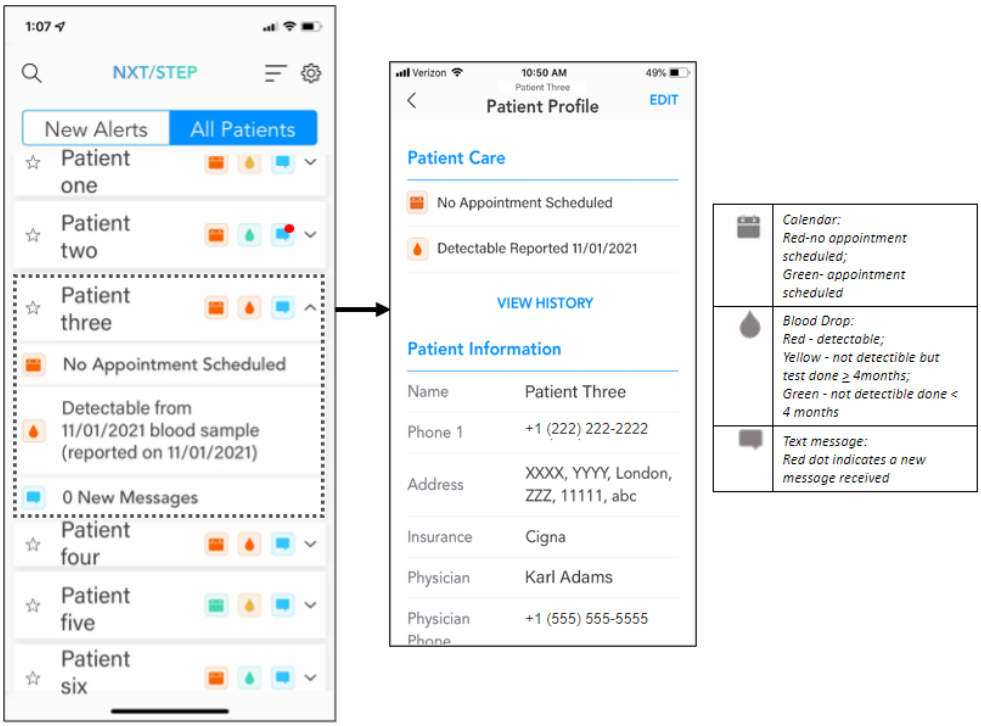


Table 1. Patient NxtSTEP app.

Task	Description	Patient support staff action
Appointment data	Tab to record the date, time, and place of an upcoming HIV care appointment	Patient support staff or patient can enter appointment data
Appointment reminders	Patient automatically receives reminders about upcoming appointments (3 days prior). The day after the scheduled appointment, patient receives the prompt, "Did you go to your appointment yesterday?" (Yes or No) If "Yes," patient received a message saying, "Great job keeping your appointments!"	Patient support staff contacts patient, if alerted (see Table 2)
Ability to directly message patient support staff	Patient can click on prompts (eg, "I need help setting an appointment" or "I need help with") or send a free text message to patient support staff	Patient support staff contacts patient, if alerted (see Table 2)
Control over messages	Patient has the option to type STOP if he or she prefers not to receive a type of message	Not applicable

Table 2. Patient support staff NxtSTEP app.

Task	Description	Patient support staff action
HIV data of participants in mLAR[a] arm	Participant viral load (dated) automatically uploaded from eHARS[b] (through BCHD[c] lab-based reporting surveillance protocols)	Value not applicable
Viral load status alerts	Automatic "out of care" alert if no viral load for >4 months or viral load >200	Patient support staff communicates with the participant. Contact attempts are recorded.
Automatic appointment alerts	Automatic alert if no next appointment is documented in the patient app. "Missed appointment" alert if patient responds 'No' or does not respond to prompt, "Did you go to your appointment yesterday?"	Patient support staff communicates with participant. Contact attempts are recorded.
Patient initiated direct messaging	Automatic alerts for all patient-initiated messages, for example, "Patient needs help with appointment," "Patient needs help with transportation," or if the patient has typed a request with free text.	Patient support staff communicates with participant. Contact attempts and outcomes are recorded. For social determinants (housing, transportation, and substance use), patient support staff assists patient with access to community and clinical-based resources.

NxtSTEP is available in English and Spanish. Spanish-speaking patients with limited English proficiency (LEP) are assigned a bilingual patient supporter who communicates with them in their preferred language. The study team had experience with cultural and linguistic adaptations of interventions and elicited feedback from the steering committee (see below) to ensure messages were tailored to the health literacy and language proficiency of the target population [30,31].

Outcomes

Clinical Outcomes

The primary outcome of the trial is virologic suppression at 12 months, defined as a viral load <200 copies/ml within a 6-month window (ie, 3 months before or after the 12-month follow-up). The secondary effectiveness outcome of the trial is retention in care at 12 months, defined as having a viral load within a 6-month window (ie, 3 months before or after the 12-month follow-up). Data for the primary and secondary outcomes will be obtained from the MDH surveillance HIV viral load data reported to eHARS. All laboratory assessments will be conducted as part of clinical care. Participants with a suppressed viral load (HIV RNA <200 copies/ml) within the follow-up period will be fully engaged in HIV care. While some individuals can maintain immune control over HIV in the absence of ART, this occurs in only <1% of infected persons [32].

Implementation Outcomes

Using a hybrid study design, we incorporated implementation science evaluation methods to assess important implementation questions [33]. Hybrid designs are efficient approaches to obtaining information that can help understand research findings in terms of internal validity and external generalizability and provide data to facilitate translating research into real-world policies and programs [34]. LEAN implementation processes will be evaluated in terms of core factors in the Reach, Effectiveness, Adoption, Implementation, and Maintenance (RE-AIM) approach (Table 3) [33] and informed by concepts from the IMB theoretical framework.

IMB framework dynamics will be explored through open-ended qualitative methods. The evaluation will engage the intervention's consumers (HIV-positive patients randomized to mLAR) as well as other stakeholder groups, including patient supporters, clinicians, and public health officials at the BCHD. Engaging this range of stakeholders will provide a holistic understanding of the barriers and facilitators to successfully implement the intervention, enhance service delivery, and assess the feasibility of scaling up the intervention if it is effective.

Table 3. Summary of mobile health–enhanced linkage, adherence, and retention implementation evaluation using the Reach, Effectiveness, Adoption, Implementation, and Maintenance approach.

Component	Research question	Assessment methods	Outcomes of interest
Reach	Who received the intervention?	• Program data • In-depth interviews	• Proportion of eligible patients successfully engaged in intervention. Differences between those reached and those not reached. Reasons why.
Effectiveness	What impact did the intervention have on patient-oriented outcomes?	• End-of-study viral load • In depth interviews	• Viral suppression • Engagement in care • Acceptability of the intervention
Adoption	Did the providers, patient supporters, and staff (implementers) adopt the intervention?	• Program data, in-depth interviews	• Frequency of contacts between patient supporters and patients. Services provided and received. Perceptions and attitudes of implementers.
Implementation	Was the intervention delivered as intended?	• Program data, in-depth interviews	• Program fidelity. Adaptation to design over time.
Maintenance	Was the intervention sustained and institutionalized over time?	• Program data, in-depth interviews	• Consistent implementation and effectiveness over time. Retention.

Client Satisfaction Survey

All participants (control and intervention, n=450) will be asked to complete a brief client satisfaction survey using a validated Client Satisfaction Questionnaire (CSQ-8) [35]. Participants in the intervention arm will be asked to complete the validated System Usability Scale to assess the acceptability and ease of use of the NxtSTEP app [36].

Qualitative Data

In-depth interviews will be conducted with 3 key stakeholder groups: patient supporters, study participants, and clinic leadership and public health officials. Interviews with patient supporters will occur before and 12 months after the implementation of mLAR to assess the nature of service delivery, client interactions and how this differs from standard linkage activities, barriers and facilitators of engaging out-of-care patients, challenges and solutions to the service delivery, and recommendations for service delivery improvements and expansion of reach. We will also conduct interviews with study participants randomized to the control or intervention arms. All participants will be asked about their experiences living with and engaging in HIV care, including facilitators and barriers to appointments and medication adherence, past experiences dropping out of care, impressions of HIV-related services they received, as well as recommendations for additional services. Participants randomized to the intervention arm will also be asked about

XSL•FO
RenderX

their experience using the app, their satisfaction with features of the app such as the automated messaging they received, their motivation for engaging the patient supporter–delivered SMS text messages, their perception of the impact of app usage on their care, and their suggestions for other ways the mobile phone may facilitate HIV retention in care and adherence to medications. We will also assess facilitators and barriers to app use. Interviews with clinic leaders and public health officials will explore perceptions of the intervention's integration into linkage and engagement of care activities at clinics or the health department, as well as recommendations for service delivery improvements. These interviews will provide insights about policy, acceptability, political buy-in for the intervention, and the potential for sustainability and adoption in other settings going forward.

Process for Feedback and Intervention Refinement

During implementation, results from the interviews and client satisfaction surveys will be shared at regular intervals with patient supporters, program administrators at the BCHD, and the steering committee. Sharing these data will facilitate the use of the information for problem-solving, community engagement, and an opportunity to improve the quality of the intervention.

Statistical Procedures

We will conduct a test for the equality of proportions of virologically suppressed, not suppressed, or missing viral load individuals at 12 months between the 2 study arms, in line with the randomized design of the study. Secondary to this, and to adjust for any residual confounding, we will conduct a log-binomial regression using individual outcomes (yes or no suppressed) with the study arm as the main predictor and adjusting for patient demographic characteristics, socioeconomic status at baseline, and other factors. The observed virologic suppression in the control arm is higher than the estimate used in the design phase of the study. We will thus further conduct a difference-in-differences analysis to evaluate the effect of the study arm over time. This will be conducted using a log-binomial regression and will investigate the time (enrollment vs 12 months) by arm interaction term, adjusting for baseline sociodemographic covariates and robust standard errors to account for within-participant clustering.

A subgroup analysis will be conducted to assess the effects of the intervention among African American people and people of Hispanic or Latinx descent, and if most of our recruited participants come from 1 site, we will conduct a subgroup analysis focusing on this site alone. Sensitivity analysis using propensity-score weighting to adjust for imbalances in study arm allocation by site will be conducted.

Power Calculation

The reported virologic suppression or lack of a viral load measurement rate under standard of care among HIV-positive African American and Latinx people in Baltimore City is 33% [37]. In order to detect an improvement of 13%, such that 46% of the mLAR group have a viral load and achieve virologic suppression with 80% power at an α=5% level of significance, a total sample size of 442 (n=221 per arm) is required. A total of 450 participants will be enrolled in the study to account for participants who decide to withdraw from the study after enrollment. Because this is a pragmatic implementation study and the primary outcome is viral load obtained from surveillance data, patients who are lost to follow-up will still be included in the analysis. According to the protocol, patients who are lost to follow-up and do not have a viral load recorded in the surveillance database within the window period will be considered virologic failures.

Qualitative Data Analysis

Transcripts from in-depth interviews and key informant interviews will be entered and managed in Atlas.ti (Scientific Software Development GmbH). Separate coding schemes will be developed for HIV-positive patients (the control and intervention arms) and the other staff (patient supporters, program managers, and health officials). An iterative coding process will be used to conceptually name the data and reduce it to manageable units of information that cover broad and general categories. Codes will be informed by the questions in the qualitative guides, and new themes that emerge from the data will be analyzed through a constant comparison approach, allowing for themes to emerge and ensuring that the knowledge assembled from the observational data is not subjected to the ideas solely established through the interview guide. For each group, 2 coders will conduct open-coding on 3 transcripts to develop an initial coding scheme. The draft codebook will continue to be revised as needed as additional transcripts are coded and discussed. Once a final coding scheme is established, the transcripts will be systematically coded. Through weekly meetings, a team approach to data analysis will be used, whereby different analysts provide feedback on emerging interpretations and check emerging categories against the raw data. In this way, an "audit trail" will be used to help ensure the trustworthiness of findings, gather input from multiple perspectives, and enhance reliability.

Data Management and Quality Assurance

Data collected by the NxtSTEP app is sent in real time to a secure server, where linkage activities and data can be accessed through a simple web interface. Only authorized study personnel have access to this data. A triple level of data encryption is used to ensure confidentiality of data and HIPAA-compliance. Patient supporter devices and access to the patient supporter and patient apps are password protected. To further protect patients' confidentiality, the patient's app and messages to the patient include nonspecific terms without mention of HIV or other personal health information. Data will be cleaned at Johns Hopkins and deidentified before analysis.

Ethics Approval

This study was approved by the Johns Hopkins School of Medicine Institutional Review Board (IRB00195120).

Results

Study enrollment began February 2020 and was suspended in March 2020 until June 2020 due to the COVID-19 pandemic. As of August 11, 2022, 411 people had been enrolled in the study. Study enrollment of 450 participants was completed on December 1, 2022. Follow-up of these participants will continue

XSL•FO
RenderX

until early 2024, and study assessment and data collection will be completed by January 31, 2024.

Discussion

This trial should provide evidence on whether an mLAR intervention improved viral suppression and engagement in care when compared to existing standard-of-care clinic HIV LAR protocols. Compared to prior work, this study will generate rigorous randomized, controlled trial-level evidence with hard biologic outcomes for an intervention used within real-world programs. Study strengths include the rigorous study design, multiple study sites, and a user- and community-informed app design and implementation. Study limitations include potentially imbalanced recruitment from the various study sites, COVID-19–related adaptations, and unforeseen technological challenges.

Informed by the community advisory board, we will implement (or develop) a robust dissemination plan that includes not only peer-reviewed publications and presentations at scientific conferences but also presentations among community-based organizations that offer HIV services and to city and state policy makers and funders of HIV programs.

The rigorous evaluation of a pragmatic HIV LAR to care approaches, especially in settings like Baltimore, where African American and Latinx people carry a disproportionate burden of HIV infections, is desperately needed. The results of this randomized study will contribute to the evidence on the effectiveness of an mHealth-enhanced LAR initiative implemented by the local health department and clinics that provide care to people living with HIV. Evidence supporting the feasibility, effectiveness, and implementation considerations of this intervention will be important for the BCHD and other health departments as they make decisions on the allocation of limited resources to address the HIV epidemic in their jurisdictions. As value-based reimbursement becomes the norm for payors including Medicare and Medicaid, this study will contribute to the evidence regarding insurance coverage for mHealth interventions to improve patient outcomes. The information will also be relevant to Ryan White officials responsible for allocating federal dollars to support clinical and ancillary services to improve HIV outcomes, particularly among patients who are uninsured or underinsured. Finally, and most importantly for patients and providers, the primary outcome of this study (virologic suppression) is directly related to improved clinical outcomes (improved survival and lower morbidity) and reduced HIV transmission in affected communities.

In summary, the LEAN trial seeks to test the impact of an mHealth-enhanced linkage to care, adherence, and retention strategies among vulnerable, mostly minority persons living with HIV in a real-world setting. If found to be effective, potential future directions for this intervention include scaling it up and adapting it to other settings as an important tool to reach HIV epidemic control.

Acknowledgments

Research reported in this publication was fully funded through a Patient-Centered Outcomes Research Institute (PCORI) Award Grant number AD-2018C1-11244. The statements in this publication are solely the responsibility of the authors and do not necessarily represent the views of the PCORI, its Board of Governors, or its Methodology Committee. We are especially grateful to the health professionals, service providers, and patients who participated in the steering committee and provided invaluable input.

Data Availability

After completion of this study and publication of primary and secondary trial outcomes, a deidentified data set will be submitted for publication to JMIR Data.

Conflicts of Interest

Abstract

Background: The World Federation of Obesity warns that the main health problem of the next decade will be childhood obesity. It is known that factors such as gestational obesity produce profound effects on fetal programming and are strong predictors of overweight and obesity in children. Therefore, establishing healthy eating behaviors during pregnancy is the key to the primary prevention of the intergenerational transmission of obesity. Mobile health (mHealth) programs are potentially more effective than face-to-face interventions, especially during a public health emergency such as the COVID-19 outbreak.

Objective: This study aims to evaluate the effectiveness of an mHealth intervention to reduce excessive weight gain in pregnant women who attend family health care centers.

Methods: The design of the intervention corresponds to a classic randomized clinical trial. The participants are pregnant women in the first trimester of pregnancy who live in urban and semiurban areas. Before starting the intervention, a survey will be applied to identify the barriers and facilitators perceived by pregnant women to adopt healthy eating behaviors. The dietary intake will be estimated in the same way. The intervention will last for 12 weeks and consists of sending messages through a multimedia messaging service with food education, addressing the 3 domains of learning (cognitive, affective, and psychomotor). Descriptive statistics will be used to analyze the demographic, socioeconomic, and obstetric characteristics of the respondents. The analysis strategy follows the intention-to-treat principle. Logistic regression analysis will be used to compare the intervention with routine care on maternal pregnancy outcome and perinatal outcome.

Results: The recruitment of study participants began in May 2022 and will end in May 2023. Results include the effectiveness of the intervention in reducing the incidence of excessive gestational weight gain. We also will examine the maternal-fetal outcome as well as the barriers and facilitators that influence the weight gain of pregnant women.

Conclusions: Data from this effectiveness trial will determine whether mami-educ successfully reduces rates of excessive weight gain during pregnancy. If successful, the findings of this study will generate knowledge to design and implement personalized prevention strategies for gestational obesity that can be included in routine primary care.

gestational obesity; mHealth; primary care; randomized controlled trial

Introduction

The World Obesity Federation warns that the main health problem of the next decade will be childhood obesity [1,2]. Obesity and its consequences have their origin in intrauterine life [3]. A study showed that the consumption of "junk" food (high in energy and poor in micronutrients) during pregnancy was a predictor of high birth weight and the child's future preference for foods high in fat, sugar, and salt [4]. The risk of obesity in childhood is increased if the mother has a high level of adiposity or develops gestational diabetes, or if the baby is not breastfed or experiences poor nutrition that leads to delayed birth [2]. Excessive gestational weight gain (eGWG) is a predictor of overweight and obesity in children in the short-, medium-, and long-term, with evidence of effects up to 21 years after delivery [5-7]. In this sense, according to Barker theory, nutrition and other environmental factors to which the mother is exposed during pregnancy alter intrauterine life [8]. Gestational obesity produces deep effects on the programming of the fetal genome, thereby inducing changes in the prenatal metabolism that extend to the postnatal period, which is also associated with increased susceptibility to developing cardiovascular and metabolic diseases in adulthood [5-7,9,10].

eGWG during early pregnancy has been repeatedly associated with increased adiposity in childhood and adolescence [11-15]. Thus, adequate maternal nutrition during pregnancy is the window of opportunity to strengthen the health status of the mother and fetus and reduce the risk of adverse birth outcomes, such as preterm birth and low birth weight associated with eGWG [16]. The first trimester of pregnancy is critical for short-term interventions to break the "transmission" of obesity from one generation to the next [17]. For many women, pregnancy is a powerful motivator for self-care, as they are more aware of personal risks and have a strong emotional response toward adopting risk-reducing behaviors [18]. Quantitative literature suggests that the key to maintaining a healthy pregnancy and the primary prevention of maternal-fetal complications is establishing healthy dietary behaviors during gestation [19,20]. Even though many women are aware of the importance of healthy eating during pregnancy, the lack of nutritional self-care knowledge represents a substantial barrier to weight control during this stage [21,22]. Nutrition education improves nutritional knowledge, thus influencing practices aimed at achieving adequate nutrition [22]. Several studies recommend the continuous use of educational interventions on nutrition during pregnancy in routine obstetric practice to improve the quality of life of pregnant women and their offspring [6,23-25]. Regarding this, a study performed on the Chilean population evaluated the efficacy of a low-intensity, high-coverage nutritional intervention at the primary health care level [26]. This high-coverage intervention included training health professionals on nutritional recommendations, counseling pregnant women on diet and physical activity, and appropriate referral to primary health care centers' dieticians. The study found that the intervention reduced gestational weight gain and has the potential for successful scale-up [26].

New strategies to engage the target population are required to maintain nutritional recommendations as a priority in the daily decision-making (top of mind) of pregnant women [27]. Interventions based on behavioral theories provide a greater understanding of the underlying mechanisms that determine health-related behavior change and have the potential to be more effective in promoting adherence to weight gain control [28]. The social cognitive theory [29,30] considers the social dimension of the individual since each individual has a belief system and the capacity for self-motivation and positive behavioral changes [29,31,32]. Therefore, technologies such as mobile phones can be useful to effectively address this problem. Mobile phone ownership is widespread among all sectors of society, regardless of socioeconomic status, which gives us the possibility to introduce the mobile health (mHealth) intervention as an important component of future health care practice [32].

mHealth programs are potentially more effective than face-to-face interventions since they make it possible to cover a larger part of the population; moreover, face-to-face interventions are more labor-intensive, time-consuming, and expensive. Furthermore, they are especially useful during public health emergencies, like the recent COVID-19 pandemic [33]. According to the World Health Organization, mHealth has been defined as "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices" [34]. Mobile phones are personal, portable, and connected devices [30]. This means that messages can be proactively delivered directly to people, while face-to-face activities or visiting a web page require "going" to look for the information, that is, the self-determined motivation of pregnant women. In this sense, a recent meta-analysis that included 12 randomized controlled trials (RCTs) conducted in an adult population of different ages and conditions demonstrates the efficacy of interventions based on mobile phone apps for weight loss [35]. The combined findings of 10 of the studies included in the meta-analysis showed a substantial reduction in BMI (−0.45 kg/m^2) and body weight (−1.07 kg) in the intervention group [35]. A recently published RCT that aimed to evaluate the efficacy of a digital health intervention on maternal and perinatal outcomes in pregnant women with obesity who attended the maternal-fetal department of the Hospital-Clinic of Barcelona [31] demonstrates that the digital intervention, which was delivered by the midwife through an app, including advice on gestational weight gain and physical activity, found that gestational weight gain was lower and physical activity increased in obese pregnant women in the intervention group [31]. Hence, we aim to evaluate the effectiveness of an mHealth intervention, based exclusively on mobile phone–delivered messages directed to the cognitive, emotional, and psychomotor

XSL•FO
RenderX

behavior, called mami-educ, to reduce excessive weight gain in pregnant women who attend family health care centers in urban and predominantly rural areas (Figure 1). The intervention will last 12 weeks and consists of sending messages through the multimedia messaging system (MMS), with food education addressing the cognitive, affective, and psychomotor domains. According to the literature, the basic factors for adopting a healthy behavior are the perceived susceptibility to the perceived threat of a disease, the perceived consequence, such as severity, the perception of the positive benefits of the action, the perceived barriers to action, and the confidence in the ability to succeed, which is perceived as self-efficacy for action [36]. Thus, the messages that address the cognitive domain of learning are aimed at helping pregnant women understand the benefits of a healthy diet and the harm of a diet rich in fats and sugars during pregnancy, while the affective domain will address the beliefs, barriers, and opportunities to achieve the consumption of healthier foods and contribute to the health of the mother-child binomial. Behavior change is initiated and sustained when people feel that they can execute the desired behavior (ie, self-efficacy) and have a reasonable expectation that the behavior will lead to the desired outcome [37]. In this sense, the psychomotor domain seeks to promote self-efficacy by delivering messages about preparations with adequate nutrition for pregnancy and planning actions to avoid eGWG.

Figure 1. Schematic diagram of the proposed solution. The solution called "mami-educ" consists of sending cognitive, affective, and psychomotor messages through MMS to pregnant women that assist family health centers in urban and rural areas. MMS: multimedia messaging system.

Methods

Study Design and Participants

The design of the intervention corresponds to a classic RCT, a design that allows us to prospectively study pregnant women, in which it is intended to compare the effect of the intervention versus the control condition, to establish a cause-and-effect relationship. This design allows us to reduce the risk of comparability bias. The study will be carried out with pregnant women who control their pregnancy in Family Health Centers (CESFAM) of the Metropolitan Region (the capital city of Chile) and the Aconcagua Valley, Valparaiso Region (88 km to the north of the capital). The CESFAM work under the Comprehensive Health Model with a Family and Community Approach, focusing on prevention and health promotion, and are responsible for basic health care, including home care and health rehabilitation actions. These centers focus on families and communities, give importance to community participation, and work with a primary health team that attends to the whole family in health and sickness throughout the life cycle.

Control Group

Pregnant women enrolled in the prenatal control program receive routine care at the CESFAM.

Intervention Group

Pregnant women enrolled in the prenatal control program receive routine care at the CESFAM and messages on nutrition (intervention).

Inclusion Criteria

Chilean- or Spanish-speaking immigrant pregnant women older than 18 years who receive care at the 6 CESFAM in El Bosque, Metropolitan Region and in Segismundo Iturra CESFAM in San Felipe, Aconcagua Valley, Valparaiso Region; who have gestational ages ≤12 weeks (first trimester); who have a single pregnancy; who declare to have a normal pregnancy at the time of starting the intervention; who agree to be randomized; and who have voluntarily signed the informed consent can participate in this study. The pregnant women who participate in the study must have a mobile device that allows the use of MMS.

Exclusion Criteria

Exclusion criteria include multiple pregnancies, conditions requiring a special diet, participants with psychiatric illnesses or other prepregnancy pathology, and a history of recurrent miscarriages.

Sample Size Calculation

The total sample consists of 511 participants, which will be divided into 2 groups. In the El Bosque CESFAM, 280 pregnant women were recruited, with an estimated dropout rate of 30% (based on the pilot study carried out) to guarantee the required sample size of 210 pregnant women with a confidence level of 90% and a 5% error. At Segismundo Iturra CESFAM, 231 pregnant women were recruited, with the same estimated dropout rate, to ensure a sample size of 178 pregnant women with a confidence level of 90% and a 5% error. For the calculation of the sample size, the official records of the DEIS regarding the number of pregnant women between 20 and 44 years of age who were treated for prenatal control in the CESFAM of the El Bosque commune and Segismundo Iturra were considered. The recruitment period will be 6 months.

Randomization and Masking

The pregnant women who meet the inclusion criteria are invited to participate in the study, as are those who accept and sign the informed consent form. These pregnant women receive the link to the diagnostic survey on their telephones and are then randomized to be included in the intervention. At the end of each month of the recruitment period, the researchers will randomize the pregnant women who were recruited during that

XSL•FO
RenderX

month. A stratified randomization will be carried out to ensure a sample that is as balanced as possible. The sample will be divided into 4 strata according to their pregestational weight, classifying them as underweight (BMI<18.5 kg/m^2), normal weight (BMI 18.5-24.9 kg/m^2), overweight (25-29.9 kg/m^2), and obese (BMI≥30 kg/m^2). Simple random selection will be carried out then by generating a table of random numbers without repetition, from 1 to n, and deciding a priori that it will be read from left to right, with even numbers assigned to the control group and odd numbers to the intervention group.

A single-blind study will be carried out since the CESFAM personnel who will oversee the recruitment will be blinded to the randomization of the subjects to avoid bias in routine care.

Procedures

The recruitment of pregnant women will be done for a period of 6 months. The study will end when all the participants with intervention have completed the 12-week message period.

Immediately after randomization, the researchers will send the MMS with the link that leads to a web-based survey. The survey will be the same for the control group and intervention group and will recollect demographic information, nutritional habits, and physical activity. Pregnant women in the intervention group who respond to the survey will receive the intervention messages by MMS.

Routine care visits will be scheduled usually by CESFAM's midwifery professionals. Such visits should occur monthly until the 28th week of gestation, biweekly during the 28-36 weeks of gestation, and weekly until delivery. During prenatal control, the nutritional evaluation is carried out according to the technical standard, and a referral to a nutritionist is made if necessary. These care visits may also include participation in the "Elige Vivir Sano" and "Chile Crece Contigo" programs and everything associated with the prenatal control program.

Intervention

The intervention consists of 3 MMS messages with nutritional information per week for 12 consecutive weeks. The messages were reviewed by a perinatal psychologist. The messages will be sent as follows: Monday at 3 PM, the message that addresses the cognitive domain will be sent; Tuesday at 3 PM, the message that addresses the affective domain will be sent; and Thursday at 3 PM, messages that address the psychomotor domain, together with the weekly user satisfaction survey, will be sent. This delivery scheme was validated in the pilot study that was carried out. The 12 topics related to nutrition during pregnancy will be addressed, 1 will be addressed per week, and 3 messages will be sent for each topic. At the beginning of each month, messages will be sent to pregnant women who were recruited during the immediately previous month. In the development of the project and to prevent pregnant women from incurring additional expenses for participating in the intervention, we will directly recharge the phones of the users who participate in the study.

Follow-up

The team of midwives will keep a record of the weight of the pregnant women who attend their prenatal checkups monthly. Therefore, the monitoring of the weight of both groups will be done through the midwives in order not to request sensitive data via MMS.

Dropouts

A record of the number of pregnant women who drop out of the study will be kept, as well as their characteristics for subsequent statistical analysis.

Primary and Secondary Outcomes

The primary outcome will be to assess the effectiveness of the mHealth mami-educ intervention in reducing the incidence of eGWG compared to routine care. Secondary outcomes will include identifying the barriers and facilitators influencing weight gain in pregnant women to compare the maternal outcome of pregnancy, in terms of complications developed during pregnancy (pre-eclampsia, gestational diabetes, and gestational hypertension), and the perinatal outcomes (prematurity and birth weight) of the pregnant women in the control and intervention groups.

Statistical Analysis

The data analysis plan will be governed by the intention-to-treat principle, as we will include all participants who were randomly assigned after recruitment, assuming that participants who drop out are treatment failures. The effectiveness of the treatment will be measured using the chi-square test (χ^2), comparing the intervention group with the control group in terms of the percentage of women who are classified as having excessive weight gain at the end of pregnancy. To confirm the effectiveness of the intervention, a significant decrease (P<.001) of women with eGWG in the intervened group will be expected. For data analysis, the statistical software GraphPad Instat 3.0b and GraphPad Prism 6.0f (GraphPad Software Inc) will be used. P<.001 (determined by a 2-sided test) will be considered statistically significant.

Ethics Approval

This research will be conducted in accordance with the Declaration of Helsinki. The study was approved by the Scientific Ethics Committee of the Aconcagua Health Service (protocol number: 26/2021, approved October 12, 2021) and the Scientific Ethics Committees of the South Metropolitan Health Service (protocol number: 07-27012022, approved February 7, 2022). Informed consent will be obtained from all participants invited to participate in the study before proceeding with the initial survey. The data will be treated respecting the ethical principles that guarantee the anonymity of the participants.

Results

The study was funded by the National Research and Development Agency of Chile in December 2021. The data collection began on May 2, 2022. Study staff have been engaged in activities associated with study including enrollment and data

XSL•FO
RenderX

collection. As of November 30, 2022, a total of 222 pregnant women have been admitted for the first prenatal appointment, 127 meet the inclusion criteria, and 76 agree to participate and answered the diagnostic survey. The expected timeframe for completing recruitment and data analysis is November 2023.

Discussion

Principal Findings

It is well known that pregestational obesity has been recognized as a risk factor for several perinatal complications, such as fetal macrosomia, gestational diabetes, hypertensive disorders, failed induction, premature rupture of membranes, and cesarean section [38]. Nevertheless, this risk is increased when eGWG is present [39,40]. Prevention strategies in primary care are key to fighting this problem; in this regard, strategies that target behavior change by promoting self-efficacy have been proposed [37]. A recent study conducted focus groups with 66 women between 16 and 24 weeks' gestation [19], and the participants expressed that the difficulties in operationalizing the information in the guidelines and that provided by health care providers were one of the important barriers to self-care. For this reason, care providers' advice on nutrition and physical activity was perceived as minimal and ineffective. We propose the integration of social cognitive theory with mHealth to provide nutritional information to pregnant women in primary care. In this study, the structure of the messages addresses 3 learning domains (cognitive, affective, and psychomotor) that promote self-efficacy [37]. The hypothesis of this study is that the mHealth intervention called mami-educ is effective in reducing eGWG in pregnant women who attend family health care centers in an urban area and another predominant rural area. From a public policy perspective, effective health communication is very important; mHealth provides fast, easy-to-use, and cost-effective communication. We designed this study to address the gap in evidence-based primary prevention strategies regarding the use of mHealth to reduce eGWG. Overall, this proposal has the potential to reduce the incidence of perinatal complications through adequate gestational weight gain. To ensure the reproducibility of the study for future research and reduce the risk of comparability bias, the design of the intervention corresponds to a classic RCT. This design allows us to carry out a prospective study of pregnant women in which it is intended to compare the effect of the intervention versus the control condition to establish a cause-and-effect relationship.

The results of this study may serve to implement evidence-based primary prevention strategies and help a broader group of pregnant women maintain adequate weight gain during pregnancy and prevent pregnancy pathologies associated with obesity. This would ultimately influence health care costs. In Chile, it has been described that the cost of overweight and obesity increases to US $455 million by year, representing 2% of the total health budget, which means that obesity costs 4-fold higher than normal weight health care [41]. Through this observation, the projected health costs for 2030 related to overweight and obesity will reach 3.4% of the total health budget (US $3 billion). Furthermore, it is estimated that a weight reduction of 7%-10% in the obese population would translate into a 40% decrease in spending on obesity-associated comorbidities [42]. Thus, promoting adequate weight gain during pregnancy in women with obesity could improve maternal, fetal, newborn, and offspring health and could significantly reduce public health care costs. Lastly, the data collected in this study can play a central role in the development of public policies based on mHealth directed exclusively to the population of pregnant women.

Limitations

A limitation of this study is the reliance on smartphones to access interventions. In addition, the recruitment of pregnant women must occur during the first trimester of gestation, and this may be hindered because some pregnant women begin prenatal care in the second trimester. Another limitation is that the pregnant woman may decide not to interact with the messages by blocking the number of the intervention.

Acknowledgments

Authors thank Mrs Rina Torres and the midwives team from Centro de Salud Familiar (CESFAM) of the Segismundo Iturra, San Felipe, and also, Marcela Gonzalez and the midwives team from CESFAM of the El Bosque commune, for the logistic assistance. Abstract

Background: Suicide is the leading cause of death among Australians. One commonly cited explanation is the impact of social media, in particular, the ways in which young people use social media to communicate about their own experiences and their exposure to suicide-related content posted by others. Guidelines designed to assist mainstream media to safely report about suicide are widespread. Until recently, no guidelines existed that targeted social media or young people. In response, we developed the #chatsafe guidelines and a supporting social media campaign, which together make up the #chatsafe intervention. The intervention was tested in a pilot study with positive results. However, the study was limited by the lack of a control group.

Objective: The aim of this study is to assess the impact of the #chatsafe social media intervention on young people's safety and confidence when communicating on the web about suicide.

Methods: The study employs a pragmatic, parallel, superiority randomized controlled design. It will be conducted in accordance with the Consolidated Standards of Reporting Trials statement over 18 months. Participants will be 400 young people aged 16-25 years (200 per arm). Participants will be recruited via social media advertising and assessed at 3 time points: time 1—baseline; time 2—8-week postintervention commencement; and time 3—4-week postintervention. They will be asked to complete a weekly survey to monitor safety and evaluate each piece of social media content. The intervention comprises an 8-week social media campaign including social media posts shared on public Instagram profiles. The intervention group will receive the #chatsafe suicide prevention content and the control group will receive sexual health content. Both groups will receive 24 pieces of content delivered to their mobile phones via text message. The primary outcome is safety when communicating on the web about suicide, as measured via the purpose-designed #chatsafe online safety questionnaire. Additional outcomes include willingness to intervene against suicide, internet self-efficacy, safety, and acceptability.

XSL•FO
RenderX

Results: The study was funded in November 2020, approved by the University of Melbourne Human Research Ethics Committee on October 7, 2022, and prospectively registered with the Australian New Zealand Clinical Trials registry. Trial recruitment began in November 2022 and study completion is anticipated by June 2024.

Conclusions: This will be the first randomized controlled trial internationally to test the impact of a social media intervention designed to equip young people to communicate safely on the web about suicide. Given the rising rates of youth suicide in Australia and the acceptability of social media among young people, incorporating social media–based interventions into the suicide prevention landscape is an obvious next step. This intervention, if effective, could also be extended internationally, thereby improving web-based safety for young people not just in Australia but globally.

KEYWORDS

suicide; young people; social media; intervention, sexual health, randomized-controlled trial

Introduction

Background

Suicide is the leading cause of death among Australians younger than 25 years, and rates have been increasing over the past 10 years [1]. The pathways that lead a young person to feel suicidal are complex and diverse; however, 1 commonly cited explanation for the recent rise in rates of youth suicide is the impact of social media [2].

Young Australians spend over 3 hours per day on social media, and this sometimes includes communicating with others about their own experiences of suicide and being exposed to suicide-related content posted by others [2-4]. While there are many potential benefits to communicating on the internet about suicide, such as the ability to seek and provide support from others in an accessible and nonstigmatizing manner [3,5], the potential for harm also exists. For example, there are concerns that certain types of content (eg, graphic information or images) may cause distress, lead to imitative suicidal behavior, and have been thought to contribute to suicide clusters [6]. In addition, young people may be exposed to expressions of suicide risk posted by others but feel ill-equipped to respond [7].

Guidelines designed to assist mainstream media outlets to report on suicide in a sensitive manner are widespread and have led to improved safety and quality of communication about suicide [8]. They also appear to be linked to a reduction in suicide rates [9]. However, until recently, no guidelines existed that targeted either social media or young people, who are now creators of their own content.

In response to this, we developed the #chatsafe guidelines [10], which were the first set of guidelines in the world specifically designed to better equip young people to communicate safely on social media about suicide. They were developed using the Delphi consensus method in partnership with young people, media, and suicide prevention professionals [11]. The guidelines consist of five sections: (1) things to consider before you post about suicide; (2) sharing your own thoughts, feelings, or experience with suicidal behavior; (3) communicating about someone you know who is affected by suicidal thoughts, feelings, or behaviors; (4) responding to someone who may be suicidal; and (5) memorial websites, pages, and closed groups.

The guidelines were supported by a national social media campaign designed to make the content of the guidelines more accessible to young people. The campaign was co-designed with young people from across Australia [12] and was initially rolled out nationally in 2019, reaching around 1.5 million young people. Together, the guidelines and campaign make up the #chatsafe intervention.

Aims and Hypotheses

The overall aim of the study is to assess the impact of the #chatsafe social media intervention on young people's safety and confidence when communicating on the internet about suicide. In this study, the treatment group who will receive the #chatsafe social media intervention will be compared to the control group who will receive social media content providing education on sexual health and well-being.

It is hypothesized that (1) At postintervention (T2), the treatment group will have higher mean scores than the control group on their understanding and compliance with the #chatsafe guidelines, as measured by the #chatsafe online safety questionnaire. Specifically, this will be assessed by improvements in their understanding of language to use or not use, support services available to them, how to share their own experiences of suicide safely, how to communicate about those who have died by suicide, and how to support someone that they are worried about. (2) At the postintervention time point (T2), the treatment group will have higher mean scores than the control group on self-reported (i) safety and confidence when communicating on the internet about suicide, (ii) willingness to intervene against suicide on the internet, and (iii) perceived internet self-efficacy. (3) It will be safe and acceptable to share the #chatsafe intervention with young people entirely via social media (assessed weekly throughout the intervention and postintervention [T2]). (4) Knowledge gains made in the intervention group at T2 will be maintained at T3.

Subgroup differences in perceptions toward the intervention and outcomes of the intervention (ie, gender, sexuality, age groups, and level of social media usage) will also be examined.

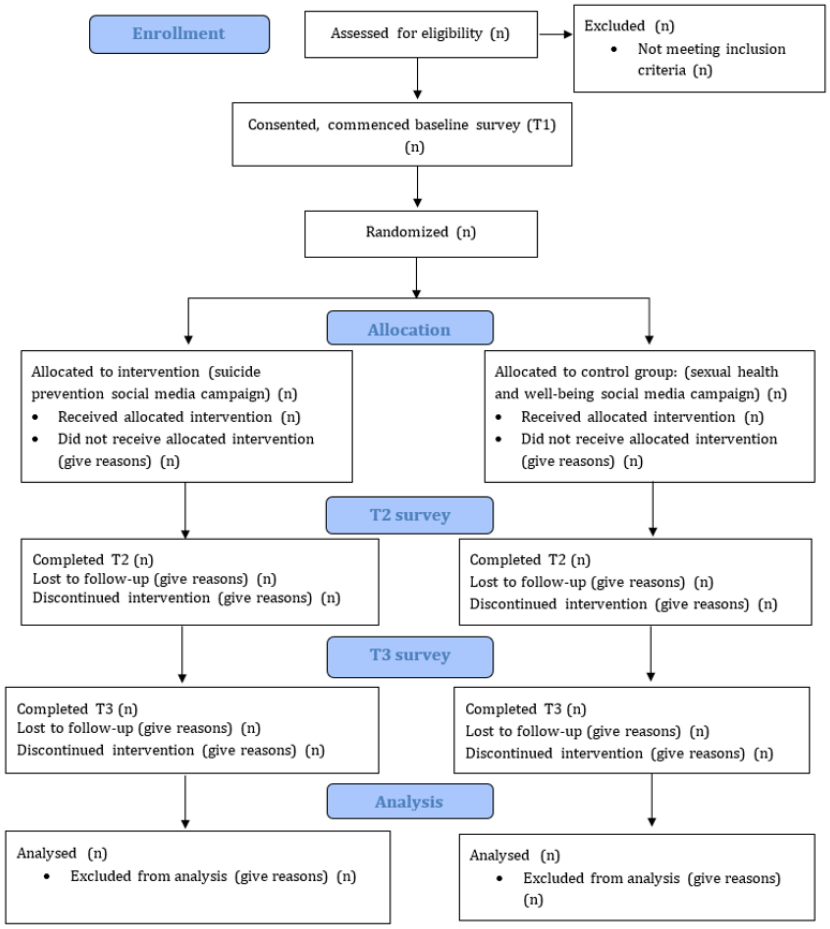
XSL•FO
RenderX

Pilot Data

The #chatsafe intervention was tested in a pilot study in 2019-2020 [13]. The aims were to assess the acceptability, safety, and feasibility of the intervention as well as its impact on perceived self-efficacy, willingness to intervene against suicide on the internet, and safety of web-based communication about suicide. The study adopted a single-group pre- and posttest design. Participants were 189 young people aged 16-25 years recruited from 3 states in Australia via social media advertising. The intervention comprised 3 #chatsafe posts each week on the #chatsafe Instagram page. Participants were sent 1 post via direct message each week, for a period of 12 weeks. The results indicated that participants found the intervention acceptable. Participants also demonstrated improvements in perceived ability ($P<.001$) and intent to intervene against suicide ($P<.001$), and in several domains of internet self-efficacy, for example, problem-solving on the internet ($P<.001$). They also demonstrated improved web-based behavior, including monitoring their social media posts and responding directly to someone who may be suicidal.

Although these findings painted a promising picture, the pilot study was limited by the lack of control group. Therefore, the aim of this study is to test the efficacy of the #chatsafe intervention in a randomized controlled trial (RCT).

Methods



Study Design

The study uses a pragmatic, parallel, superiority randomized controlled design, where the intervention condition (the #chatsafe suicide prevention intervention) is compared to a control condition (sexual health content). It will be conducted over an 18-month period with up to a 12-month recruitment period and an 8-week intervention phase.

Participants will be assessed via self-report surveys at 3 time points: time 1 (T1)—baseline; time 2 (T2)—8-week postintervention commencement; and time 3 (T3)—4-week postintervention. In addition, participants will be asked to complete a short weekly survey to monitor safety and allow evaluation of each piece of social media content. All participants will be reimbursed for their time at a rate of Aus $45 (US $31.95) per hour.

The study is being led by researchers based at Orygen and the Centre for Youth Mental Health, University of Melbourne, Melbourne, Victoria, Australia. It will be conducted and reported in accordance with the Consolidated Standards of Reporting Trials statement [14] (Figure 1).

Figure 1. Consolidated Standards of Reporting Trials flow diagram of participants for enrollment, allocation, T1, T2, T3, and analysis stages.

XSL•FO
RenderX

Participants and Recruitment

Participants will be 400 young people (200 per arm of the trial). Inclusion criteria are being aged between 16 and 25 years, living in Australia, having used social media to communicate about suicide or self-harm *or* having seen suicide- or self-harm–related information on social media, having not previously participated in a research study that was focused on evaluating suicide prevention or sexual health–related content on social media, considering oneself as being an active social media user, and being willing to share one's mobile phone number with the research team so that one can be contacted with regard to trial-related communications.

Participants will be recruited via social media advertising using Orygen's social media accounts. Young people who wish to participate will be directed to a brief self-assessment questionnaire to assess eligibility. They will then automatically be directed to a web-based consent form, which explains the key aspects of study involvement and consent process. This is followed by the T1 questionnaire, after which, participants will be randomly allocated to either the intervention group (#chatsafe intervention) or the control group.

The participant flowchart is shown in Figure 1.

Intervention

The intervention comprises an 8-week social media campaign. Intervention material will take the form of social media posts shared on public Instagram profiles created for the purpose of this study. As shown in Figure 1, the intervention group will receive the #chatsafe suicide prevention content, and the control group will receive the PROSPEct sexual health content. Both groups will receive 24 pieces of content; that is, 3 per week. All content will be delivered to participants' mobile phones via SMS text messaging via REDCap (Research Electronic Data Capture), an electronic data capture tool hosted at The University of Melbourne. A description of the #chatsafe intervention (group A) is provided in Textbox 1. The content is based on the #chatsafe guidelines and was developed in partnership with young people; examples are provided in Multimedia Appendix 1.

The control content will comprise 8 weeks of sexual health content (PROSPEct content). A description of the control content (group B) is provided in Multimedia Appendix 2, and examples from both the treatment and control conditions are shown in Multimedia Appendix 1.

XSL•FO
RenderX

Textbox 1. The intervention content (group A, #chatsafe condition) by week.

Week 1: introduction

- Co-design—how the campaign was developed in partnership with young people
- Campaign overview: introduction to campaign learning objectives
- What is safe and unsafe communication about suicide?

Week 2: have you seen posts on the internet about suicide?

- What is safe and unsafe communication about suicide? (continued)
- What to do if you've seen content that you think is unsafe
- What happens when you report content online?

Week 3: sharing your own experiences of suicide on social media

- Sharing experiences in a way that is helpful to you
- Sharing experiences in a way that is helpful to others
- Content warnings

Week 4: asking someone if they are feeling suicidal

- Myth busting—it is safe to ask about suicide
- Things to do before you approach someone
- Asking the question

Week 5: navigating the conversation about suicide

- If they say yes—What you can say to someone in suicidal distress?
- What to say and do if they say no
- How to exit the conversation and looking after yourself

Week 6: when someone has died by suicide

- Safely sharing the news online
- Checking in on your friends (and yourself)
- Memorializing the deceased or communicating after the death

Week 7: helping a friend who has lost someone to suicide

- Checking in with yourself
- Planning how to approach your friend
- Helpful things to say or do to help a friend affected by suicide

Week 8: thank you and wrap up

- Available resources and supports
- Co-design
- Thank you

Study Outcomes

The primary outcome is safety when communicating online about suicide, as measured via the purpose-designed #chatsafe online safety questionnaire at T2. This measure was specifically designed for this purpose by 3 study authors (JR, LLS, and CC).

Secondary outcomes are (1) confidence when communicating on the internet about suicide, as measured via the purpose-designed #chatsafe online safety questionnaire at T2; (2) willingness to intervene against suicide on the internet, as measured via the Willingness to Intervene Questionnaire at T2 [15]; (3) internet self-efficacy, as measured by the Internet Self-Efficacy Questionnaire at T2 [16]; (4) safety of the weekly #chatsafe content, as measured by the purpose-built weekly evaluation and engagement survey; (5) acceptability of the #chatsafe intervention, as measured by the purpose-built T2 evaluation questions; and (6) safety of the #chatsafe social media intervention (as a whole), as measured by the number of (or absence of) adverse events recorded throughout the trial.

XSL•FO
RenderX

Participant adverse events include (1) participant response to item 9 on the 9-item Patient Health Questionnaire [17] at baseline (time 1), time 2, or time 3. (2) Participant response to the 9-item weekly evaluation survey indicates distress, measured by participants selecting "very distressed" in response to the question "To what extent did you find the content this week distressing?" (3) Participant response to the T2 evaluation questionnaire indicates that a particular piece of campaign content made them feel distressed or at risk of suicide. (4) The participant directly contacts the research team via social media or email and reports distress or risk of harm to self. All adverse events will be responded to by the study team, in line with the study's safety management strategy. (7) Feasibility of the #chatsafe social media intervention was measured by campaign reach via social media analytics, and participant retention or attrition via audit of study enrollment and withdrawal logs. (8) Self-reported evaluations of the acceptability of receiving the #chatsafe social media intervention were measured by purpose-designed study questions. Exploratory outcomes are as follows: (1) subgroup differences (gender, age, previous exposure to, previous experiences of suicide and self-harm, and level of social media usage) at T2 and (2) self-reported open-ended evaluations of the safety, feasibility, and acceptability of receiving the PROSPEct social media intervention for sexual health promotion in the control group at T2.

Outcome Measures

Outcome measures together with the assessment schedule are presented in Table 1. Note that all participants complete the same questionnaires (T1, T2, T3, and purpose-designed 3-item weekly evaluation and engagement survey) regardless of the arm they are allocated to.

Table 1. Schedule of assessments and measures.

Measure	Baseline (T1, week 1)	Intervention (weeks 2-9)	Postintervention (T2, week 9)	Follow-up (T3, week 13)
Purpose designed #chatsafe online safety questionnaire	✓	N/A[a]	✓	✓
Patterns of Social Media Use Questionnaire (including 12 items to assess social media usage for the purposes of communicating about suicide and-self harm specifically)	✓	N/A	✓	✓
Perceived Internet-Self Efficacy Scale	✓	N/A	✓	✓
Willingness to Intervene Against Suicide Questionnaire	✓	N/A	✓	✓
Patient Health Questionnaire-9	✓	N/A	✓	✓
Purpose designed 7-items assessing exposure to, and personal experiences of, suicide and self-harm	✓	N/A	✓	✓
Purpose designed 9-item Weekly Evaluation and Engagement survey	N/A	✓	N/A	N/A
Purpose designed 1-item assessing participant reasons for withdrawal/noncomplete	✓	✓	✓	✓
Purpose designed 10-items assessing participants' evaluations of the intervention content immediately postintervention	N/A	N/A	✓	N/A
Sexual Health Capacity Scale	✓	N/A	✓	✓
Self-Efficacy Protective Sexual Behaviours Scale	✓	N/A	✓	✓
Sexual Health Questionnaire	✓	N/A	✓	✓

[a]N/A: not applicable.

Randomization and Treatment Allocation

Participants will be randomized to the intervention or the control group using block randomization with varying block sizes. The allocation ratio will be 1:1. The randomization schedule is computer generated by independent information technology personnel with guidance from the study statistician (MS). The schedule will then be implemented by a member of the study team (other than the statistician) into the REDCap database management software for allocating treatments to individual participants. Except for the study statistician, the study team members are not blinded to the treatment allocations. The study statistician will not have access to the randomization component of the database and will not be informed about the treatment allocations and will therefore remain blinded. As the study statistician will not be involved in any aspect of this study's operations other than data analysis, there are no circumstances we could foresee under which the study statistician would be required to be unblinded.

Statistical Analysis

At baseline, state of residence, postcode, age, Aboriginal or Torres Strait Island status, gender identity, sexual orientation, primary language spoken at home, cultural background, and educational and occupational background will be reported using descriptive statistics and will be checked for imbalance between trial arms. The moderating effect of gender (male, female, trans, and gender diverse), age group (ie, 16-20 and 21-25 years), time spent on social media, psychological distress, and previous experience of suicide and self-harm will be considered in analyses as covariates.

XSL•FO
RenderX

Analyses will be performed on an intention-to-treat basis, where all individuals randomized will be included in the analysis by their allocated trial arm status regardless of whether they received all, part, or none of the intended treatments. For the primary analysis, we will use linear regression to estimate the difference in the mean changes between the intervention and control arms at T2 in the outcome safety when communicating online about suicide, as measured via the #chatsafe online safety questionnaire. This analysis will adjust for T1 scores. Multiple imputation will be used to address attrition bias, with 50 imputation samples generated using chained equations. We will conduct 2 sensitivity analyses. One sensitivity analysis will be undertaken using complete cases only (ie, repeating the primary analysis but only analyzing participants who have complete T1 and T2 data). The second sensitivity analysis will use multiple imputation and include the following potential moderating factors as covariates: gender (male, female, transgender, and gender diverse), age group (ie, 16-20 and 21-25 years), time spent on social media, psychological distress, and previous experience of suicide and self-harm.

The secondary outcomes at T2 and T3 will be analyzed based on the primary analysis and the 2 sensitivity analyses. We will use linear regression for continuous outcomes, logistic regression for binary outcomes, and negative binomial regression for counts.

Potential iatrogenic effects will be analyzed on a weekly basis and will serve as an interim analysis throughout the course of the study. If the weekly content is assessed as “very distressing” by more than 20% of participants per week, the safety monitoring committee (SMC) will be consulted, and the content may be withdrawn. The acceptability of each week’s content will be analyzed and reported as descriptive statistics (frequencies and percentages).

Sample Size and Statistical Power

This is the first study to investigate the #chatsafe intervention in an RCT and the first to use the proposed measures. As such, there are no previous data to guide the possible effect of the intervention, and therefore the sample size is required; however, a sample of ~400 participants (200 per arm) should be sufficient to assess the primary study outcome with a 5% significance level and 80% power.

The pilot study [13] recruited a total of 507 participants within a 3-month period, resulting in a final sample of 189 young people who completed all 3 time points. Note that the intervention period for this study was 12 weeks compared to 8 weeks in this study. As such, data from the pilot study on rates of recruitment and attrition indicate that the recruitment period of up to 12 months will be more than sufficient to achieve the required sample size.

In an effort to reduce attrition, all participants will be sent a SMS text message by a research team member halfway through the intervention period (week 4), as well as at T2 and T3 if they have not completed their survey 4 days after being sent their survey. This will encourage participants to complete their survey if they have not already done so and will provide them the opportunity to raise any concerns or questions.

Ethical Considerations

The study has been approved by the University of Melbourne Human Research and Ethics Committee (ID 2022-24238-32907-3). All participants will be required to provide written consent prior to commencement of the study.

The study will be carried out in accordance with the principles contained in the Declaration of Helsinki and the Australian National Health and Medical Research Council (NHMRC) National Statement on Ethical Conduct in Human Research and the NHMRC Australian Code for the Conduct of Research. In addition to being assessed at T2, safety will also be tracked using the weekly evaluation and engagement survey to identify any distress that is attributed to the intervention (see Table 1). Previous distress and suicide risk will be deemed as that reported during the baseline assessment. Further relevant risk will not be reported unless adverse events are reported by the participant or other study team members, which are deemed to possibly having been caused by study activities such as distress because of the intervention or because of interaction with the study team.

As per the pilot study, an SMC has been established. The main purpose of the committee is to oversee the safety of the trial. It comprises the study Chief Investigator (JR), members of the study team, as well as an Orygen Sponsor Operations representative, a statistician, a clinician, and a subject-matter expert. An initial meeting will be held prior to the commencement of recruitment to review the study risk assessment and the determination of safety oversight procedure. The research team will meet fortnightly for the duration of the trial, and a standing function of these meetings will be to review safety incidents and refer any relevant matters to SMC. All members of the SMC will be convened on a study-specific basis (ie, any time a serious safety concern is raised). The SMC will make recommendations as to appropriate risk assessment and mitigation measures, including but not limited to decisions as to whether the study should be amended or put on hold.

Finally, detailed safety protocols have been established and overseen by the trial psychologist (SR) and Orygen’s Sponsor Operations team (Multimedia Appendix 3).

Youth Participation

Young people have been involved in the preparation of this study in multiple ways. First, the entire #chatsafe program of work has been conceptualized, designed, and conducted in partnership with young people. The #chatsafe guidelines were created using the Delphi consensus method, with young people as an expert panel [11]. The first #chatsafe social media campaign was cocreated in partnership with over 140 young people [12].

The study was presented to Orygen’s Youth Research Council in November 2021, and feedback on intervention development and study conduct was obtained. A total of 3 co-design (N=46) and 1 user testing (N=10) workshops were conducted in April and May 2022 to help create the trial content. A total of 3 youth advisors helped to develop the participant information consent form and the #chatsafe online safety questionnaire. Finally, we are currently recruiting 2 paid youth advisors to this study to assist with participant recruitment and engagement. At the end

XSL•FO
RenderX

of the study, they will assist with the interpretation and dissemination of the study findings, including conference presentations and journal articles.

Results

The funding for this project was awarded in November 2020 by the Australian Research Council; however, progress was delayed down due to the impacts of the COVID-19 pandemic. Approval from the University of Melbourne Human Research and Ethics Committee was provided in October 2022. Recruitment into the trial began in November 2022 and study completion is anticipated by June 2024. The trial is registered with the Australian and New Zealand Clinical Trials Registry (ACTRN12622001397707).

Discussion

This will be the first RCT internationally to test the impact of a social media intervention designed to better equip young people to communicate safely on the internet about suicide.

Social media platforms are commonly used by young people to communicate about suicide. While users rarely set out to cause harm to themselves or others, the potential for harm exists [18,19]. Therefore, it is essential that young people are adequately equipped to safely communicate on the internet about suicide. Guidelines regarding safe reporting of suicide exist for mainstream media [20]; however, until recently, no such guidelines have been developed by, and for, young people. Also, existing media guidelines do not specifically address the challenges and opportunities offered by social media. Although media campaigns are gaining traction in the suicide prevention sector, to date, they have not been developed with young people in mind nor have their impact on behavior change, in particular among young people, been tested.

The development of the #chatsafe intervention not only addresses these gaps, but it also represents a paradigm shift. It shifts the narrative away from advising young people to avoid engaging in suicide-related communication on social media—a strategy that is clearly not working—toward an approach that seeks to better equip young people to communicate safely. The guidelines themselves have already had significant traction not just in Australia but also internationally. They have been adapted for 11 additional countries and downloaded around 120,000 times [21]. In addition to being freely available on the Orygen website, they are also available via both the Facebook and Instagram Safety Centers, thereby significantly extending their reach [22,23]. The social media content has been widely disseminated via platforms such as Instagram, Facebook, Snapchat, and YouTube. There are few suicide prevention interventions that have the potential to be delivered at scale in this way.

This study proposes a rigorous and novel methodology. Until now, research into suicide and social media has been largely cross-sectional in nature and has examined the association between social media use and suicidal thinking. No studies have tested suicide prevention interventions delivered via social media using robust research designs. This study will build on a previous pilot study (La Sala et al, unpublished data) and will provide a robust evidence base for this work.

This work is timely. Given the rising rates of youth suicide in Australia and the acceptability of social media among young people, incorporating social media–based interventions into the suicide prevention landscape is an obvious next step. This intervention, if effective, could also be extended to international settings, thereby improving online safety for young people not just in Australia but globally.

Acknowledgments

The study received funding from the Australian Research Council (DP210101097). The #chatsafe project also receives funding from the Commonwealth Department of Health under the National Suicide Prevention Leadership and Support Program. JR is funded by an NHMRC Investigator Grant (ID2008460) and a Dame Kate Campbell Fellowship from the University of Melbourne. LLS is funded by a Suicide Prevention Australia post-doctoral fellowship. SR is funded by an NHMRC Career Development Fellowship (APP1158881) and a Dame Kate Campbell Fellowship from the University of Melbourne. JP is funded by a National Health and Medical Research Council Investigator Grant (GNT1173126) and a Dame Kate Campbell Fellowship from the University of Melbourne. MS is a recipient of an Australian Research Council Future Fellowship (FT180100075) and a Dame Kate Campbell Fellowship from the University of Melbourne.

Data Availability

All data analyzed during this study will be included in any published articles (and their supplementary information files). The participants of this study did not give written consent for their data to be shared publicly, so due to the sensitive nature of this research, supporting data are not available.

Abstract

Background: Dyspnea is a prevalent symptom in individuals with hypermobile Ehlers-Danlos Syndrome (hEDS) and generalized hypermobility spectrum disorder (G-HSD), yet its contributors have not been identified. One known contributor to dyspnea is respiratory muscle weakness. The feasibility and effectiveness of inspiratory muscle training (IMT) in combination with standard-of-care rehabilitation (aerobic, resistance, neuromuscular stabilization, and balance and proprioception exercises) in improving respiratory muscle strength and patient-reported outcomes in patients with hEDS or G-HSD have not been evaluated.

Objective: This study aims to evaluate dyspnea, respiratory muscle strength, and patient-reported outcome measures (PROMs) in hEDS or G-HSD compared with healthy controls and to assess the feasibility of a randomized controlled trial of IMT and standard-of-care rehabilitation for improving respiratory muscle strength, exercise capacity, and PROMs compared with standard-of-care rehabilitation in hEDS and G-HSD.

XSL•FO
RenderX

Methods: The study will include 34 participants with hEDS or G-HSD and 17 healthy, age- and sex-matched controls to compare respiratory muscle structure and function and PROMs. After baseline assessments, participants with hEDS or G-HSD will be randomized into the intervention group and provided IMT combined with Ehlers-Danlos Syndrome standard-of-care rehabilitation or into the usual care group, and provided only standard-of-care rehabilitation for 8 weeks. The intervention group will be prescribed IMT in their home environment using the POWERbreathe K5 IMT device (POWERbreathe International Ltd). IMT will comprise 2 daily sessions of 30 breaths for 5 days per week, with IMT progressing from 20% to 60% of the baseline maximal inspiratory pressure (MIP) over an 8-week period. Feasibility will be assessed through rates of recruitment, attrition, adherence, adverse events, and participant satisfaction. The primary pilot outcome is MIP change over an 8-week period in hEDS or G-HSD. Secondary outcomes will include the evaluation of dyspnea using Medical Research Council Scale and 18-point qualitative dyspnea descriptors; diaphragmatic thickening fraction using ultrasound; respiratory muscle endurance; pulmonary function; prefrontal cortical activity using functional near-infrared spectroscopy; aerobic capacity during cardiopulmonary exercise testing; quality of life using Short Form-36; and scores from the Depression, Anxiety, and Stress scale-21. These measures will also be performed once in healthy controls to compare normative values. Multivariable regression will be used to assess the contributors to dyspnea. Paired 2-tailed *t* tests will be used to assess the changes in MIP and secondary measures after 8 weeks of IMT.

Results: Study recruitment began in August 2021 and, with several disruptions owing to COVID-19, is expected to be completed by December 2023.

Conclusions: This study will provide a better understanding of the factors associated with dyspnea and the feasibility and effectiveness of IMT combined with standard-of-care rehabilitation. IMT may be a novel therapeutic strategy for improving respiratory muscle function and patient-reported outcomes in individuals with hEDS or G-HSD.

Introduction

Background

Ehlers-Danlos Syndrome (EDS) is a group of hereditary connective tissue disorders characterized by multisystem manifestations involving musculoskeletal and nonmusculoskeletal domains [1]. Currently, the International Classification of EDS and related disorders includes 14 subtypes based on a set of clinical criteria, with the most common subtype being hypermobile EDS (hEDS), which comprises 80% to 90% of EDS cases [1-3]. Patients who present with symptomatic generalized joint hypermobility and chronic pain but do not meet the International 2017 classification criteria are classified as having generalized hypermobility spectrum disorder (G-HSD) [3]. The clinical manifestations of the disease vary according to the EDS subtype, and our understanding of this disorder has evolved to recognize multisystem manifestations beyond the musculoskeletal system, including gastrointestinal, neurological, cardiovascular, and respiratory involvement [1]. These manifestations arise from abnormal collagen or proteins that bind collagen that affect the connective tissue throughout the body [1]. Given the multisystem nature of hEDS and G-HSD, several symptoms such as pain and fatigue may contribute to reduced health-related quality of life (HRQL), physical deconditioning, anxiety, and depression [4-8].

Respiratory Manifestations in EDS and G-HSD

Our research group and others have recently highlighted that respiratory manifestations are common in hEDS and G-HSD and include, but are not limited to, dyspnea, cough, asthma, and respiratory muscle weakness [2,9]. The collagen abnormalities lead to impairments throughout the respiratory system, which may contribute to the respiratory abnormalities observed in this population [2,10]. In individuals with hEDS, the prevalence of dyspnea is estimated to be approximately 50% [11]. Dyspnea has been described in a few studies on individuals with G-HSD, but its prevalence and determinants have not been well characterized [12]. A study reported that up to 26% of the patients with G-HSD presented with cardiorespiratory manifestations such as dyspnea, palpitations, and chest pain, which were commonly attributed to autonomic dysfunction [13].

Respiratory symptoms in EDS and G-HSD have also been associated with worse outcomes such as lower physical activity levels and function. Individuals with EDS or G-HSD experienced increased dyspnea while walking on a flat level compared with healthy controls [12]. Furthermore, a study investigating physical activity levels between patients with hEDS or G-HSD with autonomic dysfunction and those without autonomic dysfunction observed that autonomic dysfunction was associated with exercise intolerance, which is often attributed to increased symptoms of dyspnea and chest pain [14]. Postural orthostatic tachycardia syndrome, a more severe form of autonomic dysfunction, has also been observed to be associated with dyspnea, chest pain, and impairments in HRQL [15,16]. Thus, respiratory manifestations in individuals with hEDS or G-HSD have important consequences on exercise tolerance, HRQL, and functional abilities.

XSL•FO
RenderX

Contributors to Dyspnea in hEDS and G-HSD

Functional impairments in respiratory muscle weakness occur in >75% of individuals with hEDS and can result in dyspnea and a restrictive pattern of ventilation [11]. The diaphragm is the main respiratory muscle, and alterations in collagen can lead to impairments in the respiratory muscle structure and function [17]. Respiratory muscle weakness has also been associated with lower vital capacity, which may contribute to dyspnea [18,19]. Thus, strengthening the respiratory muscles through modalities such as inspiratory muscle training (IMT) may improve dyspnea and pulmonary function [20].

Some individuals with hEDS or G-HSD have been observed to have chest wall deformities and increased rates of asthmatic symptoms, which can contribute to dyspnea and peripheral airway abnormalities [12,21,22]. There is also an increased tendency for dynamic airway collapse despite normal chest imaging, which highlights altered lung mechanics, including airway pressures and lung volumes [12]. Furthermore, deconditioning has been described as a contributor to low physical activity levels in the population with EDS or G-HSD as a consequence of increased joint laxity, pain, and peripheral muscle weakness [23]. Physical deconditioning may further exacerbate dyspnea and contribute to low exercise tolerance [23]. In conditions such as chronic obstructive pulmonary disease (COPD), cortical neural activity in the prefrontal cortex (PFC) has been shown to be associated with dyspnea and exercise intolerance and may be another contributor to dyspnea in hEDS or G-HSD [24,25]. Modalities such as functional near-infrared spectroscopy (fNIRS) have been used to assess PFC activity in individuals experiencing dyspnea during exercise testing [24]. Taken together, respiratory muscle weakness, peripheral airway changes, physical deconditioning, and autonomic dysfunction may contribute to the multifactorial nature of dyspnea in hEDS or G-HSD. These factors can be evaluated clinically and may help us understand the mechanisms that contribute to dyspnea and, importantly, tailor effective respiratory management strategies.

IMT and Standard-of-Care Rehabilitation

IMT has been established as an effective intervention for improving respiratory muscle structure and function in populations with chronic lung diseases [26,27]. A study observed that among 104 individuals with hEDS, 80 (77%) individuals had respiratory muscle weakness [11]. After 6 weeks of IMT, respiratory muscle strength measured with sniff nasal inspiratory pressure improved by 20% (pre-IMT intervention: mean 41, SD 17 cm H_2O vs post-IMT measurement: mean 49, SD 18 cm H_2O; $P<.001$) in patients with hEDS. Furthermore, the 6-minute walk distance improved by 13% (pre-IMT measurement: mean 455, SD 107 m vs post-IMT measurement: mean 515, SD 127 m; $P=.003$) along with forced expiratory volume in 1 second by 10% (pre-IMT measurement: mean 94%, SD 14% vs post-IMT measurement: mean 103%, SD 11%; $P=.01$). Thus, IMT may be an effective intervention for improving respiratory muscle strength, lung function, and exercise capacity in patients with hEDS or G-HSD.

Physical rehabilitation involving whole-body exercises such as aerobic and strength training has been shown to improve dyspnea in healthy populations and populations with chronic lung diseases such as COPD and idiopathic pulmonary fibrosis [28-31]. In a meta-analysis of 14 randomized controlled trials (RCTs), resistance training and endurance training were associated with improved dyspnea tolerance during exercise training, along with resting dyspnea levels, in patients with COPD [30]. This is often attributed to improved physical fitness owing to exercise training, which increases the efficiency of the muscles and decreases the level of ventilatory demand [30]. Unlike other populations, research on the effects of exercise training on individuals with hEDS or G-HSD is in its early stages, with only 5 RCTs performed in this area to date [32]. Following rehabilitation, in patients with hEDS or G-HSD, improvements have been observed in exercise capacity, muscle strength, mood, HRQL, and performance of daily activities [32].

Although the IMT RCT highlighted the safety and feasibility of IMT in hEDS, the study did not evaluate the mechanisms of dyspnea or assess diaphragm structure and function [11]. Furthermore, physical activity and other concurrent training, which may provide synergistic beneficial effects on respiratory symptoms and exercise capacity, were not considered. Several studies on chronic lung disease have demonstrated that IMT in combination with whole-body exercises, such as aerobic exercise, offers synergistic benefits on respiratory muscle strength and endurance and exercise capacity in comparison with whole-body exercises alone [23,33,34]. IMT alone has been shown to be an effective intervention in populations with asthma, populations with COPD, and populations with interstitial lung disease for improving maximal inspiratory pressure (MIP), respiratory muscle endurance, and diaphragm function [26,27,35] and thus may be an effective strategy in the population with hEDS or G-HSD.

The efficacy of both IMT and standard-of-care rehabilitation in ameliorating dyspnea and improving aerobic capacity and respiratory muscle structure and function in the population with hEDS or G-HSD has not been investigated to date. It is also unclear whether IMT in combination with standard-of-care rehabilitation is a feasible intervention, specifically for the population with hEDS or G-HSD, given the increased comorbidities. Furthermore, the efficacy of IMT has only been evaluated in hEDS and yet to be studied in G-HSD. This study aims to address these gaps.

Study Aims

The aims of this study are (1) to compare respiratory muscle strength and patient-reported outcome measures (PROMs) between individuals with hEDS or G-HSD and healthy, age- and sex-matched controls, as well as evaluate the main contributors to dyspnea in individuals with hEDS or G-HSD, and (2) to assess the feasibility of an RCT of IMT and standard-of-care rehabilitation (aerobic, resistance, neuromuscular stabilization, and balance and proprioception exercises) for improving respiratory muscle strength, exercise capacity, and PROMs compared with standard-of-care rehabilitation in hEDS or G-HSD.

XSL•FO
RenderX

Hypotheses

We hypothesize that (1) individuals with hEDS or G-HSD will have lower respiratory muscle strength, higher peripheral airway resistance, lower HRQL, and higher anxiety and depression levels than age- and sex-matched healthy controls and that (2) the delivery of IMT and standard-of-care rehabilitation will be feasible and result in a significant improvement in respiratory muscle strength (MIP) over an 8-week period.

Methods

Study Design

Participants with hEDS or G-HSD will complete assessments at baseline (T_0; Table 1) and will be randomized into the intervention arm (IMT and standard-of-care rehabilitation) or usual care group (standard-of-care rehabilitation). The standard-of-care rehabilitation at the GoodHope EDS Clinic at Toronto General Hospital comprises active exercise training involving aerobic, resistance, neuromuscular stabilization, and balance and proprioception exercises, and is a part of the GoodHope Exercise and Rehabilitation Program (GEAR) [36].

Age- and sex-matched healthy controls will undergo the same T_0 assessments as those that the EDS and G-HSD intervention and usual care groups will undergo. The respiratory muscle structure and function, dyspnea, exercise capacity, and collected PROMs will be compared. Only the participants with hEDS or G-HSD (intervention and usual care groups) will repeat the T_0 assessments after 8 weeks, as described in the subsequent section on assessments.

Table 1. Summary of study measurements.

Measurement	Baseline assessments[a]	
	Intervention and usual care groups	Healthy control group
Dyspnea		
Medical Research Council Dyspnea Scale	✓	✓
18-Point Qualitative Dyspnea Scale	✓	✓
Pulmonary function tests		
Oscillometry	✓	✓
Spirometry and lung volumes	✓	✓
Respiratory muscle endurance[b]	✓	✓

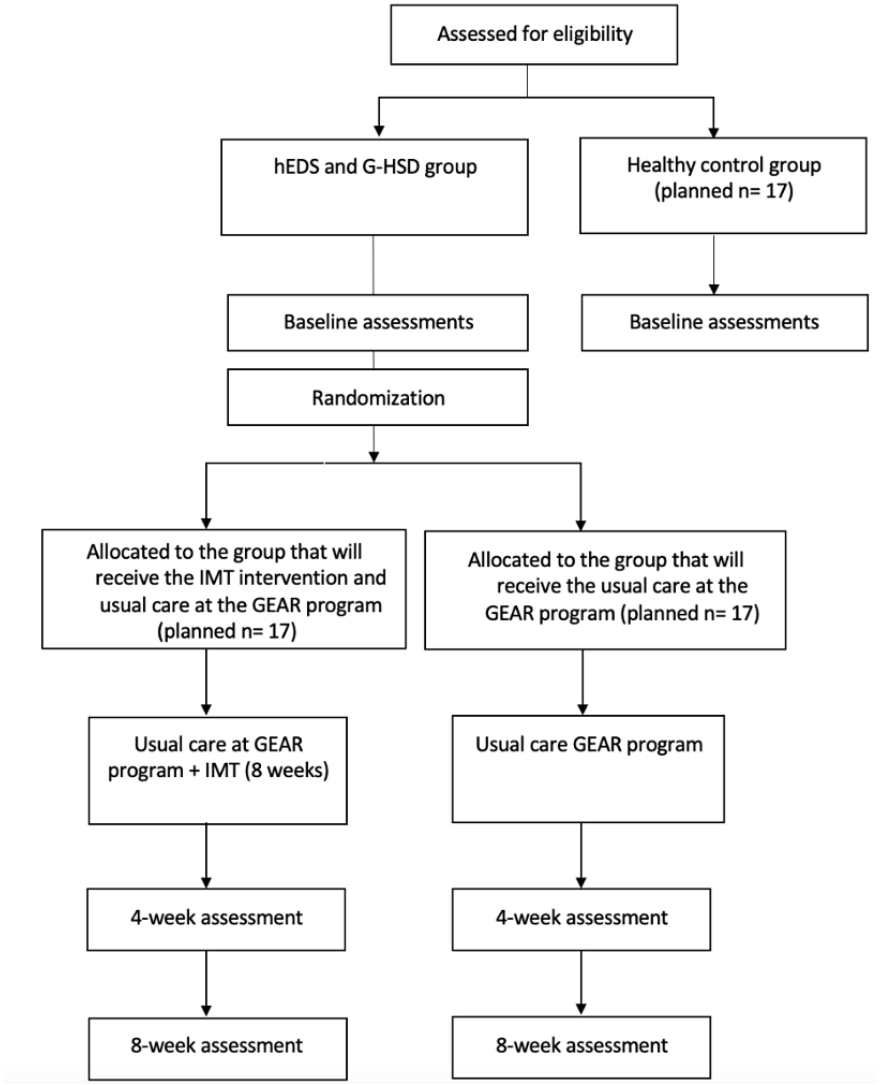
Diaphragmatic measures	✓	✓
PROMs[c]		
Health-related quality of life: Short Form-36	✓	✓
Mood: Depression, Anxiety, and Stress scale	✓	✓
Physical activity volume: Godin Leisure-Time Exercise Questionnaire	✓	✓
Demographic questionnaire	✓	✓

[a]All baseline measures will be repeated after 8 weeks for the participants with hypermobile Ehlers-Danlos Syndrome or generalized hypermobility spectrum disorder.

[b]Respiratory muscle endurance will be repeated at 4 weeks.

[c]PROM: patient-reported outcome measure.



Ethics Approval

Ethics approval has been obtained from the research ethics board at the University Health Network (ID: 20-6346.0) and University of Toronto (ID: 42667). The study has been registered at ClinicalTrial.gov (NCT04972565).

Written informed consent will be obtained from all participants before the commencement of any research activities. The Standard Protocol Items: Recommendations for Interventional Trials, the CONSORT (Consolidated Standards of Reporting Trials) statement, and the Consensus on Exercise Reporting Template will be used [37-39]. Refer to Figure 1 for the CONSORT flow diagram.

XSL•FO

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram with healthy controls. GEAR: GoodHope Exercise and Rehabilitation Program; G-HSD: generalized hypermobility spectrum disorder; hEDS: hypermobile Ehlers-Danlos Syndrome; IMT: inspiratory muscle training.

Recruitment and Screening

Participants with hEDS or G-HSD will be recruited from the GEAR program at Toronto General Hospital, which is a major teaching hospital in Toronto, Canada. The GEAR program evaluates approximately 12 new participants per month. Potential participants are screened for study eligibility by exercise professionals who are part of the GEAR program. The research team will confirm the eligibility criteria, discuss study participation, and obtain consent among interested participants. The study flow of participants is shown in Figure 1.

Participants With hEDS or G-HSD

The sample will comprise adult individuals (aged ≥18 years) diagnosed with hEDS or G-HSD by the EDS medical team at Toronto General Hospital based on the 2017 diagnostic criteria [3]. Participants will be included if they have started their participation in the GEAR program within 4 weeks.

The following exclusion criteria will be applied:

1. Diagnosis of other subtypes of EDS (eg, classical and vascular)
2. Have a cardiac pacemaker, defibrillator, neuromuscular disease, severe autonomic dysfunction, or other cardiovascular manifestations limiting exercise or other exercise contraindications
3. Recent respiratory infection (<1 month) or known diagnosis of obstructive or restrictive parenchymal disease
4. History of pneumothorax, acute otitis media (fluid behind the eardrum), or rupture of tympanic membranes, given the risk owing to IMT
5. Participation in formal exercise training or IMT program within the last 3 months
6. Insufficient English fluency to provide informed consent or inability to follow study protocols
7. Self-reported pregnancy
8. No internet access for IMT or web-based assessments

Healthy Controls

Healthy adults (aged ≥18 years) will be age- and sex-matched with the participants with EDS and G-HSD. Individuals will be excluded from the study if they meet the following criteria:

XSL•FO
RenderX

1. Diagnosis of a respiratory, cardiovascular, or musculoskeletal condition that may contribute to exercise limitation
2. Presence of cardiac pacemaker or implantable defibrillator
3. Insufficient English fluency to provide informed consent or inability to follow study protocols
4. Self-reported pregnancy
5. Active smoker (cigarettes or marijuana)

Assessments

At T_0, the participants with hEDS and G-HSD will undergo pulmonary function tests (PFTs), cardiopulmonary exercise test (CPET) with fNIRS on the PFC, PROMs, and diaphragm ultrasound. The same assessments will be performed for healthy controls. Please refer to Table 1 for a detailed list of T_0 measurements. At 4 weeks, respiratory muscle endurance assessment will be repeated for the participants with hEDS and G-HSD. All T_0 assessments, including PFTs, CPET, PROMs, and respiratory muscle endurance assessment, will be repeated at 8 weeks for the participants with hEDS and G-HSD.

The following tests will be used to assess the primary and secondary outcome measures in the PFT laboratory at Toronto General Hospital.

Respiratory Parameters

Assessment Using PFTs

Spirometry and Lung Volumes

Forced expiratory volume in 1 second, forced vital capacity, total lung capacity, and lung volumes (tidal volume, inspiratory capacity, expiratory reserve, and residual volumes) will be evaluated in accordance with the American Thoracic Society guidelines before CPET [40].

Oscillometry

This will be performed before other PFTs according to the European Respiratory Society Guidelines, as previously described [41,42]. Oscillometry provides detailed information regarding respiratory mechanics by measuring respiratory impedance, a complex sum of respiratory resistance, and reactance [43]. This technique uses sound waves to capture disturbances in airway resistance and can be a more sensitive marker of peripheral airway obstruction than spirometry [44,45]. Because it is performed during normal breathing, oscillometry is independent of effort and is not influenced by respiratory muscle strength. We will follow the quality assurance and control guidelines developed by our group using the tremoflo device (Thorasys) [46].

Respiratory Muscle Strength

MIP and maximal expiratory pressure will be evaluated using the American Thoracic Society standards. These measures will be repeated 3 times, and the highest value (cm H_2O) that is 10% within the lower measures will be used [47,48].

Respiratory Muscle Endurance

The threshold loading device (Threshold IMT trainer [Philips]) [49] will be used to evaluate respiratory muscle endurance. We will assess the time that can be sustained at respiratory endurance at 30% of MIP obtained as part of the T_0 measures after a brief familiarization session with the loading device. The maximum endurance that the threshold loading device can reach is 41 cm H_2O. The endurance assessment will be repeated within 5 minutes if the participant stops the protocol early (<1 minute) because of severe coughing or lack of familiarity with the loading device. The maximum endurance that participants will be asked to perform is 15 minutes. Oxygen saturation will be concurrently monitored with pulse oximetry during the assessment.

Diaphragm Ultrasound

While the participant is in semirecumbent position, the research coordinator will place an ultrasound probe perpendicular to the chest wall in the 8th or 9th intercostal space between the anterior and midaxillary lines using a 5-13 MHz transducer (GE Logiq e Laptop Ultrasound System [GE Medical Systems]) [50]. Bright-mode ultrasound will be used to visualize the diaphragm, and motion-mode ultrasound will be used to assess the amplitude of the cranio-caudal diaphragmatic excursion during quiet and deep breathing. Diaphragm thickness will be measured as the distance between the leading edges of the diaphragmatic pleura and peritoneum at resting end expiration and after peak inspiration. Thickening fraction, an established marker of diaphragm strength, will be calculated as follows: ([diaphragm thickness at end expiration–diaphragm thickness at peak inspiration] divided by diaphragm thickness at end expiation) × 100 [50].

Assessment Using CPET

Overview

Symptom-limited CPET will be performed on a cycle ergometer (Elema), with exhaled gas measurements captured breath by breath, as routinely applied in our PFT laboratory. Testing will start with 2 minutes of complete rest on the bike, followed by unloaded pedaling for 2 minutes, and then exercise intensity will be increased by 10 to 20 W per minute using a ramp protocol. Blood pressure, 12-lead electrocardiogram, and peripheral oxygen saturation will be continuously monitored. Inspiratory capacity, tidal volumes, and respiratory rate will be measured throughout the exercise to assess for any dynamic hyperinflation and ventilatory reserve. Heart rate (HR) response, peak aerobic capacity, oxygen pulse (measure of cardiac stroke volume), and minute ventilation (product of tidal volume and respiratory rate) will be collected throughout the exercise and up to 2 minutes after test completion with unloaded pedaling, with percent predicted values reported. HR recovery (difference between peak HR and HR 1 minute after exercise) and the chronotropic response index ([peak HR – resting HR × 100] / [220 – age] – [resting HR]) will be collected as a measure of autonomic function [51-53]. Chronotropic incompetence is the inability to decrease HR after exercise or the inability to reach 80% of the maximal age-predicted HR because of abnormal sympathetic activation [51]. Symptom intensity for breathing and leg discomfort with exercise will be measured at rest and every 3 minutes throughout the exercise using the Borg dyspnea [54] and leg fatigue scales [55]. The reasons for exercise cessation will be ascertained from the participants (ie, dyspnea, leg fatigue, both, or other). To ensure participant safety before

XSL•FO
RenderX

CPET, 12-lead electrocardiograms will be performed for both the participants with hEDS or G-HSD and healthy controls.

Assessment Using fNIRS

fNIRS is a noninvasive method that uses continuous optical topography to evaluate increases in oxygenated hemoglobin levels, an indicator of PFC activity that has been suggested to be associated with dyspnea [56-58]. The change in oxyhemoglobin and deoxyhemoglobin will be monitored using the Artinis fNIRS device (Artinis Medical Systems) [59], which will be secured over the participant's forehead, with the center of each sensor pad vertically aligned with the iris. Light intensity data at 2 wavelengths (730 and 850 nm) will be obtained during CPET from the left and right sides of medial PFC and dorsolateral PFC using a cognitive optical brain imaging software at a sampling frequency of 4 Hz. Detector gain settings will be adjusted for light intensity, and filters will be applied to attenuate the physiological artifacts of respiration and pulse.

Assessment Using PROMs

Dyspnea

The Medical Research Council (MRC) dyspnea scale [60], Borg dyspnea scale [54], and 18-item qualitative dyspnea descriptors will be used [61]. This will allow us to evaluate the quantitative and qualitative changes in respiratory symptoms.

1. *MRC dyspnea scale*: the MRC dyspnea scale (1-5) will be used to assess the effect of breathlessness on daily activities at T_0 [60]. It allows patients to indicate the extent to which breathlessness limits their daily functioning [60].
2. *Borg dyspnea scale*: the highest score on a 10-point Borg scale at the beginning and end of CPET will be measured. The participants will also be asked to indicate their daily Borg dyspnea score before and after their IMT practice in their participant logs [62].
3. *Qualitative dyspnea descriptors:* the qualitative dyspnea descriptors scale comprises a list of 18 dyspnea descriptors. Qualitative descriptors of dyspnea will be ascertained at T_0 and at the end of CPET [61].

Exercise Behaviors and Physical Activity

Exercise behaviors will be measured using the 3-item Godin Leisure-Time Exercise Questionnaire—Leisure Score Index, which is a reliable and validated measure for this population [63]. This index assesses the frequency of mild, moderate, and strenuous bouts of leisure physical activity performed for at least 15 minutes over the past week. In addition, physical activity will be measured using a tracking device (Fitbit), which will record daily steps and active minutes for the study participants with hEDS or G-HSD [64,65].

Measurement of HRQL

The Short Form-36 Health Survey (version 1.0) will be used to assess generic HRQL [66]. It comprises 8 health domains that contribute to 2 physical and mental component scores (ranging from 0 to 100), with higher scores representing better HRQL. A 5-point change in the physical component scores or mental component scores is considered clinically significant [66].

Depression, Anxiety, and Stress

The Depression, Anxiety, and Stress scale has 21 items to assess mood (depression, anxiety, and stress) and has been administered to patients with hEDS [8]. It has acceptable to excellent internal consistency, and normative data are available [67].

Anthropometric Measures

Standard anthropometric measures will be captured for all the participants. Height, weight, waist circumference, and BMI information will be collected for the participants with hEDS or G-HSD from the electronic patient charts. The same measures will be collected for healthy controls during the T_0 assessments.

Clinical Assessments

We will abstract standard GEAR program measures from the medical charts for all the participants with hEDS or G-HSD: 6-minute walk distance, lower extremity function (5-repetition sit-to-stand test), hand-grip strength, Bristol questionnaire, and Godin Leisure-Time Exercise scale. The Beighton score [68], Charlson comorbidity index [69], and medications such as opioids that can impact dyspnea will be abstracted from chart review.

Sociodemographic Parameters

We will abstract information on demographics such as age, ethnicity, sex, employment status, education level, and lifestyle factors (eg, smoking status) from the medical charts for the participants with hEDS or G-HSD. Demographic data will be collected from healthy controls via a demographic survey.

Randomization

After T_0 assessments, the participants will be randomly allocated to the intervention or usual care group using a 1:1 ratio stratified by hEDS or G-HSD. The allocation of the participants to their groups will be randomized (blocks of 2 to 4) using shuffled, opaque envelopes by a biostatistician. The study participants and the research team and coordinator supervising the IMT will be aware of the group assignments.

Study Arms

Overview

The participants in both the intervention and usual care groups will receive the standard-of-care rehabilitation in the GEAR program. Those in the intervention group will receive IMT in addition to the GEAR program components, as shown in Table 2.

XSL•FO
RenderX

[a]IMT: inspiratory muscle training.

[b]hEDS: hypermobile Ehlers-Danlos Syndrome.

[c]G-HSD: generalized hypermobility spectrum disorder.

[d]GEAR: GoodHope Exercise and Rehabilitation Program.

[e]MIP: maximal inspiratory pressure.

[f]N/A: not applicable.

[g]PFT: pulmonary function test.

Usual Care Group

The standard-of-care rehabilitation in the GEAR program comprises 8 weeks of aerobic, resistance, neuromuscular stabilization, and balance and proprioception exercises performed in the home environment [1]. The participants in the GEAR program attend in-person or web-based exercise training sessions at the following intervals: T_0, 4 weeks from T_0, 8 weeks from T_0, and 20 weeks from T_0 to observe maintenance [46]. The GEAR program comprises three major elements: (1) an individualized home-based rehabilitation and exercise therapy, (2) education on the self-management of hEDS or G-HSD symptoms, and (3) a community resource engagement plan. These components are delivered by a team of physiotherapists and kinesiologists.

Intervention Group (IMT)

The participants in the intervention group will receive an individual and personalized prescription for an IMT program for 8 weeks. This IMT program will use the POWERbreathe K5 IMT device in the participants' home environment combined with the standard-of-care rehabilitation as part of the GEAR program, as described earlier. A research coordinator will facilitate these training sessions and monitor the participants via the web for the first 3 sessions in the first week and once a week from weeks 2 to 8. Over 8 weeks, 2 daily IMT sessions of 30 breaths (<5 min/session) will be performed for 5 days per

XSL•FO
RenderX

week, starting with 20% of the participants' T_0 MIP up to a maximum of 60%. This protocol was developed based on the previous literature on IMT applied in lung transplant candidates at our center [70-72]. The total workload per session (product of inspiratory muscle force and inhaled volume expressed in Joules) will be abstracted from the IMT device. Additional variables abstracted from the device will include inspiratory muscle load (cm H_2O), mean power per breath (W), and mean volume per breath (Liters).

The participants will be asked to record their resting and post-IMT Borg dyspnea scores for 5 days of the week (2 sessions per day), along with any side effects for each session. The median Borg dyspnea score for the previous week will be reviewed by the research coordinator, and IMT intensity will be increased by 5% to 10% of the T_0 MIP if the median weekly Borg dyspnea score is <7 (very severe breathlessness with IMT) [54].

The participants will be asked to maintain IMT diaries to assess adherence. They will receive instructions and feedback on how to optimize their home training efforts based on direct observation of their IMT with the POWERbreathe K5 device and review of IMT workload from the device. They will have the possibility to schedule additional sessions with the study team during the week, if further support is needed.

Trial Outcomes

Estimates of Intervention Feasibility

Study feasibility will be assessed through recruitment rate, attrition, IMT program adherence, safety, and satisfaction (Textbox 1).

Textbox 1. Feasibility estimates.

- Recruitment
  - We will evaluate the recruitment rate as the number of participants who consented and enrolled relative to the total number of eligible patients approached for eligibility assessment by the research coordinator. The reasons for nonparticipation in the study will be documented. A successful recruitment rate will be defined as 20% in this study.
- Retention
  - Retention will be evaluated through participant attrition throughout the intervention period. For each arm of the study, the retention rate will be assessed by measuring the number of participants who completed all assessments compared with the number of participants who enrolled and randomized. A successful retention rate will be defined as ≥80% in this study.
- Adherence
  - Adherence to inspiratory muscle training (IMT) in the intervention group will be tracked electronically and through participant logs (number of completed sessions of 30 breaths out of 10 planned sessions per week) with the IMT device over the 8-week period. Adherence will also be assessed during weekly communications with participants as well as through completed daily IMT logs, which will capture IMT training days and IMT prescription (percentage of maximal inspiratory pressure). These data will also be verified after the IMT device is returned. The number of completed IMT sessions will be reviewed from the recordings on the device.
  - The physical activity and exercise behaviors prescribed through the GoodHope Exercise and Rehabilitation Program will be monitored in both the intervention and usual care groups. Daily step counts will be assessed from the Fitbit device. The participants with hypermobile Ehlers-Danlos Syndrome or generalized hypermobility spectrum disorder will be asked to download the Fitbit app on their smartphones or tablets. A 1-page document highlighting the key steps for setting up the Fitbit tracker will be provided. We will also work with the participants via the web to set up the device if any problems arise. The exercise behaviors of the study participants in both groups will be reviewed using the self-reported exercise logs, which capture the exercise type, frequency, intensity, and duration on a daily basis. At the end of the baseline assessment, the study participants in both the usual care and intervention groups will be provided with documents explaining the maintenance and use of the study devices (eg, Fitbit, respiratory muscle endurance trainer, and IMT device for the intervention group).
- Safety
  - The participants will log any adverse effects during the IMT program, which will be reviewed weekly by the research coordinator. Adverse effects are rare; however, symptoms previously observed during IMT include mild chest discomfort, worsening respiratory symptoms (eg, dyspnea), and possibly nausea related to hyperventilation [73]. The participants will also be strongly encouraged to immediately contact a member of the research team if they notice any adverse events. Study personnel will also inquire about chest discomfort or delayed-onset muscle soreness during IMT in weekly meetings to adjust IMT prescriptions and ensure tolerability of training intensity.
- Satisfaction
  - Participation satisfaction and motivation to engage with the IMT program will be assessed in the intervention group using a standardized questionnaire administered at weeks 1, 4, and 8 after study enrollment.

Primary Pilot Outcome

The primary pilot outcome will be the change in MIP over the 8-week study period to demonstrate the efficacy of IMT, which has been shown to be an important physiological measure in several IMT studies [11,26,35,73].

XSL•FO
RenderX

Secondary Outcomes

The secondary outcome measures evaluated will include dyspnea, respiratory muscle structure and function, mood, and HRQL assessed at T_0 and 8 weeks, as shown in Table 3.

Table 3. Study outcomes.

Outcome	Assessment measurement	Time point
Primary outcome		
Respiratory muscle strength	MIP[a] (cm H_2O)	Baseline (T_0) and 8 weeks (T_2)
Secondary outcomes		
Pulmonary function		
Spirometry and lung volumes	FEV1[b] (L), FVC[c] (L), TLC[d] (L), RV/TLC[e] (%)	Baseline (T_0) and 8 weeks (T_2)
Oscillometry	Oscillometry: respiratory impedance, reactance, and resistance	Baseline (T_0) and 8 weeks (T_2)
Respiratory muscle endurance time	Time (seconds) using the Philips Threshold trainer at 30% of baseline MIP	Baseline (T_0), 4 weeks (T_1), and 8 weeks (T_2)
Diaphragm structure and function	Diaphragm thickness and thickening fraction	Baseline (T_0) and 8 weeks (T_2)
PROMs[f]		
Dyspnea	MRC[g] scale ratings, Borg dyspnea scale ratings, and Qualitative Dyspnea Scale ratings	Baseline (T_0) and 8 weeks (T_2)
Exercise and physical activity volume	Godin Leisure-Time Exercise Questionnaire scores	Baseline (T_0) and 8 weeks (T_2)
HRQL[h]	SF-36[i] scores	Baseline (T_0) and 8 weeks (T_2)
Depression, anxiety, and stress	Depression, Anxiety, and Stress scale scores	Baseline (T_0) and 8 weeks (T_2)
Cardiopulmonary exercise parameters		
Aerobic and anaerobic capacity	Peak aerobic capacity, anaerobic threshold, breathing reserve, and cycling power output	Baseline (T_0) and 8 weeks (T_2)
HR[j] response and chronotropic response	HR recovery (HR at 1 minute after CPET[k] – HR at the end of CPET) and chronotropic response index adjusted for age ([peak HR – resting HR × 100] / [220 – age] – [resting HR])	Baseline (T_0) and 8 weeks (T_2)
Neural activity during exercise (prefrontal cortex)	Oxyhemoglobin and total hemoglobin concentration changes	Baseline (T_0) and 8 weeks (T_2)

[a]MIP: maximal inspiratory pressure.

[b]FEV1: forced expiratory volume in 1 second.

[c]FVC: forced vital capacity.

[d]TLC: total lung capacity.

[e]RV/TLC: residual volume/total lung capacity ratio.

[f]PROM: patient-reported outcome measure.

[g]MRC: Medical Research Council.

[h]HRQL: health-related quality of life.

[i]SF-36: Short Form-36.

[j]HR: heart rate.

[k]CPET: cardiopulmonary exercise test.

Statistical Analysis

Proposed Data Analyses

For objective 1, we aim to compare respiratory muscle structure and function and PROMs between patients with hEDS or G-HSD and healthy controls and to evaluate the main correlates with dyspnea in patients with hEDS or G-HSD. Descriptive statistics will be used for continuous variables (mean and SD or median and IQR), and frequencies will be used for categorical variables. We will use multivariable regression analysis to compare any differences between groups across respiratory parameters and PROMs, adjusted for EDS subtype (hEDS or G-HSD). We will explore the associations with peak Borg dyspnea scores during CPET using multivariable regression, with possible determinants being MIP, diaphragm thickening fraction, PFC activity, and PFT parameters.

XSL•FO
RenderX

For objective 2, we aim to assess the feasibility of IMT and standard-of-care rehabilitation for improving respiratory muscle strength, exercise capacity, and PROMs compared with standard-of-care rehabilitation alone in patients with hEDS or G-HSD. Descriptive statistics will be used to summarize program adherence, recruitment, participant satisfaction, attrition, and safety in the hEDS or G-HSD study groups. Estimates of within- and between-group differences at T_0, 4 weeks, and 8 weeks will be reported using means and 95% CI. Paired *t* tests and *t* tests will be used to compare the changes in the primary pilot outcome (MIP) and secondary measures over the 8-week study period within and between the 2 randomized groups.

Sample Size

Objective 1

With the prevalence of dyspnea (MRC score: 2 out of 5) in 50% of the patients with hEDS and G-HSD, we estimate that 75% of the patients with hEDS will report a Borg dyspnea score of ≥4 (moderate dyspnea) compared with 25% of healthy controls after cardiopulmonary exercise, as previously observed at our center [74]. Thus, with a sample size of 34 patients with hEDS or G-HSD and 17 healthy controls, we will have 90% power to observe a significant difference in moderate dyspnea (α level=.05). Furthermore, given an estimate of 10 participants for each covariate in multivariable regression modeling, we reckon that enrollment of 34 participants with hEDS or G-HSD will allow us to explore at least 3 determinants of dyspnea in our models.

Objective 2 (Primary Pilot Outcome)

Given an estimated MIP comparable with that of moderate COPD patients (mean 51, SD 15 cm H_2O), we anticipate a mean increase of 10 (SD 3.5) cm H_2O in MIP in the IMT and exercise training group compared with the hEDS or G-HSD usual care group (exercise training alone; 5 cm H_2O) [75]. Assuming a maximum attrition rate of 20% among the 34 RCT participants with hEDS or G-HSD, we will have 90% power (α=.05) to observe a significant difference in MIP with 17 participants per group.

Data Management and Quality Assurance

Our research team is trained in the measurement protocols and has expertise in performing physical assessments and PROMs in individuals with respiratory conditions. The research team has critically appraised the peer-review comments from the 2020 GoodHope Ehlers-Danlos Syndrome foundation grant (Multimedia Appendix 1) and has incorporated them into the study protocol. Most of the study assessments will be conducted at the PFT laboratory of Toronto General Hospital by experienced respiratory technicians. All equipment (ultrasound, fNIRS, and oscillometry) has been applied in the laboratory setting previously. In addition, our research team has expertise in conducting web-based assessments in the participants' home environment, including IMT, given the COVID-19 environment.

The research coordinator will guide the participants through each step of the study process. Standard operating procedures will be generated for each step related to data collection, data entry, and data handling. The research coordinator will ensure accuracy by periodically auditing the data in our research database. Although the research coordinator will attempt to have the participants complete the entirety of the assessments and questionnaires, if there are unanswered questions or missing data, the data will not be imputed, and analysis will be performed on the available data.

The current institutional and national research ethics guidelines will be followed to ensure data privacy, security, and protection. Participant data will only be accessible by the research study team, and participants will be assigned a random participant ID, which will be linked to all the data. All the study data will be securely stored on a password-protected server. In the event of inappropriate data breaches, the following actions will be undertaken: (1) prevent further breach of information and attempt to retrieve breached information and (2) notify the institutional research ethics board immediately. Further action might be taken according to the recommendations from the research ethics board. Modifications to the study protocol will be approved by the research ethics board before implementation, communicated to funding agencies, and outlined in future publications.

Results

This research was funded in January 2021, and study enrollment began in August 2021 and will continue until December 2023. As of January 2023, a total of 4 participants with hEDS or G-HSD in the intervention group and 4 participants in the usual care group have completed the study, with 5 other participants with hEDS or G-HSD enrolled. A total of 11 healthy controls have completed the study. The results will be submitted for publication once data collection and assessments are complete.

Discussion

Summary

This study will help characterize the multifactorial nature of dyspnea experienced by individuals with hEDS and G-HSD. Given the known impairments in respiratory muscle strength in this population, this study will allow us to assess the synergistic effects of IMT and standard-of-care rehabilitation on dyspnea, PROMs, and exercise capacity, which have not been previously characterized. The findings of this study will inform the feasibility of a larger study using IMT and standard-of-care rehabilitation that will be appropriately powered to assess the effects of IMT on PROMs and clinical outcomes. Furthermore, this study has the potential to inform our understanding of the mechanistic effects that IMT may have on diaphragm structure and function, lung physiology, and neurocognitive adaptations in this population.

The literature describing respiratory manifestations in EDS and G-HSD has generally been limited to a few observational studies and case series involving mainly 4 subtypes: classical EDS, vascular EDS, hEDS, and G-HSD [2,9]. We chose to focus on the population with hEDS, as hEDS comprises the major subtype of EDS, and there is also a study highlighting respiratory muscle weakness and effectiveness of IMT [11]. The population with

XSL•FO
RenderX

G-HSD was also chosen, as G-HSD is defined to be on the continuum of EDS and represents one of the most common diagnoses in our GEAR rehabilitation program, and the respiratory sequelae of G-HSD have not been well characterized [3]. Another important consideration factored into our selection of the EDS population was the risk of pneumothorax, which is generally lower in individuals with hEDS and G-HSD than in those with other subtypes. Thus, the inclusion of patients with hEDS and patients with G-HSD is owing to the representation of the majority (>90%) of the patients with EDS followed in our program.

We hypothesize that IMT and standard-of-care rehabilitation will provide a positive synergistic effect on respiratory muscle function, PROMs, and clinical outcomes. IMT has been shown to improve dyspnea by increasing respiratory muscle strength [76]. In addition, aerobic and strength training has been shown to increase the strength of the respiratory and limb muscles and improve oxygen use, ventilatory efficiency, and exercise capacity [20,31]. Furthermore, IMT can have positive effects on dyspnea through neurocognitive adaptations [77]. Breathing exercises may induce motor-sensory neural adaptations in the diaphragmatic and respiratory muscles, which can improve dyspnea tolerance [77]. It is also postulated that improvements in exercise capacity and dyspnea levels through IMT may result in greater independence in daily activities and improved HRQL [78]. Despite the proposed beneficial effects of IMT, the ideal duration remains to be determined, with 8 weeks chosen for this study based on the recommendation that a duration of at least 6 weeks is required to derive respiratory muscle adaptations [79-81].

Owing to the COVID-19 environment, a large proportion of research assessments and in-person care visits have transitioned to a web-based environment [82,83]. Patients often express concerns about the possibility of COVID-19 exposure and travel expenses for in-person assessments. Furthermore, the GEAR program has also adapted its format, with a proportion of web-based training sessions performed. Thus, we are closely monitoring enrollment numbers and if recruitment proves to be challenging because of the requirement for in-person visits, we will be able to amend the protocol to allow assessments to be performed via the web. In fact, most of the assessments in this study can be administered via the web, including all PROMs, respiratory muscle endurance testing, and IMT with electronic tracking on the device itself. The results of this study will demonstrate the potential of performing web-based IMT, especially with the emergence of tele-rehabilitation programs.

Limitations

This study has several limitations that need to be highlighted. First, our study focuses on hEDS and G-HSD, which represent most EDS disorders in our program. However, the findings may not be generalizable across less prevalent EDS subtypes (eg, classic EDS or vascular EDS). Second, all participants in this RCT will be enrolled in the GEAR program, and we anticipate that any differences in training volumes or physical activity levels will be negligible between the groups after randomization, but any differences over the 8-week IMT program will be explored. Third, we are unable to monitor adherence to the GEAR program in the intervention group. Moreover, IMT may not be suitable for all participants because of time restrictions, training preferences, and work-school schedules. However, the web-based environment provides participants with the flexibility to uptake the IMT program that best suits their schedules.

Conclusions

This study aims to provide a better understanding of the contributors to dyspnea in hEDS or G-HSD and highlight the association between dyspnea and respiratory muscle function, PROMs, and exercise capacity. The combination of IMT and standard-of-care rehabilitation training may provide a novel therapeutic strategy to improve respiratory muscle function and PROMs. A better understanding of the feasibility and efficacy of IMT and standard-of-care rehabilitation will provide insight into the use of IMT in the population with EDS and the population with G-HSD, given a shift toward tele-rehabilitation programs in the COVID-19 environment. This research will pave the way for future studies to evaluate respiratory management strategies in this population.

DR receives research support from the Sandra Faire and Ivan Fecan Professorship in Rehabilitation Medicine. NAK receives financial research support from the Canadian Institute of Health Research Canada Graduate Scholarship–Master's Program. The study sponsors had no role in the design of the study protocol and will have no involvement in the data collection process, data analysis, interpretation of the results, or manuscript preparation. This study is sponsored by the University Health Network.

Data Availability

The study data will be made available for review after trial completion and publication upon reasonable request from the corresponding author.

Authors' Contributions

DR conceived the study and participated in the design of the protocol and development of the intervention. DR, EG, LM, LL-H, WDR, CWC, CMR, DK, EH, KC, SR, DSM, and NM are the grant holders. SN coordinates the study under the direct supervision

XSL•FO
RenderX

of DR. SN, ECP, and NAK are responsible for the implementation of the study. SN supervises the inspiratory muscle training home-based exercise program. DR and NAK helped draft this manuscript. ECP, SN, EG, LM, LL-H, WDR, CWC, CMR, DK, EH, KC, SR, SM, DSM, HC, and NM provided expert advice and reviewed the protocol. All the authors approved the final manuscript for submission.

Conflicts of Interest

None declared.

Abstract

Background: Healthy eating can improve the course of type 2 diabetes mellitus (T2DM) considerably. As changing eating behaviors in everyday is challenging, there is a need for a nutritional strategy with an eye for everyday life of people with T2DM. A theory centered around the everyday life context is salutogenesis. Salutogenic principles have been operationalized in a new nutritional program for T2DM on food literacy and well-being: the Salutogenic Intervention for Type 2 Diabetes (SALUD) program.

Objective: This study aims to describe the protocol of the invention study that will examine the quantitative and qualitative effects of the SALUD program.

Methods: A semiblinded randomized controlled trial will be performed in the Netherlands. A sample size of 56 (including a 30% dropout rate) people with T2DM has been calculated, of whom half (n=28, 50%) will follow the SALUD program (intervention) and half (n=28, 50%) will receive usual care (control). Recruitment strategies consist of advertisement via local health care professionals, posters, social media, and local newspapers. The SALUD program consists of 12 weekly web-based group sessions under the supervision of a certified lifestyle coach. Fidelity of the delivery is guaranteed by selecting a salutogenic coach, use of an intervention manual, training of the coach, weekly evaluation forms, and recording several sessions. The theoretical salutogenic principle of the intervention is mobilizing 2 important psychosocial resources required for organizing healthy eating in everyday life: self-identity and social support. Measurements will be performed at 3 times: at baseline (T0), after 12 weeks (postintervention; T1), and after 24 weeks (follow-up; T2). The primary outcome is food literacy, measured with the self-perceived food literacy scale questionnaire (expected effect size=0.9). Secondary outcomes are self-efficacy, quality of life, sense of coherence, diet quality, body weight, BMI, and waist-hip ratio. All outcomes will be tested with linear mixed models, following an intention-to-treat approach and standard principles of randomized controlled trials. In addition, a qualitative analysis will be performed.

Results: The proposed study will provide useful information on the effects of a salutogenic program on healthy eating and well-being in people with T2DM in everyday life. Recruitment started on October 1, 2021. The intervention participants followed the SALUD program between January and August, 2022. The acquisition of the data was completed on August 1, 2022; publications are expected in 2023.

Conclusions: This study will be one of the first salutogenic interventions for T2DM, which will provide valuable information on what salutogenic intervention entail. The SALUD program may serve as a concrete, web-based tool. The combination of

XSL•FO
RenderX

quantitative and qualitative measures allows a comprehensive evaluation of effects. These insights can be used for further optimalization of T2DM interventions.

Introduction

Background

Healthy eating is important for the disease course and quality of life (QoL) of people with type 2 diabetes mellitus (T2DM) [1]. Healthy eating may lower hemoglobin A_{1c} (HbA_{1c}) to a similar extent as medical treatments for T2DM [2,3]. In some cases, healthy eating can put the disease in remission [4-12]. However, people with T2DM indicated that implementing healthy eating recommendations in their everyday lives is challenging [5,7,8].

Several strategies are available to support people with T2DM with healthy eating. The strategies approach healthy eating in dissimilar manners that could be broadly categorized as dietary prescription, lifestyle counseling, and behavioral therapies [13]. Dietary prescription is characterized by a "top-down" and biomedical approach: the therapist actively provides the solution in the form of a strict calorie-restricted diet, and the main goal is to achieve weight loss or improved HbA_{1c} levels (eg, [12]). In lifestyle counseling, the participant has a more active role: the therapist provides lifestyle education, meal plan templates, and personalized advice to implement nutritional recommendations. The main goal is adherence to a healthy lifestyle (eg, the Look AHEAD [Action for Health in Diabetes] trial [14] and the Diabetes Remission Clinical Trial [DIRECT]; [15]). Behavioral counseling is characterized by a more "bottom-up" and holistic approach: the starting point is the participant's preferences; the goals and approaches are collaboratively planned. The therapist has an enabling role in the process: stimulating the participant's problem-solving abilities and self-efficacy by motivating and supporting the participant. The main goal is achieving a mindset that favors healthy lifestyle behaviors (eg, [16]).

All of these strategies have been successful in initiating health benefits such as weight loss and improved HbA_{1c} levels [12,16,17] but have struggled with maintaining the benefits in the long term [8,18-21]. Even after the most well-known T2DM interventions—the Look AHEAD [14] and the DIRECT trial [15]—health benefits gradually disappeared. The Look AHEAD trial (restricted caloric intake using portion-controlled meal plans, calorie-counting techniques, and meal replacements combined with moderate physical activity) demonstrated average weight loss of 8.6% (SD 6.9%) in the intervention participants, but half of the initial weight loss was regained after 5 years of follow-up [22,23]. The DIRECT trial (a very low–calorie diet, followed by stepwise food reintroduction) demonstrated that almost half of intervention participants achieved T2DM remission at 12 months, but this percentage declined to 36% at 24 months [24].

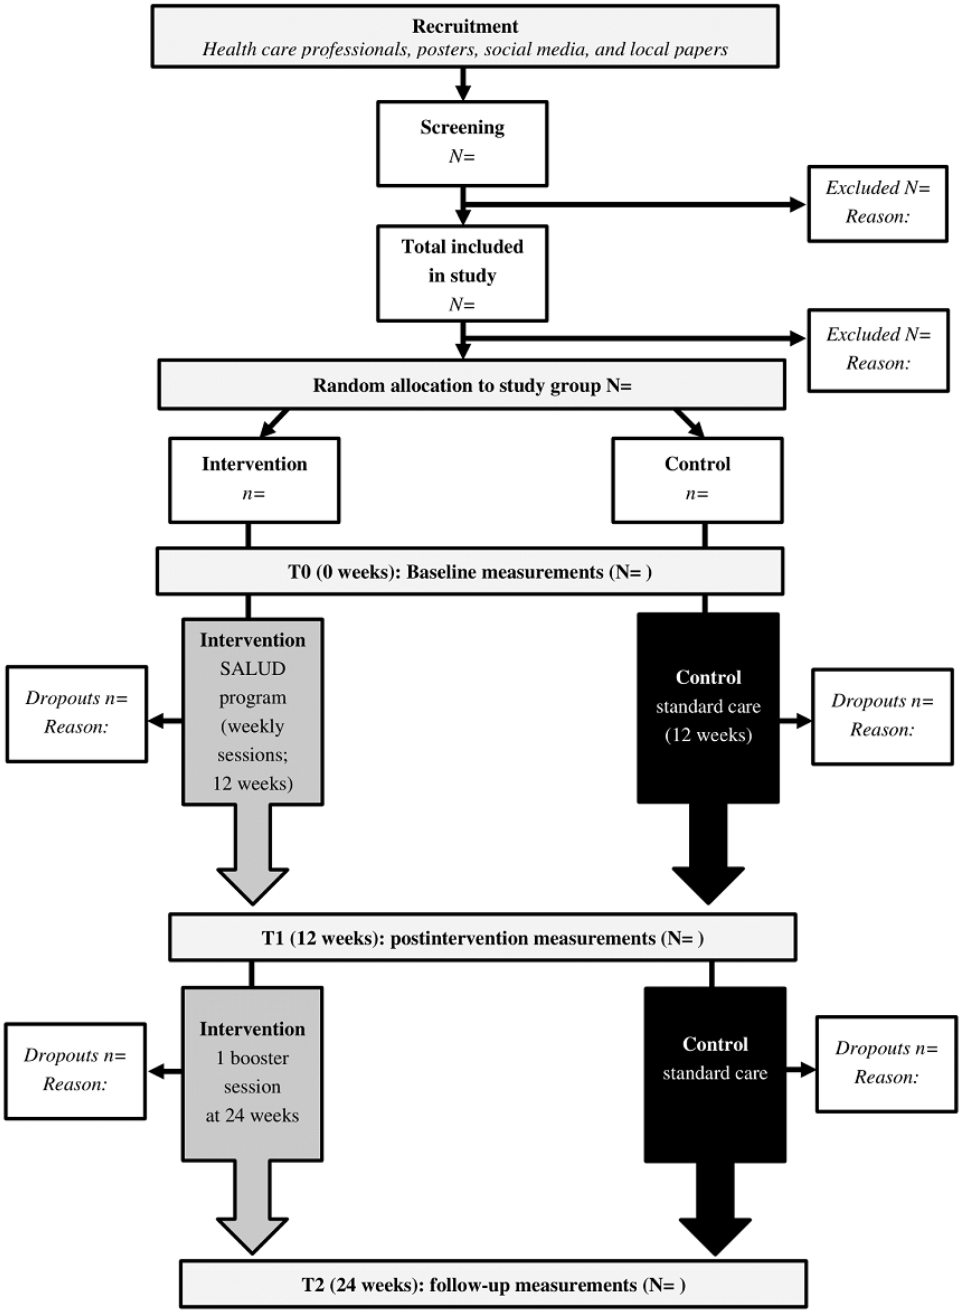
Most previous studies used dietary description or lifestyle counseling strategies. These strategies either included strict (ie, very low–calorie) diets or were performed in highly controlled research settings (intensive intervention regarding diet and physical activity combined with frequent contact with health care providers) [12,25,26]. However, people may experience difficulties when they return from these clinical and controlled research settings to their everyday lives. In everyday life, healthy eating requires a scale of personal and social resources, ranging from practical cooking skills to personal agency [27-29]. It is not only about *what* people eat but also *why* and *how* they eat: the ability to prepare food, social economic resources, the food environments, social support, self-image, mental health, etc. This may explain why the Mediterranean diet is considered as one of the healthiest diets with (long-term) health benefits [30]; the Mediterranean diet is not a strict diet, rather *a way of life* that includes seasonal cooking, freshly cooked meals, and socializing with others [31].

Objectives

Hence, there seems to be a need for a strategy with an eye for everyday life of people with T2DM to promote long-term healthy eating. A health theory centered around the everyday life context is salutogenesis. Applying salutogenesis to nutritional research leads to the assumption that healthy eating is not regarded as a central goal in life but as a resource for greater enjoyment of life [32]. It requires to accept a holistic viewpoint on health and real-life complexity as starting points for conducting and evaluating nutritional interventions. In salutogenesis, health results from the continuous everyday life interactions between the individual and the social, economic, cultural, physical, mental, and biochemical stressors [33]. The central concept in salutogenesis is the sense of coherence (SoC), which is the individual capability to mobilize and use health-promoting resources [33]. Understanding the *resources* that facilitate coping with these stressors in a health-promoting manner can help to unravel underlying principles of creating health [34]. Salutogenesis guided the development of the Salutogenic Intervention for Type 2 Diabetes (SALUD) program [35].

The aim of this study protocol is to outline the randomized controlled trial (RCT) in which the SALUD program is compared with the Dutch usual care for T2DM. The theoretical principle behind the program is mobilizing 2 important

XSL•FO
RenderX



psychosocial resources required for organizing healthy eating and improved well-being in everyday life: self-identity and social support [35]. The present hypothesis is that mobilizing these resources will initiate a process of empowerment, leading to improved food literacy (direct effect) and improved health (indirect effects). Food literacy is the capability to navigate different food situations to make healthy eating choices [36], which is important for healthy eating and well-being in the long term. It is a measure that combines all relevant aspects for healthy eating in everyday life, that is, knowledge, skills, and behaviors. Hence, the primary objective is to determine the effect of the SALUD intervention on food literacy. Diet quality as well as several physical and psychosocial outcomes will be evaluated as secondary outcomes.

Methods

Study Design

A 2-arm, semiblinded RCT will be conducted with 56 people with T2DM in the Netherlands. The whole study duration will be 24 weeks, with measurements planned at baseline (T0), after 12 weeks (postintervention; T1), and 24 weeks (follow-up; T2). Participants will be randomly allocated to the intervention group (SALUD program) or to the control group (usual T2DM care [37]). The SALUD program will consist of 1 individual intake session (at the start), group sessions for 12 consecutive weeks, and 1 booster session (at 24 weeks). The study procedure is outlined in Figure 1.

Figure 1. Salutogenic Intervention for Type 2 Diabetes (SALUD) study procedure.

Ethics Approval

Medical Ethical Committee Oost-Nederland has granted medical ethics approval for this study on August 8, 2021 (Medical Ethical Committee number 2021-12949).

Trial Registration

The study has been registered at Netherlands Trial Registry with registration number NL8963 [38] (registered on October 12, 2020).

Participants

The target population consists of Dutch-speaking men and women with T2DM. Inclusion criteria are as follows: officially diagnosed with T2DM by a general practitioner (GP); aged ≥18-75 years; fluent in Dutch, competent to make own decisions; and in possession of a computer device with internet connection. Exclusion criteria are as follows: pregnant, lactating, or intention to become pregnant in the upcoming 6 months; severe chronic illnesses or condition or comorbidities (other than T2DM, eg, kidney failure, severe form of chronic obstructive pulmonary disease [gold III or IV], heart failure [class 2-4], cancer, dementia, or severe depression); bariatric surgery in the past; and eating disorders (eg, anorexia or bulimia).

Recruitment

Participants are recruited via posters in GP practices, advertisements in local papers, social media, and websites of national diabetes organizations. In addition, several local GPs and practice nurses approach clients during regular health appointments or via phone or mail. Before commencement, all participants receive the information brochure that explains the study in detail and a phone call from the investigator for further explanation. At least 7 days after the phone call, participants sign an informed consent form and send it to the investigators before the start of the study. Participants are informed (written and verbally) that they will be randomly allocated to either the intervention or control group.

Randomization and Blinding

Randomization of participants will be performed by an independent researcher (not involved in the study) with use of a web-based randomization tool. The data analysis for the primary outcome will be run blinded by an independent researcher. Treatment codes will be broken after finalization of the data analyses. Participants and researchers are not blinded during the measurements owing to the nature of the intervention.

Intervention: SALUD Program

Theory Operationalization

For the development of the SALUD program, 3 main principles of salutogenesis were operationalized:

- The participant as a whole: in salutogenesis, health is a complex and dynamic concept incorporating multiple aspects of well-being that relate to the whole person [39]. This requires interventions that aim to improve multiple aspects of health. Hence, in the SALUD program, physical and psychosocial health are valued equally.
- The participant's active involvement: to facilitate the mobilization of health resources, intervention strategies should be adjusted to real life to increase the chance of successful implementation of newly adopted behaviors in everyday life. This can only be done successfully and respectfully when people with T2DM and their health care providers are actively involved in the development of interventions. Hence, people with T2DM, health care professionals, and scientists of different disciplines provided their perspectives multiple times during intervention development (the participatory developmental process has been described by Polhuis et al [35]). The participatory developmental process revealed that self-identity, social support, food literacy, disease acceptance, and stress management were crucial resources to enable healthy eating in everyday life.
- The participant's individual learning process: salutogenesis complements traditional information-providing approaches by supporting individuals in a learning process to mobilize personal and environmental health-promoting resources to cope with stressors. Hence, the strategy of the intervention was to enhance the generalized resistance resources (GRRs) and specific resistance resources (SRRs) for enabling healthy eating through a reflective and empowering approach. The main strategy was based on mobilizing the GRRs self-identity and social support; session themes were based on the identified SRRs food literacy, disease acceptance, and stress management (Table 1).

XSL•FO
RenderX

Table 1. Summary of the Salutogenic Intervention for Type 2 Diabetes (SALUD) program sessions.

Session topic	Setting	Goals
0. Intake	Coach and participant one on one (web-based)	• Getting to know the participant; personal history, motivations, and goals
1. Building trust	Coach and peer-group (web-based)	• Establishing a safe place • Social bonding
2. Goal setting	Coach and peer-group (web-based)	• Formulating at least one personal Specific, Measurable, Achievable, Relevant, and Time-Bound (SMART) health goal
3. Food literacy I	Coach and peer-group (web-based)	• Reflection • Question hour with a dietician • Setting up an individualized diabetes-proof week menu • Practical skills for meal planning, grocery shopping, and cooking
4. Food literacy II	Coach and peer-group (web-based)	• Reflection • Learning and sharing recipes (SALUD recipe book)
5. Stress management	Coach and peer-group (web-based)	• Reflection • Stress management • Diabetes-related stress • Mindfulness exercises (body scan and breathing exercises)
6. Nature break	Coach and peer-group (web-based)	• Reflection • Stress management • Boosting positive emotions • A mindful, individual walk outside (20 minutes)
7. Measuring progress	Coach and peer-group (web-based)	• In-depth reflection, evaluation, and adjustment of health goals • Social support
8. Social support	Coach and peer-group (web-based)	• Involve partner or friend in the health process • Opportunity for partners or friends to ask questions about program or health • Social support
9. Self-identity	G Coach and peer-group (web-based)	• Reflection • Why do you eat what you eat? • Values and life goals • Disease acceptance • Social support: question hour with role model
10. Open session	Coach and peer-group (web-based)	• The participants choose the topic of this session during session 7
11. Measuring progress	Coach and peer-group (web-based)	• In-depth reflection, evaluation, and adjustment of health goals • Social support • Long-term health strategies
12. Festive closure	Coach and peer-group (web-based)	• Reflection on personal learning trajectory • Boosting positive emotions • Long-term health strategies
13. Booster session	Coach and peer-group (web-based)	• Reflection and sharing of experiences over the past 12 weeks • Social bonding • Long-term commitment to a healthy lifestyle

Setting

The SALUD program takes place in a web-based group setting (7-8 participants per group) under supervision of a certified and experienced lifestyle coach. The communication platform Microsoft Teams (Microsoft) is used for hosting the sessions. The job of lifestyle coach in the Netherlands entails coaching and motivating people to sustainable lifestyle changes regarding nutrition, physical activity, sleep, and stress. Certified lifestyle coaches are extensively trained in various communication and coaching techniques. They have basic knowledge of lifestyle-related diseases, physiology, and nutrition. The current coach has been externally hired for the study by the authors and is not part of the research team. The coach is specifically

XSL•FO
RenderX

experienced in group coaching (>5 years), particularly people with T2DM. The participants will be divided into separate groups on different days (based on their availability), all under supervision of the same coach.

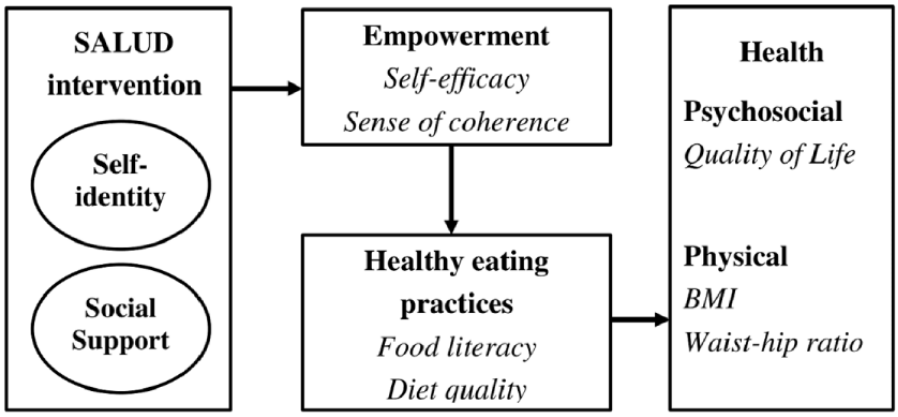
Content

The SALUD program consists of 1 individual intake session (at the start), 12 weekly group sessions, and 1 booster session. Each weekly session has its own theme and goals (summary in Table 1). The sessions' themes are based on the GRRs and SRRs that were identified during the participatory intervention development: self-identity, social support, food literacy, disease acceptance, and stress management. A "learning by experience" approach will be used to equip participants with practical tools and skills. The coach uses several reflective (on- and off-screen) exercises related to diet, health, stress, and life during each session. The sessions are intended to be highly interactive and informal. Most sessions end with a practical home exercise (eg, "cook a new recipe this week"). A registered dietician will be invited to 1 of the sessions to answer specific nutrition-related questions. In 2 of the sessions, participants are encouraged to bring an important person (their best friend, partner, neighbor, or family member). Session 10 is deliberately left "open" to provide the participants with the opportunity to choose a topic based on their needs. More details about the intervention content can be found in the study by Polhuis et al [35].

Fidelity of Delivery

Fidelity of the intervention delivery is assured by the following:

- selecting a coach in line with salutogenic principles, that is, whole person view on health and a participatory and empowering way of coaching
- using a program manual in which the program's core (salutogenic) values, the sessions, the exercises, and goals are outlined
- thoroughly discussing with the coach about the (salutogenic) approach of the program before the start of the study
- weekly evaluating forms that will be filled in by the coach after each session to keep track of deviations from the manual and feedback of participants
- weekly checkups between the coach and the principal investigator (KP) to evaluate the previous session and to discuss the upcoming session
- recording a (small) number of sessions (with permission of the participants).



Control: Usual T2DM Care

The participants in the control group receive the usual Dutch T2DM care according to the Dutch General Practitioners Association (Nederlands Huisartsen Genootschap) protocols [37]. The usual care of T2DM is based on medical treatment, education, and lifestyle advice. Newly diagnosed persons and persons who require insulin administration are referred to a dietician by the GP. In some cases, the GP recommends a referral to a psychologist for help with dietary advice or to a physical therapist to help with physical activity. The GP refers to a specialist in case of complications (such as retinopathy and nephropathy). Generally, a person with T2DM has 4 quarterly checkups with the practice nurse and 1 yearly checkup with the GP. However, the exact frequency of the appointments depends on the specific agreements between the health care provider and the patient.

Quantitative Evaluation

The primary outcome is food literacy; secondary outcomes are self-efficacy, QoL, SoC, diet quality (Dutch Healthy Diet Index 2015 [DHD-15 index]), body weight, BMI, and waist-hip ratio (WHR). Self-efficacy and SoC are measured to evaluate the empowerment process of the SALUD program; diet quality to assess changes in nutritional intake; QoL to assess effects on psychosocial health; and body weight, BMI, and WHR to assess the effects on physical health (Figure 2). All measurements take place at the participants' homes.

Figure 2. Proposed mechanism of action of the Salutogenic Intervention for Type 2 Diabetes (SALUD) program.

Food Literacy (Self-perceived Food Literacy Scale)

The self-perceived food literacy scale (SPFLS) [36] is used to determine the capability to make healthy food choices in different contexts, settings, and situations. The SPFLS is a relatively new tool developed by Dutch researchers and validated among healthy Dutch adults (with a high internal reliability; Cronbach α=.80) [36] as well in people who underwent kidney transplant [36,40]. In the general population and in the patients who underwent kidney transplant, higher food literacy was associated with a healthier nutritional intake [36,40]. The SPFLS scale is proven to be capable of distinguishing between different populations [36,40]. The

XSL•FO
RenderX

SPFLS contains 29 items related to 8 domains: food preparation skills, resilience and resistance, examining food labels, daily food planning, healthy budgeting, and healthy food stockpiling, healthy snack manners, and social and conscious eating. Response options include a 5-point Likert scale (1="not at all/never" to 5="yes/always"), eventually providing a score between 29 and 145. A higher score indicates higher food literacy. Domain scores and a total score are computed for each participant. Permission to use the SPFLS in this research has been formally granted by the developers of the SPFLS.

Self-efficacy (Dutch General Self-Efficacy Scale)

The Dutch General Self-Efficacy Scale (DGSES) [41] is a unidimensional free accessible questionnaire that measures the confidence someone has in their own abilities to cope with external challenges. The original DGSES was developed in German and is currently adapted to 32 languages [41]. Internal consistencies yielded typically Cronbach α between .76 and .90 [41]. Criterion validity is documented in numerous correlation [41]. The DGSES consists of 10 questions related to how people generally think and act. The response options include a 4-point Likert scale (1=completely false; 4=completely true), eventually providing a score between 10 and 40, with a higher score indicating higher self-efficacy. A total score will be computed for each participant.

QoL (World Health Organization Quality of Life Questionnaire)

The Dutch and abbreviated version of the World Health Organization Quality of Life-100 (WHOQOL-100) questionnaire is used to determine how people perceived their QoL over the last 2 weeks [42]. The abbreviated WHOQOL-100 is known as WHOQOL-BREF. The WHOQOL-BREF has been validated by comparing it with the original WHOQOL-100 domain scores (domains scores correlate at around 0.9 with the original) [43]. Internal validity is high (Cronbach α>.70) [44]. The WHOQOL-BREF contains a total of 26 questions that assess 5 domains of health and well-being: general perceived QoL, physical health, psychological health, social relationships, and environment. Response option includes a 5-point Likert scale (1=not at all; 5=extremely true), eventually providing a score between 26 and 130. Higher scores denote better QoL. A score is computed for each QoL domain as well as a total QoL score. Permission to use the Dutch version has been granted by the World Health Organization.

SoC (13 Items of the Orientation to Life Questionnaire)

The Dutch version of the 13 items of the Orientation to Life Questionnaire (SoC-13) is used to assess the participants' SoC [34]. The SoC measures to what extent participants perceive the world as comprehensible, meaningful, and manageable. The SoC-13 has been validated in multiple countries with a high internal validity (Cronbach α between .70 and .92 [45]). The Dutch version is validated among Dutch adults (Cronbach α=.86; based on the validation study of Swan, E, unpublished data, June 2013). Response options include a 7-point Likert scale (1=very often; 7=almost never), eventually proving a score between 13 and 91, with a higher score indicating a stronger SoC. Domain scores for manageability, comprehensibility, and meaningfulness as well as a total SoC score are computed for each participant. Permission to use the SoC-13 has been granted to the authors.

Diet Quality (DHD-15 Index)

The DHD-15 index is used to assess the diet quality via a scoring system based on the Dutch food-based dietary guidelines [46]. The DHD-15 index is a relatively short food frequency questionnaire consisting of 40 questions. The DHD-15 index has been validated with 24-hour recalls and food frequency questionnaire data among Dutch adults with a Dutch dietary pattern [46]. The DHD-15 index calculates a score for 16 food components: vegetables, fruit, wholegrain products, legumes, nuts, dairy, fish, tea, fats and oils, coffee, red meat, processed meat, sweetened beverages and fruit juices, alcohol, salt, and unhealthy food products (snacks and cookies). Each component is scored on a scale ranging from 0 (implies nonadherence) to 10 (optimal adherence), eventually providing a total score between 0 and 160. A higher score indicates a more optimal diet quality (ie, a diet in line with the Dutch dietary guidelines). For the calculation of the scores, specific cutoff and threshold values were used as suggested by Looman et al [46]. A separate score for each component as well as a total score will be calculated. Formal permission to use the DHD-15 index was granted by the developers to the authors.

Anthropometry

Body weight is measured at the participant's home with use of a scale (type: UC-411PBT-C) that measures to 2 decimals precisely. The scale will be calibrated before each measurement. The researcher makes sure the measurements are performed in similar circumstances (time of the day, placement of the scale, and layers of clothing). In addition to weight, height is measured once (during the first measurement). The scale calculates BMI (BMI [kg/m^2]=*body weight [kg]/height [m]*^{2}) and estimates fat percentage (%), muscle mass (kg), and basal metabolic rate (kcal).

Waist Circumference and WHR

Waist circumference and WHR are simple and useful measures of fat distribution. The measurements are performed according to the instructions of the World Health Organization [47]. In short, the participant must stand with arms at the sides, feet positioned close together, and weight evenly distributed across both feet. The measurement is performed at the end of a normal expiration. The researcher uses a measuring tape to measure the midpoint between the lower margin of the least palpable rib and the top of the iliac crest to determine waist circumference. Hip circumference is measured around the widest portion of the buttocks, with the tape parallel to the floor. All measurements are performed at the same time of the day (morning, afternoon, or evening). WHR is calculated using the following formula: *WHR=waist circumference (cm)/hip circumference (cm)*. A healthy WHR is considered ≤0.90 for men and ≤0.85 for women [47].

Participant Characteristics

A questionnaire consisting of personal contact details (name, age, address, phone number, and email), living situation,

XSL•FO
RenderX

ethnicity, educational level, and clinical details (disease duration, medication use, and smoking [past and present]) is filled out during screening.

Qualitative Evaluation

Consecutive to the 12th session, participants are invited to a focus group to provide feedback and share their personal experiences with the program. The participants' partners are also invited to the focus group. One week before the focus group, the coach instructs the participants to bring an object that symbolizes their experiences with the SALUD and to think about what they liked or disliked about the program. The focus groups will be video recorded and used for qualitative effect analysis of the program. In the video recording, all participants (and partners) are asked to provide informed consent to record the session and to use the video recording for qualitative analysis. The following sample question will be used:

- If you were the program director of SALUD, what would you change? Why?
- Would you recommend SALUD to other people? Why? Why not?
- What did SALUD mean to you? Which parts were valuable/useful for you?
- Which elements of SALUD were not valuable/useful for you?
- Did you change things in your everyday life because of SALUD (eg, daily life, interactions with others, and the way you think)? Why?

The video recording will be transcribed ad verbatim and pseudonymized. Two researchers of the research team analyze the transcripts independently. First, the transcripts are read and reread to engage with the data. Then, the transcripts are open coded on a descriptive and interpretative level. More specifically, transcripts will be coded on active components of the intervention, the mechanism of action, health-promoting resources, and the influence on everyday life. Subsequently, the codes are clustered in preliminary themes. Then, the 2 researchers compare and discuss the preliminary themes until consensus is reached. The overarching themes are the result of various discussions between the researchers. The themes will be displayed with pertinent participant quotes and detailed interpretative commentary. The Dutch quotes will be translated into English by a professional translator.

Sample Size Calculation

Sample size calculation is based on the known mean value and SD of the SPFLS (food literacy measure) for the Dutch general population [36]. There are no RCTs with lifestyle interventions in the scientific literature that assessed food literacy (measured with SPFLS or another measure for food literacy) as a primary outcome. However, as RCTs evaluating lifestyle interventions that targeted psychosocial outcomes such as self-efficacy have demonstrated effect size of between 1.1 and 1.7 [48,49], it seemed reasonable to expect an effect size of 0.9. With use of the Cohen *d* calculation for effect size, an anticipated mean of 4.20 SPFLS score in the intervention group, and an anticipated mean of 3.83 (SD 0.41) in the control group is expected at T1 (based on references values [36]). With a standard power of 80% and a significance level of 5%, a total of 19 participants per group (38 participants in total) are needed. Adding a 30% dropout rate, the ideal sample size was set at 28 participants per group (56 in total).

Statistical Analyses

Statistical analyses are carried out using IBM SPSS Statistics for Windows, version 28 (released in 2021; IBM Corp). Two-sided *P* values <.05 are regarded as statistically significant. Analyses are performed with the intention-to-treat principle, meaning that all patients were analyzed in their original allocation group regardless of the extent to which they followed the intervention. Dropouts are counted, and reasons for dropping out are recorded. If missing is completely at random, all available data at T0 (baseline), T1 (12 weeks), and T2 (24 weeks) are used to conduct the analyses. If missing is at random, multiple imputation techniques are used to impute the missing data.

Scores are calculated for multiple-item instruments (ie, DGSES, WHOQOL-BREF, SoC-13, DHD-15 index, and SPFLS). Randomization will be checked, and variables will be normalized if needed. Descriptive statistics are performed to tabulate mean (or median) values of all study characteristics and baseline values of the independent variables. Chi-square tests (for categorical variables) and 2-tailed *t* tests (for continuous variables) are used to compare the descriptive statistics between study groups and to identify potential covariates. Data are tabulated as mean (SD) or median (IQR) if skewed. Categorical data are presented as n (%) where appropriate.

According to a strict data analysis protocol, primary and secondary outcomes are tested with mixed models. Secondary outcomes are also tested if the primary outcome is not statistically significant. The analyses scripts will be written by the researchers; the analysis of the primary outcome will be run by an independent researcher who is blind to the intervention code. Assumptions for mixed models are checked. The mixed models will test the difference compared with baseline in the scores and values (ie, dependent variables) between intervention and control (ie, independent variable) at T1 and T2. Fixed effects are the treatment condition, time, and the covariates; random effects are the repeated measures per participant at T0, T1, and T2. Multiple models are tested; a crude model, and additional models that are adjusted for confounders commonly adjusted for in literature (eg, sex, age, education, and BMI). Variables that statistically significantly differed at baseline are also included in a model as covariates. The final results are presented in a table displaying the estimated marginal means, 95% CIs, and *P* values for the treatment effect for all primary and secondary outcomes.

Incentive

All participants receive a financial compensation of €150 (US $159.5) after completion of the study (ie, after finishing the last measurements at T2). The financial compensation is calculated based on the time commitment and invasiveness of the measurements.

Data Management

The handling of personal data complies with the European Union General Data Protection Regulation, the Dutch Act on Implementation of the General Data Protection Regulation (in Dutch: Uitvoeringswet Algemene Verordening Gegevensbescherming), and the Findability, Accessibility, Interoperability, and Reusability principles. Participants are assigned a unique participant identifier number (ie, a random 4 digits number) that does not change during the study to ensure that data cannot be tracked back to the participants. This number is linked with the name, address, and date of birth of the participant. The identifier number is used on raw and processed data files. The file that contains the link between the participant's information and the participant's identifier number is stored on a password-secured location during the study. Participants indicate in the informed consent form whether their data may be used for other studies. If a participant indicates that they do not allow further use of their data, their data will be removed from the file that can be requested for future research. The file with the link between the participant identifier number and the personal data of the participant will be destroyed after finalizing the data files for future research.

Results

The project of which this study is part of received funding from the Edema-Steernberg Foundation in November 2016. Recruitment started on October 1, 2021. The intervention participants followed the SALUD program between January and August, 2022. The acquisition of the data was completed on August 1, 2022. The data analysis and publications are expected at the end of 2023.

Discussion

This study will be one of the first salutogenic interventions for T2DM. Both the quantitative and the qualitative effect analyses are expected to provide valuable insights for further optimalization of interventions in people with T2DM.

Strengths and Limitations

A first strength of this study includes the RCT design, especially because previous Dutch "diabetes reversal" interventions have been evaluated via an observational pre- and posttest design [4,50]. Furthermore, there is also a shortage of evaluating salutogenic programs via RCTs [51]. Although RCTs are considered the gold standard for intervention evaluation, the RCT design has also some limitations for this particular study. The SALUD program is difficult to fit the experimental framework of an RCT, as it is a multicomponent intervention that cannot be strictly standardized [52-54]. Furthermore, RCTs are limited when the implementation context is a determinant of the result [52-54]. In the SALUD study, the success of the program will be dependent on the extent to which the program integrates with the everyday lives of the participants. Nevertheless, RCTs can be helpful for evaluating multicomponent interventions if close attention is paid to contextual factors via qualitative analysis [54]. Hence, a second strength is the proposed qualitative evaluation. This will increases the value of this RCT as it may help to understand the "black box" of the SALUD program (eg, the active components of the SALUD intervention, participant satisfaction, and points of improvement) [54]. In addition, the qualitative evaluation together with the quantitative evaluation may gather new insights regarding the theory of salutogenesis [51,54]. A third strength is that participants can follow the program on the web in the comfort of their own home: it saves the participants' time and travel efforts. Considering the recent COVID-19 pandemic, it is also a safe manner of group interactions, and the group sessions can continue during a possible lockdown. It also provides valuable information on how to perform a group-based coaching program in a web-based setting. A third strength is the open and flexible nature of the SALUD program, which provides the lifestyle coach opportunities to tailor the program to situational factors and individual needs. A final strength is the inclusion of both physical and psychosocial health measurements that enable assessment of the program's effect on different dimensions of health. However, because of limited budget, the study does not include HbA_{1c} and blood measurements to assess T2DM management.

A limitation is the limited follow-up period. Ideally, measurements would be repeated over 1, 5, or even more years to determine whether the program led to sustainable change. However, the current Dutch university and funding structures make it difficult to execute such long-term research projects (eg, temporary research contracts). Challenges the study may face are the recruitment; owing to the COVID-19 pandemic, health care professionals are overflooded with work and are short staffed. Especially in the case of a new infection peak, health care professionals may be unable to assist in the recruitment of participants. Furthermore, the intervention might be specifically suited for more motivated people because of the time investment and because self-identity and self-reflection require a proactive attitude. This might cause dropouts in the intervention group.

Conclusions

The proposed study will provide useful information on the effects of a salutogenic program on healthy eating and well-being in people with T2DM in a daily life setting. The SALUD program—if effective—may serve as a concrete, web-based tool to empower people with T2DM and guide them toward a healthier dietary pattern for the long run. In addition, the study may provide valuable information on what salutogenic interventions entail as well as new insights regarding the theory of salutogenesis. The combination of quantitative and qualitative measures allows a comprehensive evaluation of the intervention's effects.

Abstract

Background: Alcohol consumption is a major modifiable risk factor for female breast cancer, even in small amounts. However, awareness of this risk remains low. National breast screening programs are uniquely positioned to provide timely and targeted health information and behavior change strategies to improve alcohol literacy and reduce consumption. A breast screening service is a novel health care setting for brief alcohol intervention, with the potential for extensive reach.

Objective: This study aimed to conduct a formative evaluation with breast screening service consumers to understand the need for, and acceptability of, brief alcohol intervention in the breast screening setting and collaboratively design a brief alcohol intervention (Health4Her); to test the effectiveness of Health4Her in improving knowledge of alcohol as a breast cancer risk factor (primary outcome), improving alcohol literacy, and reducing consumption among women attending a breast screening service; and to examine the implementation strategy through process evaluation.

Methods: This was a hybrid type II effectiveness-implementation trial comprising a randomized controlled trial (RCT) alongside a mixed methods program evaluation guided by applicable elements of the Reach, Effectiveness, Adoption, Implementation, and Maintenance framework and Consolidated Framework for Implementation Research. Formative evaluation comprised a retrospective analysis of alcohol consumption data (n=49,240), a web-based survey (n=391), and focus groups and interviews (n=31) with breast screening service consumers. Women attending routine mammography, drinking at any level, were recruited to the single-site, double-blind RCT (n=558), and completed a baseline assessment before randomization (1:1) to receive Health4Her (alcohol brief intervention + lifestyle information) or control (lifestyle information) via animation on an iPad. Follow-up assessments were performed 4 and 12 weeks after randomization. The process evaluation included evaluation of trial administrative data, participant quantitative (n=497) and qualitative feedback (n=30), and site staff qualitative feedback (n=11).

XSL•FO
RenderX

Results: This research was funded in March and May 2019. Data collection for the formative evaluation and trial recruitment occurred between January and April 2020 and February and August 2021, respectively, with finalization of follow-up data collection in December 2021. Quantitative process evaluation data were collected during trial implementation, and collection of participant and staff feedback was finalized in December 2021. Results of the retrospective analysis of alcohol consumption data from breast screening service consumers is anticipated to be published in March 2023 and the results of the RCT to be published in March 2023.

Conclusions: This study is anticipated to generate new substantial knowledge on the alcohol consumption and literacy needs of women attending breast screening and the extent to which these can be addressed using a novel, tailored brief alcohol intervention. The study design permits the evaluation of the effectiveness and implementation of Health4Her to predict and facilitate uptake in breast screening services.

Introduction

Background

Globally, alcohol use is a major modifiable risk factor for breast cancer in women, accounting for 4.4% of breast cancer cases and 10% of breast cancer deaths [1,2]. Meta-analyses demonstrate a dose-response relationship between alcohol and breast cancer [3-5] with the relative risk of breast cancer increasing by 4%, 23%, and 61% for light, moderate, and heavy alcohol consumption, respectively [3]. Lifetime and current alcohol consumption have been found to contribute to an increased risk of breast cancer [6-8]. In particular, alcohol consumption after the age of 40 years is strongly and independently associated with breast cancer risk [7]. Among women with a history of breast cancer, alcohol intake of <1 standard drink per day has been associated with an increased risk of breast cancer recurrence or development of a second primary breast cancer [9].

Despite strong evidence, awareness of the alcohol–breast cancer link has remained surprisingly low [10]; recent Australian and international estimates indicate that only 16% to 20% of the population accurately identifies alcohol consumption as a risk factor for breast cancer [11,12]. In Australia, per capita alcohol consumption is declining [13]; however, risky alcohol consumption (based on 2009 Australian Alcohol Guidelines, consuming >2 Australian standard drinks per day) has remained stable among women aged ≥40 years and has even increased among women aged between 50 and 69 years [14]. Furthermore, a prospective cohort study of Australian women with newly diagnosed first episode of invasive breast cancer found that the proportion of women drinking at the time of diagnosis and 2 years after diagnosis remained stable at 71%, with 1 in 6 women continuing to drink in excess of the national alcohol guidelines that were in place at the time (ie, >2 standard drinks per drinking day) after breast cancer diagnosis [14,15]. Despite this, alcohol consumption among middle- to older-age individuals is often underrecognized as an area of concern [16,17] and has largely been absent from breast cancer prevention strategies and health promotion.

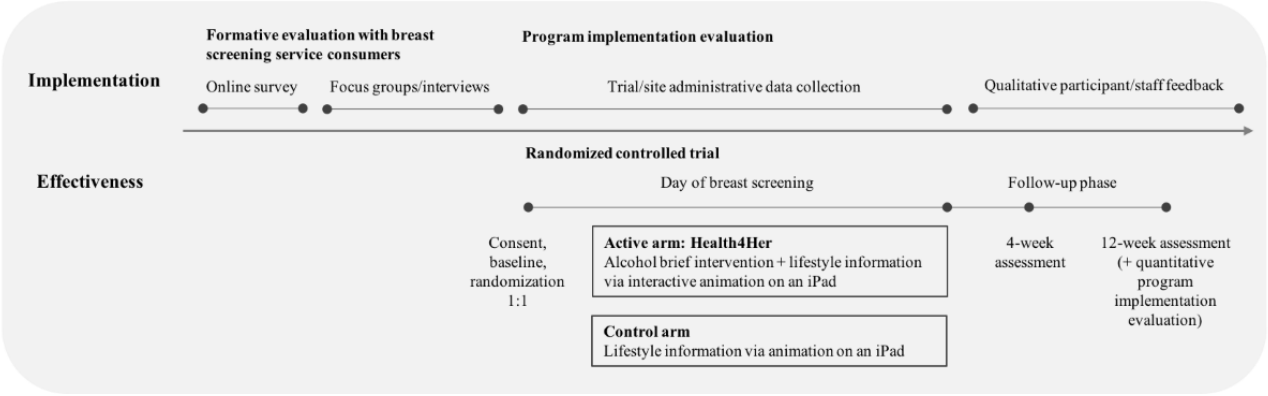
Internationally, computerized brief alcohol interventions (ie, feedback on personal drinking levels compared with age and gender norms, alongside information about alcohol risks and harms) have received strong empirical support as a simple, cost-effective method of addressing alcohol consumption and reducing related harm in primary care populations [18]. Computerized brief alcohol interventions offer a low-cost, labor- and time-efficient approach that has the potential to overcome some of the issues with implementation in busy health care environments [19,20]. Meta-analyses show that a single computerized intervention session is effective in reducing alcohol consumption and improving health-related knowledge, attitudes, and intentions [18,21] and has the potential for wide reach.

Population-based screening programs can provide a window of opportunity to receive relevant targeted health information. Approximately 43 million women participate in population breast screening programs annually in Australia, the United States, and the United Kingdom. An intervention offered within an already established national breast screening program, which could provide information on alcohol and breast cancer risk alongside behavioral change strategies, has the potential to improve women's alcohol literacy, reduce alcohol consumption, and have extensive reach. Some recent research suggests that integrating brief alcohol interventions into breast screening services is perceived by clients as acceptable [20,22]; however, the effectiveness of such an approach is yet to be established.

Objectives

The aims of this research were to (1) conduct a formative evaluation with breast screening service consumers to understand the need for, and acceptability of brief alcohol intervention in the breast screening setting and collaboratively design a brief alcohol intervention (Health4Her) with women in this setting; (2) test the effectiveness of Health4Her in improving knowledge of alcohol as a breast cancer risk factor (primary outcome), improving alcohol literacy, and reducing

XSL•FO
RenderX



consumption among women attending a breast screening service; and (3) examine the implementation strategy through process evaluation to accelerate the translation of this research into practice.

Methods

Study Design

This was a hybrid type II effectiveness-implementation trial [23,24] comprising a randomized controlled trial (RCT) alongside a mixed methods program evaluation (Figure 1), guided by applicable elements of the Reach, Effectiveness, Adoption, Implementation, and Maintenance (RE-AIM) framework and Consolidated Framework for Implementation Research (CFIR) [25,26]. A mixed methods quantitative and qualitative formative evaluation comprised a retrospective analysis of cross-sectional alcohol consumption data from a large sample of breast screening service consumers, a web-based survey, and focus groups and interviews with subsets of breast screening service consumers. The single-site, parallel group, double-blind RCT was designed to evaluate whether the Health4Her intervention is effective in improving knowledge of alcohol as a breast cancer risk factor, improving alcohol literacy, and reducing consumption among women attending a breast screening service. A mixed methods quantitative and qualitative process evaluation examined the implementation strategy via the evaluation of trial and site administrative data, quantitative and qualitative feedback from trial participants, and qualitative feedback from breast screening site staff. The RCT protocol followed the Standard Protocol Items: Recommendations for Interventional Trials guidelines (Multimedia Appendix 1) [27] and the Template for Intervention Description and Replication checklist (Multimedia Appendix 2) [28].

Figure 1. Study design.

Formative Evaluation

Setting

Researchers conducting the formative evaluation were based at Turning Point, a national addiction treatment and research center in Melbourne, Australia. To collect qualitative data from breast screening service consumers, focus groups were initially conducted on-site and replaced with telephonic interviews conducted from the end of March 2020 to comply with social distancing requirements owing to the COVID-19 pandemic.

Participants

The first component of the formative evaluation comprised a retrospective analysis of deidentified cross-sectional alcohol and sociodemographic data (collected from May 2010 to November 2019) from 49,240 women who are members of Lifepool [29], a large convenience sample of women living in Victoria, Australia, who are recruited predominantly through the state-wide BreastScreen program. For the web-based survey, 391 participants were recruited through an email invitation circulated to randomly sampled batches of Lifepool members, stratified by age, based on an anticipated response rate of 25% (total invitations e-mailed, n=1412). Women who participated in the web-based survey and were living in the Melbourne region were invited to register for participation in a focus group or interview at the end of the survey. In addition, purposive sampling was employed to recruit women living in the Melbourne region who reported drinking 3 to 4 (or more) standard drinks, 3 to 4 (or more) days per week (based on the data collected at cohort entry), to participate in a focus group or interview (additional invitations, n=199; focus group or interview participation, n=31). As with all components of this study, women with or without a history of breast cancer were able to participate.

Data Collection

For the retrospective analysis of Lifepool data, there were data available on participants' typical and heavy alcohol consumption patterns over the previous 12 months (eg, "In the last 12 months, how often did you have an alcoholic drink of any kind?" and "In the past 12 months, how often have you had more than 4 standard drinks in a day?") [30]. Sociodemographic (ie, age, education, country of birth, and identifying as being of Aboriginal and/or Torres Strait Islander descent) and health-related (ie, hours per week of moderate-intensity physical activity, BMI, menopausal status, breast cancer diagnosis, first-degree relative breast cancer history, and smoking status) variables were also examined. Postcode data were used to derive the geographical remoteness [31] and relative socioeconomic advantage [32] variables, as defined by the Australian Bureau of Statistics.

The web-based survey, developed by the research team and tested with a convenience sample of women employees at Turning Point, collected demographic information (eg, age and

XSL•FO
RenderX

education) and data on women's knowledge of breast cancer risk factors, breast cancer information sources, the acceptability of receiving cancer risk information in various health settings, and alcohol consumption patterns. Participants' typical and heavy alcohol consumption patterns over the previous 12 months was measured using quantity-frequency items (eg, "In the last 12 months, how often did you have an alcoholic drink of any kind?" and "On a day that you have an alcoholic drink, how many standard drinks do you usually have?") [30]. A visual standard drinks guide was provided alongside alcohol consumption questions to increase response accuracy and equivalence across participants.

Qualitative focus groups were facilitated by a senior research assistant, IV, and cofacilitated by at least one other researcher (ie, JG, CB, or PS). IV conducted the interviews. The semistructured focus group and interview schedule gathered information regarding women's views in relation to breast cancer risk, alcohol consumption, other lifestyle factors, information needs, and attitudes toward receiving health information in different health settings. Women participated in a collaborative design activity where they provided feedback on and generated ideas for the design of the brief alcohol intervention prototype (eg, format, alcohol messaging), as well as the planned research procedures.

Data Analyses

Summary data from the retrospective analysis of Lifepool data and the web-based survey were expressed as counts and proportions or means and SDs. For the retrospective analysis of Lifepool data, sociodemographic and health-related characteristics were compared among women drinking within or exceeding the limits set by national alcohol guidelines for weekly and daily consumption. Associations were explored using logistic regression (categorical variables, dummy coded) and linear regression (continuous variables); in separate models, each characteristic dependent variable was regressed onto the alcohol guideline independent variables. Analyses were performed using Stata (version 17; StataCorp LLC). A *P* value <.001 (2-sided) was used as the level of significance for statistical analyses.

For qualitative data, focus groups and interviews were audio-recorded and transcribed verbatim by a professional transcribing company and organized using NVivo 20 (QSR International) according to the relevant domains of the RE-AIM and CFIR frameworks. Deductive thematic analysis was conducted using the framework method [33].

Reimbursement

To optimize participation in the formative evaluation, there was an incentive of an Aus $1 (US $0.69) donation to breast cancer research for every web-based survey completed and an Aus $10 (US $6.91) donation for focus group or interview participation.

RCT Protocol

Setting

This RCT was conducted at Maroondah BreastScreen, an Eastern Health Service and part of the Victorian National Breast Cancer Screening Program in Melbourne, Australia.

Participants and Eligibility Criteria

Women who underwent routine mammography on Tuesdays and Fridays between February and August 2021 were invited to participate in the study after their appointment. Women received their usual appointment reminder emails with additional information to inform them about the study in advance. Study posters were displayed in the waiting and screening rooms, and verbal information about the study was provided by the radiographers and reception staff. A text message reminder informing women about the study the day before their appointment was introduced, in addition to the email, in May 2021. The inclusion and exclusion criteria are presented in Textbox 1. Women drinking at any level of alcohol consumption (including women who do not drink) were eligible to participate. This approach served to negate any stigma and potential unblinding that may occur by including only women who consume alcohol or drink at risky levels.

Textbox 1. Eligibility criteria.

Inclusion criteria

- Female
- Attending routine mammography
- Aged ≥40 years
- English as a first language or fluent
- Regular access to a telephone
- Able to provide informed consent to participate
- Any level of alcohol consumption (including women who do not drink)

Exclusion criteria

- Hearing impairment sufficient to prohibit a telephone interview
- Pregnancy (also an exclusion from screening)
- Unable to read or comprehend English at a level to provide informed consent or receive the brief intervention

XSL•FO
RenderX

Randomization and Blinding

Randomization was performed immediately after screening assessment, with the next consecutive allocation revealed on the protected spreadsheet. Participants were randomly assigned to the intervention or control group at a 1:1 allocation ratio. Randomization used standard computer-generated permuted blocks of a variable-size scheme. A randomization list was generated at the start of the study by a data scientist and linked to a unique identification code. The data scientist generating the random allocation sequence played no other role in the study. The study was described as a trial of two types of women's health promotion that minimized the trial's alcohol focus and concealed allocation to the intervention arm. Researcher 1, who administered the corresponding intervention per a priori generated randomization list, was not blinded to trial allocation. Researcher 2, who performed the 4- and 12-week telephone assessments, was blinded to trial allocation throughout trial data collection and may only have been unblinded once quantitative program implementation evaluation feedback was sought from trial participants before closing the 12-week call (ie, data collection that did not require blinding). Given the nature and content of the intervention and the outcome assessments, emergency unblinding procedures were deemed unnecessary.

Interventions

Overview

Interventions were delivered on an iPad using a prototype of a brief eHealth intervention (ie, researcher-administered screening alcohol questions, intervention administered by the researcher for the participant to view alone). The brief eHealth intervention model was chosen to minimize disruption to the service workflow and the need for human resources to be implemented within the busy breast screening environment. Take-home study-branded earphones were provided to each participant to view the animation privately. The Qualtrics web-based survey platform that hosted the baseline alcohol questions and intervention tracked the time participants spent viewing the intervention, permitting oversight of the intervention completion.

Active Condition: Health4Her Alcohol Brief Intervention + Lifestyle Information

The active arm received 4 minutes of brief alcohol intervention and 3 minutes of lifestyle health promotion related to modifiable breast cancer risk factors (physical activity and maintaining a healthy weight). A take-home pamphlet summarizing the alcohol information presented during the intervention was provided along with a pamphlet on nutrition to maintain a healthy weight.

The Health4Her intervention was developed in accordance with brief alcohol intervention principles [34,35], applied behavior change approaches [36-39], and findings from our formative research with breast screening service consumers. The brief alcohol intervention comprised personalized feedback and comparison to gender and age drinking norms, negative-framed messaging around alcohol risks and harms, positive-framed messaging on the health benefits of reducing alcohol intake, and alcohol harm-reduction strategies (Table 1). There were 2 versions of the Health4Her intervention, whereby messages relating to personalized normative feedback varied depending on whether participants reported that alcohol use exceeded national alcohol guidelines.

Table 1. Examples of messages included in brief intervention.

Brief intervention and applied behavior change approach	Example of message received
Personalized normative feedback	
Not exceeding Australian Alcohol Guidelines for weekly consumption	"You indicated that you are drinking within the recommended amount of 0 to 10 standard drinks per week. You're doing a good thing for your health—the less you choose to drink, the lower your risk of alcohol-related harm."
Exceeding Australian Alcohol Guidelines for weekly consumption	"You indicated that you are drinking above the recommended limit of 10 standard drinks per week. You are drinking more alcohol than three-quarters of Australian women your age, and the amount you are drinking is putting your health at risk."
Negative-framed messaging	"Did you know that alcohol is a carcinogen, meaning that it's consumption can cause cancer in humans? And there's now strong evidence that drinking alcohol increases your risk of breast cancer."
Positive-framed (or gain-framed) messaging	"The less you choose to drink, the greater the immediate and longer-term health benefits."
Alcohol harm-reduction strategies	"Here are some strategies to get you started: keep track of how much you're drinking by checking the label of any bottle or can for the number of standard drinks it contains. Plan your alcohol-free days for the week ahead, and challenge yourself to add an extra alcohol-free day."

Control condition: Lifestyle Information

The control arm received 3 minutes of lifestyle health promotion to increase knowledge of how to improve women's health and reduce breast cancer risk, not inclusive of alcohol information. Lifestyle health promotion focused on physical activity and maintaining a healthy weight and was developed to be relevant to women attending breast screening services as 2 recognized modifiable breast cancer risk factors [40,41]. A take-home pamphlet on nutrition to maintain healthy weight was also provided.

Choice of Comparator

Participants in the control arm received lifestyle health information to reduce breast cancer risk through animation and a take-home pamphlet on nutrition to maintain a healthy weight. As confirmed through the formative evaluation, embedding brief alcohol intervention within lifestyle information offered to all women attending breast screening provided the opportunity

XSL•FO
RenderX

to target harmful alcohol consumption in a discrete, nonstigmatizing way and increased Health4Her's relevance for all women. As such, lifestyle information in the control condition was also provided in the intervention condition. This also served to maintain equivalence across the treatment conditions. Data from several studies suggest that alcohol assessment reactivity (ie, mere exposure to screening and baseline alcohol questions can prompt awareness and behavioral self-regulation) can bias trial results toward the null and lead to underestimation of the true effects of interventions [42,43]. While participants in the control arm were anticipated to experience some benefits from trial participation and alcohol assessments, it was expected that the effects on primary and secondary end points would be less than those observed for the intervention arm.

Outcomes

Primary and secondary outcomes of the RCT are detailed in Textbox 2.

Textbox 2. Trial outcomes.

Primary outcome

- Change in the proportion of participants accurately identifying alcohol as a clear risk factor for breast cancer at 4-week postrandomization

Secondary outcomes

- Change in the proportion of participants drinking ≤10 standard drinks per week (ie, within current Australian Alcohol Guidelines) [44] at 4 week and 3 months postrandomization (14-day timeline follow-back [TLFB]) [45]
- Among participants who (1) have consumed any alcohol in the past 2 week and (2) drink >10 standard drinks per week at baseline: change in the proportion of participants drinking ≤10 standard drinks per week at 4 week and 3 months postrandomization (TLFB) [45]
- Change in alcohol consumption at 4 week and 3 months postrandomization (TLFB, Australian Institute of Health and Welfare alcohol frequency quantity items) [45-47]
- Among participants who (1) have consumed any alcohol in the past 2 week and (2) drink >10 standard drinks per week at baseline: change in alcohol consumption at 4 week and 3 months postrandomization (TLFB, Australian Institute of Health and Welfare alcohol frequency quantity items) [45-47]
- Health literacy (attitudes): change in participants' attitudes regarding alcohol and breast cancer risk at 4-week postrandomization (adapted from previous literature) [48]
- Health literacy (knowledge): change in the proportion of participants accurately identifying (1) the amount of alcohol in an Australian standard drink; (2) the number of standard drinks in an average restaurant serve of red wine; (3) the maximum number of standard drinks per week recommended by current Australian Alcohol Guidelines (multiple-choice and open-ended questions, adapted from previous literature) [10] at 4-week postrandomization.
- Health literacy (access to health information): proportion of participants who have accessed health information on (1) alcohol harms, (2) alcohol and breast cancer risk, and (3) alcohol harm-reduction at 4-week postrandomization.
- Change in general health at 4 week and 3-month postrandomization (12-item Short-Form Health Survey) [49]
- Change in quality of life at 4 week and 3-month postrandomization (European Health Interview Survey-Quality of Life-single item) [50]

Informed Consent, Enrollment, and Participation

After the breast screening appointment, women who were interested in participating in or learning more about the study were introduced to the on-site researcher (researchers held, at a minimum, an honors degree in Psychology, Population Health, or related discipline), who provided a copy of the participant information and consent form, provided a verbal explanation of the trial (aims, procedures, risks, and benefits), and answered any participant questions (Table 2). Women were advised that they could withdraw from the study at any time and that their decision to participate or withdraw would not affect their relationship with Maroondah BreastScreen or Eastern Health. For women interested in participating in the study, the researcher confirmed their eligibility and obtained verbal or written informed consent (time-dependent), which included consent for the possible future use of participants' deidentified data for related projects.

The researcher then conducted a brief baseline assessment and random allocation by manually administering the iPad to play the corresponding animation according to (1) randomization and (2) if allocated to the active arm, delivery of version the intervention consistent with the participant's level of alcohol consumption. The study explanation, informed consent, screening, baseline assessment, and participation were brief, taking approximately 15 minutes per participant (Table 2).

[b]Primary outcome.

Follow-up and Lost to Follow-up

Follow-up assessments were conducted by researcher 2 via telephone calls (<15-minutes duration) at 4 and 12 weeks after randomization, wherein baseline measures were repeated (Table 2). Participants who could not be contacted after 5 attempts were deemed missing at that data collection time point. For participants lost to follow-up at 4 weeks, the researcher attempted contact at 12 weeks following the same procedure.

Schedule of Enrollment, Interventions, and Assessments

The schedule of enrollment, interventions and assessments is outlined in Table 2.

Reimbursement

Trial participants went into a draw to win one of the 10 Aus $100 (US $69.48) supermarket vouchers to optimize the follow-up response rate [42]. The participants received no direct financial or other consideration (ie, in kind contribution) to participate in this trial.

Outcome Measures

Outcome measures of the randomized controlled trial are shown in Table 3.

Data collected	Method
Screening	
Eligibility and demographic information	Brief standard demographic characteristics (eg, age and education) and inclusion and exclusion information collected through structured questions.
Primary outcome	
Knowledge assessment of breast cancer risk factors	Participants were asked to demonstrate their knowledge of breast cancer risk associated with 6 factors (eg, family history of breast cancer, physical inactivity, antiperspirant deodorant use, alcohol, processed meats, and excess weight) by selecting from a set of scaled-response options: (1) a clear breast cancer risk factor with strong, consistent evidence; (2) a possible risk factor with some evidence; (3) not a proven risk factor with too limited evidence to determine risk; or (4) do not know. Primary outcome was the proportion of participants identifying alcohol as a clear breast cancer risk factor at 4 weeks. Adapted from Cancer Australia's 2018 definitions of breast cancer risk factors and previous research with breast screening service consumers [48,53].
Secondary outcomes	
Alcohol[a]	
14-day TLFB[b]	Alcohol consumption over past 14 days assessed with TLFB [45]. TLFB also informed personalized feedback provided in the alcohol brief intervention.
AIHW[c] alcohol frequency and quantity items	Past-month frequency of alcohol consumption and volume of alcohol consumption on a typical drinking day assessed with 2 items from the AIHW National Drug Strategy Household Survey [46,47].
Assessment of alcohol health literacy	Adapted from previous research with breast screening service consumers, participants were asked about (1) attitudes to alcohol and breast cancer risk [48]; (2) alcohol health knowledge (eg, amount of alcohol in a standard drink, number of standard drinks in an average restaurant serve of alcohol, maximum number of standard drinks recommended by current health guidelines) [10]; and (3) access to alcohol and breast cancer health information [54]. Questions were presented in multiple-choice, open-ended, or statement (ie, 5-point Likert scale from strongly agree to strongly disagree) formats.
Health and well-being	
European Health Interview Survey-QOL[d] single item	QOL rated as single item on 5-point Likert scale from very poor to very good [50].
SF-12[e]	SF-12 used as a brief measure of general health [49].
Physical activity duration [51,52] and consumption of vegetables and fruit [52]	Brief physical activity and vegetable and fruit intake questions included to ensure blinding of participants. Questions adapted from the Australian Bureau of Statistics and previous research [51,52].

[a]Alcohol assessments were nested among general health and lifestyle questions to conceal the trial's alcohol focus.

[b]TLFB: timeline follow-back.

[c]AIHW: Australian Institute of Health and Welfare.

[d]QOL: quality of life.

[e]SF-12: 12-item Short-Form Health Survey.

Data Collection and Management

Baseline data were collected by researcher 1 (on-site at Maroondah BreastScreen) and follow-up data were collected by researcher 2 (via telephone). A description of the trial schedule of the assessments can be found in Tables 2 and 3. An electronic case report form was completed for each participant using REDCap (Research Electronic Data Capture; Vanderbilt University) [55], hosted on a secure server and managed by Eastern Health IT Services with individual access via a secure login, and accessible only to approved members of the research team. REDCap stored screening and trial data, as well as identifiable data, including participant names and contact information. Identifiers were flagged in REDCap to provide additional protection for these data during data exports (ie, identifiers were automatically removed from all exported material generated by REDCap). Spreadsheets containing reidentifiable information (ie, for the purpose of conducting follow-up assessments; timeline follow-back data, which could not be collected using REDCap) were protected with unique passwords. Hardcopy data were stored and secured in a locked cabinet on-site at Turning Point. Upon completion of trial data collection, data were transferred from the electronic case report form and other source documents (eg, timeline follow-back spreadsheets) to Stata and R statistical software (R Foundation for Statistical Computing) packages for analyses. Protected health information (ie, participant name and contact information) was not exported. All data collected during this study will be

XSL•FO
RenderX

retained by the research team for at least 5 years, as outlined in the Australian Code for the Responsible Conduct of Research.

Power and Sample Size

Power and sample size estimates were carried out using PS: Power and Sample Size Calculation (version 3.1.2; Vanderbilt University) [56], assuming a type 1 error probability of <.05, 2-tailed, and equal-sized groups. Power calculations were based on the primary end point and the change in the proportion of participants who accurately identified alcohol as a clear risk factor for breast cancer. On the basis of the data from our web-based survey of breast screening service consumers (n=391) conducted as part of the study's formative evaluation, the proportion of participants identifying alcohol as a clear risk factor for breast cancer at baseline was estimated to be 22%. On the basis of a related study examining the effects of a public health campaign on awareness of the alcohol-breast cancer link [57], the response rate for participants receiving an alcohol brief intervention was estimated to be ≥12% greater at 34% at 4 weeks postrandomization. Accounting for 20% attrition at the follow-up, a sample of at least 548 participants (274 per arm) was estimated to provide 80% power to reject the null hypothesis.

Statistical Analysis Plan

Data were collated, cleaned, and validated in a database that was locked before analysis. No interim analyses were planned to be conducted, and as no substantial harm was anticipated from this trial, no formal stopping guidelines were specified. All statistical tests were 2-tailed, with the α level set at .05, and analyses were conducted using the most appropriate procedures in Stata or R All randomized participants were included in the analyses (ie, intention-to-treat) for primary and secondary outcomes. Sociodemographic characteristics will be summarized and reported by intervention arm. Analyses examined change in outcomes over time (4 weeks, 12 weeks, or 4 and 12 weeks; pre-specified for each outcome) relative to baseline. The Generalized Linear Mixed Model approach with fixed effects for treatment and time, their interaction, and random effects for subjects and assessments within subjects was applied to examine the treatment effect of the intervention on all outcomes. For outcomes assessed at a single postrandomization time point, the models were equivalent to traditional logistic regression. For consumption outcomes, subgroup analyses were conducted with participants exceeding national guidelines for weekly consumption. Mixed models are robust to missingness under the assumptions of missing at random and missing completely at random, thereby maintaining analyses based on intention-to-treat principles. For outcomes with 2 time points, Cochran-Mantel-Haenszel tests were examined.

Trial Monitoring

The trial's chief investigators performed the function of a Trial Steering Committee, because they had the technical expertise necessary to oversee all aspects of trial conduct (eg, monitor compliance with the protocol, provide ethical and clinical governance, provide standardized training and other means of quality control, and monitor trial arm fidelity). Given the minimal risks of harm associated with this brief intervention, a formal data-monitoring committee was not considered necessary. Regular liaison between the immediate research team and the principal investigator occurred to permit discussion of day-to-day trial progress and any potential concerns. The broader research team met intermittently to review the overall progress of the project and conduct the trial. Data audits were conducted at periodic intervals and were led by the trial manager.

Protocol Amendments

Protocol amendments were approved by the Eastern Health Human Research Ethics Committee. No major changes to the protocol were implemented without prior approval and there were no modifications to the intervention during the trial.

Adverse Events

The risk of harm or discomfort to participants during this trial was anticipated to be minor and transient, in line with the research team's experience conducting brief alcohol intervention research (eg, minor distress responding to questions about alcohol consumption). The research team monitored possible adverse effects throughout the trial.

Participant Withdrawal and Discontinuation

All participants were advised that they had the right to withdraw consent at any time and without consequences. Withdrawal of consent could occur verbally or in written form (ie, email or text message correspondence), and participants could elect to remove all of their previously collected data or consent for further data collection. No further contact was initiated by the research team once the participants withdrew consent.

Ancillary and Posttrial Care

Participants were advised during enrollment and at the end of participating in their allocation intervention that they should continue to engage with health care as usual while participating in the study and to contact their primary care provider if their participation in this study raised concerns about any aspect of their health (ie, alcohol use, general health, breast cancer risk).

Program Implementation Evaluation

Setting

Researchers conducting the process evaluation were based at Turning Point, with telephone or videoconferencing used to collect feedback from trial participants and breast screening staff.

Participants

The first component of the process evaluation comprised quantitative feedback about the health information received (Health4Her and control) and its implementation from the 497 women who participated in the 12-week follow-up assessment and responded to the program evaluation questions. Qualitative data about the Health4Her intervention and its implementation were collected from in-depth semistructured telephone interviews conducted with 30 participants after trial. A nested sample design was used to select a subsample of participants for the qualitative interviews [58]. All women were asked if they would be interested in being contacted for an optional qualitative telephone interview. From those who consented to

XSL•FO
RenderX

participate in this extra component of the study, systematic random sampling was used to contact participants who (1) were randomized to the active arm and (2) reported drinking alcohol at baseline to arrange an interview. Of this sample, 9 women were purposively sampled from participants who were drinking above the Australian Alcohol Guidelines at baseline assessment and who had consented to the optional interview.

Staff feedback about the intervention and implementation was obtained via 3 videoconferencing focus groups with 11 Maroondah BreastScreen staff members (managers=2, radiographers=6, and reception staff=3) held at the completion of the trial. All staff members who were interested in participating in a focus group and who were available on the day a focus group was being run were able to take part.

Data Collection

Applicable elements of the RE-AIM framework [26] guided the development of the quantitative participant feedback schedule, the semistructured participant interview, and interpretation of participant feedback to understand the Health4Her intervention's reach (eg, participants' use of health information and reach of information beyond trial participants [distributed health literacy]), efficacy (eg, intervention acceptability and perceived benefits), and implementation (eg, intervention delivered via iPad). Some elements of the CFIR [25] were also used to understand the characteristics of the intervention (eg, format and delivery) and outer setting (eg, existing health campaigns and intervention needs) from the perspectives of participants to identify factors influencing successful implementation.

Applicable elements of the CFIR [25] were used to guide the development of the semistructured staff focus group schedule and interpretation of staff feedback to understand the outer setting (eg, client needs and resources) and inner setting (eg, Maroondah BreastScreen culture, implementation climate, compatibility, and resources). Elements of the RE-AIM framework [26] were also used to understand reach and efficacy relative to staff facilitating intervention delivery (eg, letting women know about the intervention in advance), adoption (eg, factors predicted to affect the uptake of the Health4Her intervention at other breast screening services), and maintenance (eg, factors that facilitate long-term uptake of the Health4Her intervention).

Guided by the RE-AIM framework [26], the process evaluation also included the evaluation of trial and service administrative data collected during implementation (eg, intervention reach and uptake, such as the rate at which women participate in the trial of women invited to participate, reasons for nonparticipation when available, participant characteristics including health inequity factors [culturally and linguistically diverse background; lesbian, gay, bisexual, transgender, intersex, queer, and other LGBTIQ+ status; experiencing disability; low education; and living alone], intervention reach beyond trial participants [distributed health literacy], and COVID-19 impact on operations).

Data Analyses

Summary data from quantitative trial and service data and participant feedback were expressed as counts and proportions or means and SDs. For participant and staff qualitative data, interviews and focus groups were audio-recorded and transcribed verbatim by a professional transcribing company and organized using NVivo 20 according to the relevant domains of the RE-AIM and CFIR frameworks. Deductive thematic analysis was conducted using the framework method [33].

Ethics Approval

This research was conducted in accordance with the Declaration of Helsinki, the 2007 National Health and Medical Research Council National Statement on Ethical Conduct in Human Research (updated 2018), the 2000 Note for Guidance on Good Clinical Practice (CPMP/ICH/135/95), and the International Council for Harmonisation Good Clinical Practice Guidelines. This protocol and informed consent processes for each element of the research were approved by the Eastern Health Human Research Ethics Committee (LR19-011-50551) and the Monash University Human Research Ethics Committee (21,395). The trial was preregistered with ClinicalTrials.gov (NCT04715516) on January 20, 2021.

Results

This research was funded in March 2019 (Eastern Health Foundation Research and Innovation Grant) and May 2019 (VicHealth Impact Research Grant). Data collection for the formative evaluation was conducted from January to April 2020 (retrospective analysis of alcohol consumption data from Lifepool, n=49,240; web-based survey with breast screening service consumers, n=391; focus group and interviews with breast screening service consumers, n=31). Trial recruitment was conducted from February to August 2021 (n=588), with follow-up data collection finalized in December 2021. Quantitative process evaluation data were collected during trial implementation, and the collection of participant and staff feedback was finalized in December 2021 (participant quantitative feedback, n=588; participant qualitative feedback, n=30; and breast screening site staff feedback, n=11). We anticipate that the results of the retrospective analysis of alcohol consumption data from Lifepool (part of the mixed methods formative evaluation) will be published in March 2023. We anticipate that the results of this RCT will be published in March 2023. The program evaluation (comprising the preimplementation web-based survey and focus groups and interviews with subsets of breast screening service consumers and mixed methods process evaluation using trial and site administrative data and feedback from trial participants and breast screening site staff) is also planned for publication.

Discussion

Anticipated Findings

Previous research has found brief alcohol interventions to be effective in increasing alcohol-related knowledge and reducing alcohol consumption in primary care and other settings [34,59]. This is the first known hybrid effectiveness-implementation

XSL•FO
RenderX

trial to examine the benefits of a novel, tailored alcohol brief intervention among women attending the breast screening setting. The study design permits an extensive mixed methods program evaluation alongside a RCT to provide a sound understanding of the factors affecting implementation of the Health4Her intervention to predict and facilitate uptake in practice. The RCT is anticipated to provide evidence that Health4Her intervention increases the proportion of women accurately identifying alcohol as a breast cancer risk factor, improving alcohol literacy more broadly (ie, increasing the proportion of women accurately identifying the amount of alcohol in an Australian standard drink, the number of standard drinks in an average restaurant serve of red wine, and the maximum number of standard drinks per week recommended by current Australian Alcohol Guidelines), and reducing alcohol consumption. The breast screening appointment can act as a window of opportunity to increase engagement with breast cancer risk reduction information; this research will generate new substantial knowledge on the alcohol consumption and alcohol literacy needs of this population and the extent to which these can be addressed using a low-cost, scalable intervention, with the potential to contribute to the prevention of alcohol-attributable breast cancer and the related burden of disease and quality of life among this population.

Strengths and Limitations

The hybrid type II effectiveness-implementation trial design, guided by applicable elements of the RE-AIM [26] and CFIR frameworks [25], represents a key strength of this study. The integration of quantitative and qualitative data occurring at each level of the implementation evaluation [60] will build upon the outcomes of the RCT to provide real-world indicators of program implementation, to accelerate the translation of this research into practice. The RCT used a double-blind design; a typical limitation of brief alcohol intervention studies with hazardous drinkers in primary care settings is the bias introduced by difficulties with participant blinding [61]. One limitation of this research is the risk of assessment reactivity, where mere exposure to alcohol questions prompts awareness and behavior self-regulation in the trial's control group and can bias trial results toward the null and lead to underestimates of true intervention effects. In the design of the RCT, alcohol knowledge and consumption outcomes were interspersed with general lifestyle questions to minimize the salience of the trial's alcohol focus. However, control group assessment reactivity may still occur. An additional limitation is that this initial trial was powered to identify a change in knowledge of alcohol as a breast cancer risk factor and not alcohol consumption per se. Still, this study will provide preliminary data on consumption end points, rates of missing data, and participant attrition, providing important estimates for future scaled-up research.

Conclusions

The benefits of brief alcohol interventions have been demonstrated in primary care and other settings; however, their effectiveness and implementation in the breast screening setting remain to be explored. The Health4Her intervention, targeting alcohol literacy and harmful consumption among women attending the breast screening setting, has huge potential for scalability and is particularly relevant considering the increasing prevalence of risky drinking among middle- to older-age women and strong evidence that even very light alcohol consumption increases breast cancer risk. This study will evaluate both the effectiveness and implementation of Health4Her intervention to predict and facilitate uptake in breast screening services.

Dissemination Plan

The findings of this research will be disseminated to funding bodies and other relevant stakeholders, published in peer-reviewed journals, presented at national and international conferences, and presented via public talks and media and social media.

Acknowledgments

This work was supported by research grants from VicHealth and Eastern Health Foundation. The funding agencies had no role in any part of the study. We thank BreastScreen Victoria for supporting this study. We thank the staff of Maroondah BreastScreen for their support with this project at their site, and we gratefully acknowledge all Maroondah BreastScreen clients who participated in this study. We thank Freya Horn for her assistance with preparing this manuscript. Nonhuman assistance was not used in any aspect of the study or for manuscript writing and editing.

DIL, VM, RB and JG have received grants from the National Health and Medical Research Council. DIL, VM and RB have received grants from the Medical Research Future Fund. DIL, VM and JG have received funding from Shades of Pink and the Victorian Department of Health. DIL and VM have received grants from the HCF Research Foundation, the Alcohol and Drug Research Innovation Agenda, the Alcohol and Drug Foundation, the Eastern Health Foundation, the Victorian Responsible Gambling Foundation, and the National Centre for Clinical Research on Emerging Drugs. DIL has received grants from Google, the Australian Research Council, VicHealth, and the Australian Department of Health and Aged Care. VM has received funding from the Transport Accident Commission. JG has received funding from the Victorian Department of Transport and Planning. DIL is supported by a National Health and Medical Research Council Leadership Fellowship. IV is supported by an Australian Government Research Training Program stipend.

Data Availability

Only approved members of the research team had access to the final trial data set. Data were not shared, as there was no participant permission or ethics approval to do so, other than for related projects conducted by the research team.

Abstract

Background: End-stage kidney disease (ESKD) is treated with dialysis or kidney transplantation, with most patients with ESKD receiving in-center hemodialysis treatment. This life-saving treatment can result in cardiovascular and hemodynamic instability, with the most common form being low blood pressure during the dialysis treatment (*intradialytic hypotension* [IDH]). IDH is a complication of hemodialysis that can involve symptoms such as fatigue, nausea, cramping, and loss of consciousness. IDH increases risks of cardiovascular disease and ultimately hospitalizations and mortality. Provider-level and patient-level decisions influence the occurrence of IDH; thus, IDH may be preventable in routine hemodialysis care.

Objective: This study aims to evaluate the independent and comparative effectiveness of 2 interventions—one directed at hemodialysis providers and another for patients—in reducing the rate of IDH at hemodialysis facilities. In addition, the study will assess the effects of interventions on secondary patient-centered clinical outcomes and examine factors associated with a successful implementation of the interventions.

Methods: This study is a pragmatic, cluster randomized trial to be conducted in 20 hemodialysis facilities in the United States. Hemodialysis facilities will be randomized using a 2 × 2 factorial design, such that 5 sites will receive a multimodal provider education intervention, 5 sites will receive a patient activation intervention, 5 sites will receive both interventions, and 5 sites will receive none of the 2 interventions. The multimodal provider education intervention involved theory-informed team training and the use of a digital, tablet-based checklist to heighten attention to patient clinical factors associated with increased IDH risk. The patient activation intervention involves tablet-based, theory-informed patient education and peer mentoring. Patient outcomes will be monitored during a 12-week baseline period, followed by a 24-week intervention period and a 12-week postintervention

XSL•FO
RenderX

follow-up period. The primary outcome of the study is the proportion of treatments with IDH, which will be aggregated at the facility level. Secondary outcomes include patient symptoms, fluid adherence, hemodialysis adherence, quality of life, hospitalizations, and mortality.

Results: This study is funded by the Patient-Centered Outcomes Research Institute and approved by the University of Michigan Medical School's institutional review board. The study began enrolling patients in January 2023. Initial feasibility data will be available in May 2023. Data collection will conclude in November 2024.

Conclusions: The effects of provider and patient education on reducing the proportion of sessions with IDH and improving other patient-centered clinical outcomes will be evaluated, and the findings will be used to inform further improvements in patient care. Improving the stability of hemodialysis sessions is a critical concern for clinicians and patients with ESKD; the interventions targeted to providers and patients are predicted to lead to improvements in patient health and quality of life.

Introduction

Background

End-stage kidney disease (ESKD) occurs when a person's kidneys are severely damaged and can no longer function independently. Patients with ESKD require dialysis or transplantation to survive. In 2020, 480,516 Americans (61.3% of patients with ESKD) received outpatient, facility-based hemodialysis (also known as in-center hemodialysis) [1]. This includes 109,107 new patients undergoing hemodialysis in 2020 [1]. Diabetes and hypertension are the leading causes of ESKD in the United States [1]. Accordingly, most patients with ESKD have multiple chronic conditions, including cardiovascular disease. In particular, ventricular hypertrophy and varying degrees of heart failure are common among patients on dialysis, compounded by the effect of intermittent fluctuations in blood volume during intermittent (eg, thrice weekly) hemodialysis [2]. The annual mortality rate among patients on dialysis in the United States has increased by nearly 17% during the COVID-19 pandemic in 2020. However, more than half of the deaths were owing to cardiovascular disease [1]. Patients on hemodialysis also experience low quality of life [3] and considerable pain, fatigue, social restrictions, and distress [4-7].

Patients on hemodialysis treated in a dialysis treatment facility typically receive dialysis treatment sessions 3 times a week, for 12 hours per week. On average, 20% of sessions become unstable, most commonly from low blood pressure, or *intradialytic hypotension* (IDH) [8-11]. IDH, a form of cardiovascular and hemodynamic instability, affects half of all patients on hemodialysis [8-11]. IDH may precipitate cramping, dizziness, vomiting, fainting, and fatigue [4,12,13]. The chief causes of IDH are removal of more fluid in a single session than a patient can tolerate, or removal of fluid faster than a patient can tolerate [14]. In the face of preexisting diminished cardiovascular reserves, this often results in hemodialysis instability and repeated myocardial hypoperfusion with resultant cardiac wall motion abnormalities, a phenomenon referred to as *myocardial stunning* [15-17]. Evidence shows that such fluid removal may be responsible for injury resulting from hypoperfusion in other organs, including the central nervous system (eg, repetitive neurological injury leading to cognitive dysfunction) [18].

Cardiovascular and hemodynamic instability during hemodialysis sessions may be preventable. Session stability is determined by the interplay between multiple factors, many of which are modifiable. At the patient level, these factors include decisions regarding sodium and fluid intake and skipping or shortening sessions [19]. Moreover, because early intervention in an IDH episode is important to prevent worsening, patients can notify providers of related symptoms, such as nausea, vomiting, dizziness, or muscle cramping, facilitating prompt provider-based interventions such as placing the patient in the Trendelenburg position [20]. Clinician practice patterns influencing session stability include the physician's decisions regarding the patient's target posthemodialysis weight (sometimes called "estimated dry weight", or "EDW" in practice) and prescribed treatment time and how often these are revisited. Facility-level policy or practice decisions such as a threshold for fluid removal speed (ultrafiltration rate [UFR]) and flexibility toward adding an extra session per week for specific patients are also potentially modifiable factors.

Owing to the relatively recent scientific consensus regarding the cardiovascular harm of rapid fluid removal [21], hemodialysis care providers may not always routinely incorporate cardiovascular and hemodynamic stability into their patient care decisions. In other words, providers regularly choose hemodialysis session lengths, fluid removal targets, and UFRs in ways that affect cardiovascular and hemodynamic stability, perhaps without direct attention to this factor. To provide a better foundation for such decisions, a consensus statement from Medical Directors of United States hemodialysis facilities called for trials of methods for improving patient fluid management [22], we address this call in our research.

XSL•FO
RenderX

Objectives

We will independently evaluate and compare the effects of 2 facility-level interventions (multimodal provider education and patient activation interventions) on the cardiovascular and hemodynamic stability of hemodialysis care. Briefly, the multimodal provider education intervention includes a tablet-based checklist and team training for dialysis facility staff. The patient activation intervention includes tablet-based educational modules and peer mentoring. We pursue our study objectives through the following specific aims:

1. Aim 1: To conduct a cluster randomized controlled clinical trial to test and compare the effects of 2 hemodialysis facility-level interventions on the primary outcome of hemodialysis session stability over an intervention period of 24 weeks and a postintervention follow-up period of 12 weeks.
2. Aim 2: To test and compare the effects of 2 hemodialysis facility-level interventions on secondary patient-centered clinical outcomes, including patient symptoms, fluid adherence, hemodialysis adherence, quality of life, hospitalizations, and mortality over the same time frame.
3. Aim 3: To identify factors associated with the successful implementation of the interventions and ways in which implementation may influence intervention effectiveness.

Hypotheses

Our main study hypothesis is that hemodialysis session stability will significantly improve with either multimodal provider education or patient activation interventions, and that multimodal provider education will show a greater magnitude of improvement. This hypothesis is based on our expectation that some patients on hemodialysis might refuse or be unable to participate in the peer mentoring component of the patient activation intervention, potentially leading to greater reach of the provider intervention. We will test this main hypothesis and explore this potential explanation of any differential improvement as part of our planned sensitivity, mediation, and moderation analyses.

Methods

Study Design

We have translated 2 evidence-based interventions from their previous applications in inpatient safety (checklists [23] and team training [24]) and chronic disease self-management interventions (peer education and mentoring [25,26]) into the outpatient hemodialysis care context [27-29]. We will conduct a cluster randomized controlled clinical trial in 20 dialysis facilities to independently test and compare the effectiveness of each of the 2 interventions for improving the primary outcome of hemodialysis session stability, measured as the occurrence of IDH during a given session. The cluster randomized controlled trial design [30] is most appropriate to our goal of improving routine hemodialysis care. Because pragmatic intervention studies are most suited to supporting health care-related decision-making [31], the effectiveness of the interventions will be assessed under the usual conditions in which they will be applied [31]. The study will also use outcome data already gathered routinely by hemodialysis facilities [32].

Facilities will be randomized in a 2 × 2 factorial design. We selected this design because it is statistically efficient in providing a control group for testing each intervention. Furthermore, this design facilitates the comparison of the interventions' relative magnitudes of the effects and their potentially synergistic or antagonistic effects.

For aim 1 activities, the primary outcome, IDH occurrence, will be monitored for 12 weeks before the intervention (baseline period) for 24 weeks during the intervention period and for 12 weeks after the intervention period (follow-up period). We will also assess the effects of the interventions on secondary outcomes, including patient symptoms, fluid adherence, hemodialysis adherence, quality of life, hospitalization, and mortality (aim 2). The implementation of the interventions will also be assessed (aim 3).

Ethics Approval

This study has obtained institutional review board (IRB) approval for a waiver of informed consent and waiver of Health Insurance Portability and Accountability Act (HIPAA) authorization based on the "no more than minimal risk with potential direct benefits" to patients and the study's pragmatic nature (HUM00125305).

Study Organization and Partners

This study is led by a research team at the School of Information, Medical School, and the School of Public Health at the University of Michigan, Ann Arbor, United States. The study's data coordinating center, based in the Kidney Epidemiology and Cost Center at the School of Public Health, will receive deidentified patient data from a large dialysis provider organization to which all facilities in the study will belong. The National Kidney Foundation (NKF), a partner in the study, created patient educational module content and will recruit and train peer mentors for facilities assigned to the patient activation study arms. The patient activation intervention application used by peer mentors and their patient mentees will be developed by collaborators at the University of California, Irvine and at a telehealth platform company, VSee Inc. Funding for this study has been provided by the Patient-Centered Outcomes Research Institute.

Eligibility and Recruitment of Facilities

A total of 20 hemodialysis facilities were recruited from the following regions in the United States: Midwest, Northeast, Southeast, and Southwest. Facility inclusion criteria were as follows: (1) outpatient hemodialysis facilities, (2) at least 70 adult patients (aged ≥21 years) who were permanent patients at the study facility, (3) not currently involved in another study, and (4) no operational or administrative reasons that would make the trial difficult to implement at that site. Hemodialysis facility staff and providers will not be participants in the research (ie, data will not be collected from or about individual staff to answer the study research questions). Facilities were stratified by county poverty rate and then randomly selected to prevent

XSL•FO
RenderX

one region or arm of the study from having a different socioeconomic status profile than the others.

Eligibility and Recruitment of Patients

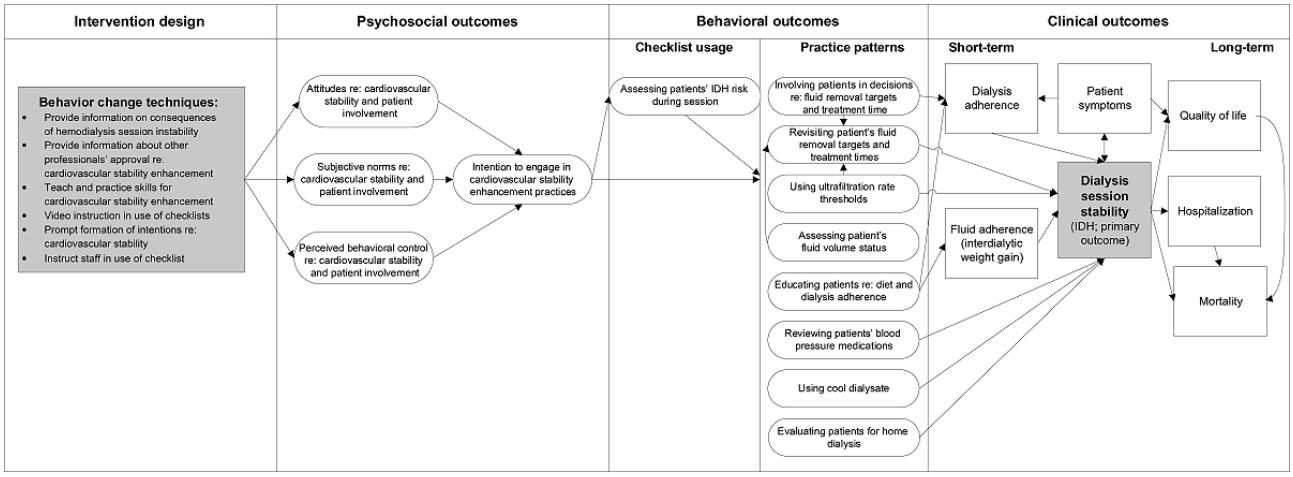
As this is a pragmatic trial, we aim to include all nonvulnerable (see definition of vulnerable below in this section) in-center patients at participating hemodialysis facilities. The trial was designed so as not to exclude any patient, including women and minorities to the extent they are represented at the hemodialysis facilities from the age group of ≥21 years. We will only exclude vulnerable patients, including those below the age of 21 years; prisoners; those with a cognitive barrier; those deemed vulnerable by the clinical manager, medical director, or social worker; and those who are unable to comprehend the patient information sheet because of lack of facility in reading English or Spanish. Following prior pragmatic research in hemodialysis care [33] and the study's IRB review results, the study uses an "opt out" process for using patient clinical data to determine test facility-level and patient-level outcomes. Each patient will have the opportunity to opt out of having their data used in the study for outcome monitoring as part of aim 1 and 2 activities. The University of Michigan will manage the opt-out process and provision of study information remotely with the assistance of facility staff. Each patient will be given an information sheet by dialysis facility staff; these staff will also be provided an IRB-approved script to use when providing patients with the information sheet. Facility staff will record that each patient has received the information sheet and if they have verbalized a decision to opt out of the study. The information sheet will also provide a 1-800 telephone number to call the University of Michigan research team to learn more about the study or opt out of the study at any time if they desire. Patients may opt out of the study at any time, but patients in facilities assigned to the provider intervention arms of the study will still benefit from multimodal provider education as this is a facility-level intervention that does not involve specific patients.

For the patient activation intervention only, we will randomly select patients, in succession, who are not vulnerable or have not opted out of the overall study, until the target number of patients in a facility accept peer mentoring. That is, every time a patient declines to participate, we will choose another patient randomly until the enrollment target is reached. On the basis of prior studies [34-36], we estimated a retention rate of at least 73% for the peer mentoring intervention.

Detailed Intervention Description

Multimodal Provider Education Intervention

As Figure 1 shows, the provider intervention is informed by the Theory of Planned Behavior, commonly used in practice change interventions involving clinicians [37,38], including a study assessing the adoption of a patient safety checklist [39]. Using this model, we predict that changes in perceived behavioral control and behavioral intentions [40,41] resulting from the training will change providers' fluid management practice patterns (including use of the checklist), which will in turn reduce rates of hemodialysis session instability.



There are 2 components to the provider intervention. The first component consists of 4 training modules that will be completed by nurses, patient care technicians, dieticians, and social workers in the study facilities. The goals of these sessions were as follows: (1) to educate facility staff on the risks of IDH, (2) to promote recognition of IDH risk factors and opportunities for prevention and early intervention, and (3) to instruct staff in use of the checklist. Staff training will be implemented by the project coordinators at University of Michigan. It will include 2 self-paced modules available on web through the facility's access to a web-based learning management system and 2 synchronous web-based meetings between the project coordinators and staff at the facilities randomized to receive the provider intervention (Textbox 1 provides an overview of the staff training sessions).

In addition, physicians, nurse practitioners, and physician assistants who are not part of the hemodialysis facility staff, but who round in study facilities, will have access to a 1-hour asynchronous web-based training module. This training program reviews the purpose of the study and its scientific rationale. It also prepares them for potential treatment changes that facility staff, particularly nurses, may discuss with the provider as a result of using the checklist.

The second intervention component is the IDH prevention checklist [27], which will be provided on tablet computers (Figure 2). The checklist aims to identify patients at increased risk of IDH; it is to be completed by a nurse for each patient's hemodialysis treatment with verbal input from the patient and patient care technician as indicated. The checklist has 4 items that may be associated with increased IDH risk: 2 pertaining to the past 5 treatments and 2 pertaining to the current session. If any risk factors are identified, a list of suggestions based on the evidence-based literature on how to prevent IDH will be presented. Suggestions include measures for preventing IDH in the current hemodialysis session (ie, placing the patient in a modified Trendelenburg position) as well as longer-term changes that may require a physician's input (ie, adjusting the patient's estimated dry weight or providing additional counseling on sodium restrictions). The data collected through the checklist will not identify the patient or the staff member, but the use will be automatically logged on a HIPAA-compliant server, including the facility, date, time, items displayed, and items clicked.

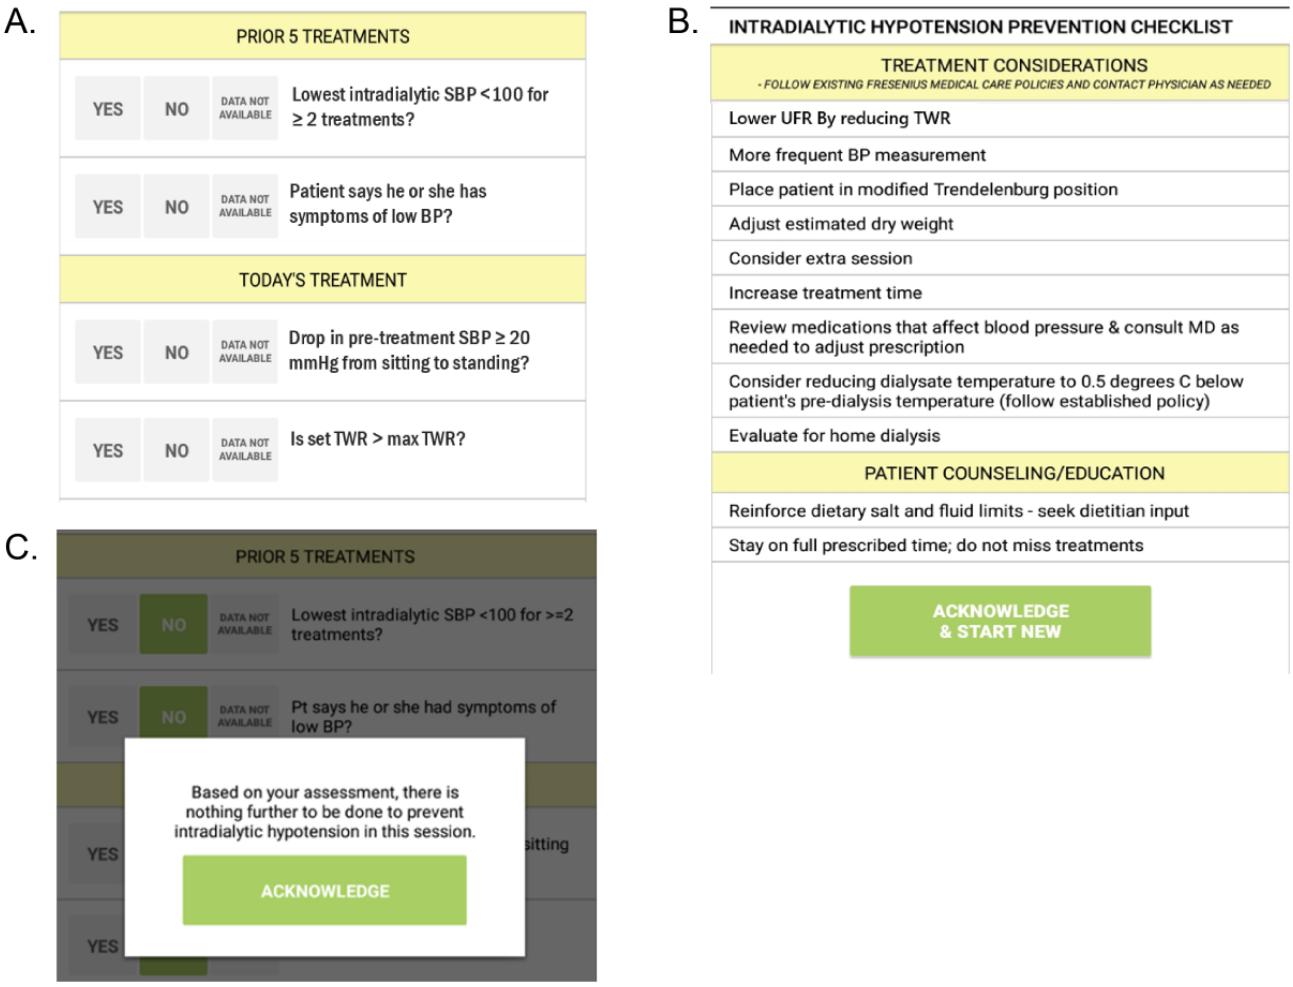
Figure 1. Theory-based model of behavior change for multimodal provider education intervention. IDH: intradialytic hypotension.



Textbox 1. Overview of the staff training intervention.

- The first training is a self-paced module through the learning management system available to the facilities. It will introduce the Dialysafe project goals and study design. Staff will refresh their knowledge on consequences of intradialytic hypotension (IDH) and identify the training requirements of their assigned study group.
- The second training is designed for active participation and discussion from the providers. Staff will consider the most susceptible points in time for patients to experience cardiovascular instability, including IDH. The training will review principles of weight and blood pressure measurement per existing facility policy. The audience will be introduced to how the nurse will use the Dialysafe IDH prevention checklist to systematically evaluate every patient for IDH risk early in the session, and how to make changes to the hemodialysis session if the patient is found to be at risk.
- In the third training, staff will review actions for increasing cardiovascular and hemodynamic stability for patients at higher risk of IDH. Key points of this training include the importance of frequently assessing a patient's dry weight and making changes as necessary, the need to review blood pressure medications, and the use of cool dialysate. These topics are some of the methods that can be used to prevent IDH; providers will also be given time to reflect on and discuss other measures they have found effective. Finally, staff will review their role in IDH prevention and consider times when they might discuss making changes to a patient's hemodialysis sessions. They will also reflect on their experience with the Dialysafe IDH prevention checklist.
- Staff training part 4 is a 15-question multiple-choice quiz hosted on the learning management system.

RenderX

Figure 2. Intradialytic hypotension (IDH) prevention checklist. A) Questions asked at each dialysis session to all patients in clinics assigned to the provider intervention. B) Suggested actions for dialysis care team if any questions from the checklist (A) are answered "yes" or "data not available." C) Screen displayed if ALL questions from the checklist (A) are answered "no ". BP: blood pressure; SBP: systolic blood pressure; TWR: target weight removal; UFR: ultrafiltration rate.

Approaches to Encouraging Participation and Retention for Provider Intervention

Several implementation strategies will be used to promote the successful adoption of the provider intervention. All facilities randomized to this intervention will appoint a *study champion* who will help convey positive messages about the study, including staff training and checklist implementation. Each of these facilities will also form an operations committee, which will include the study champion, an area manager, patients, and others selected to represent different organizational levels and perspectives, as intervention implementation will be enhanced by the early involvement of staff at various levels [42].

Checklists are more likely to be effectively used if accompanied by training that addresses the *why* and *how* questions regarding their implementation [43-46]. Therefore, the second provider training includes how to use the checklist and its associated rationale. The third training includes dedicated time for discussing the ways in which the checklist has or has not been integrated into the facility workflow to promote the sharing of learning and process improvements [47].

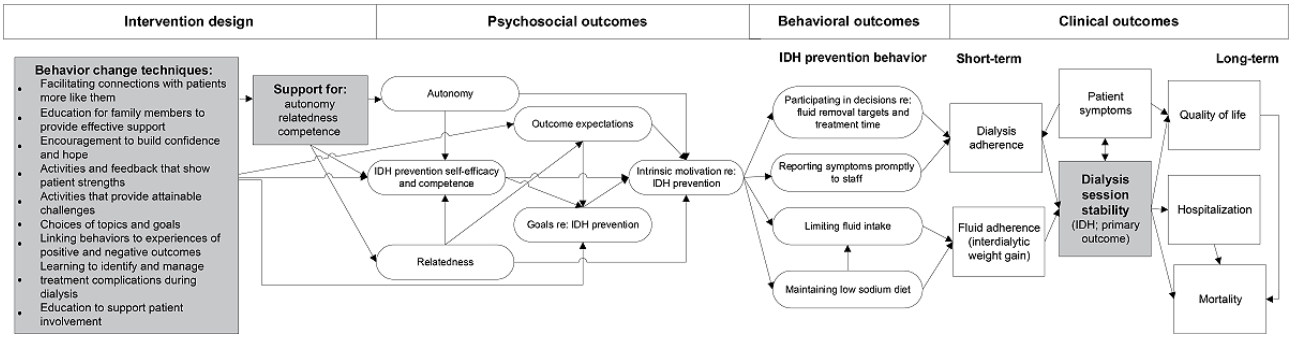
Notably, both components of the multimodal provider education intervention offer incentives for completion. We plan to offer incentives to staff in facilities that consistently use the checklist. For each month of intervention, facilities that achieve a 90% checklist completion rate will be provided lunch. Facilities that achieve a 90% checklist completion rate for the entire study will receive a certificate of recognition that can be posted in an area visible to staff and patients.

Facility-level incentives include the fact that study facilities that participate in trainings 2 and 3 and meet the requirements will receive one "Diamond" toward its 5-Diamond status. The 5-Diamond Patient Safety Program is a national initiative. The 5-Diamond Patient Safety Program was designed to assist dialysis centers with safety standards through continuous learning modules for frontline clinicians. Participating dialysis facilities are required to complete a series of safety modules each year to earn or renew their 5-diamond status, and annual participation in the 5-Diamond Patient Safety Program is already undertaken at all hemodialysis facilities in this study. In addition to the facility's diamond status, nurses and patient care technicians who attend these training sessions will be offered optional continuing education unit credit. Physicians and advanced practitioners will also be able to earn continuing medical education or continuing nursing education credit by watching the 1-hour training video described previously.

XSL•FO
RenderX

Therefore, successful completion of the provider training offers both facility-level and individual-level incentives.

Patient Activation Intervention



The patient activation intervention includes both internet-based educational modules and peer mentoring. Both intervention components were designed using Social Cognitive Theory and Self-determination Theory [28]. Social Cognitive Theory [48-50], an approach with strong empirical support in evidence-based interventions, is a key framework underlying the patient intervention. Social Cognitive Theory emphasizes the predictive power of *self-efficacy*, or confidence in one's ability to perform an action, in the likelihood of performing that action (Figure 3). This theory has led to successful peer-based chronic disease interventions [51,52]. The design of the educational modules is also informed by Self-determination Theory [53], which proposes that people are more likely to engage in a behavior when they are intrinsically motivated to perform it. Intrinsic motivation emerges when one finds an activity enjoyable or satisfying, as is the case when one's psychological needs are met when performing that activity. Self-determination Theory highlights three psychological needs: (1) autonomy (the need to feel in control of one's life), (2) competence (the need to feel effective in dealing with situations one encounters), and (3) relatedness (having meaningful relationships or having a sense of belonging in a community).

The patient activation intervention will be digitally available on tablets shipped to patients for use at home and shipped back to the university upon intervention completion. The patient activation intervention is delivered through 5 modules to be completed roughly 1 week apart from one another. Each module focuses on a different aspect of preventing IDH (Table 1 provides a detailed summary of the module's content and related behavioral goals). Each module includes the following elements: (1) a slide deck presented as an informational video; (2) an optional quiz about the video content; (3) patient experience stories presented as short video clips; (4) a goal-setting feature; (5) the option to view or email supplemental NKF handouts and suggested apps; (6) a peer mentoring session lasting 20 minutes to 1 hour supported by a discussion guide for mentors; and (7) an action plan with patient-identified goals, values, and steps to overcome barriers. The action plans will be completed by the peer mentor and emailed to the patient after the mentoring session. Multimedia Appendices 1 and 2 provide screenshots of the digital modules.

Peer mentoring sessions will be delivered via a secure, HIPAA-compliant videoconferencing platform. The intervention extends an existing peer mentoring program offered by NKF. NKF Peer Mentors are trained patients with ESKD who volunteer to support other patients. Mentors can speak from their own experience about the challenges of life on hemodialysis; thus, patients often view mentors as relatable, credible, and accessible information sources [51,54-56]. Mentors can serve as role models to encourage positive health behavior change as they share their experiences [55]. In this study, mentors will receive additional training on study-specific information and motivational interviewing. Accordingly, during the sessions, peer mentors will use discussion guides that implement motivational interviewing [57] principles based on Self-determination Theory [53]. Motivational interviewing involves encouragement, exploration of feelings, and personalized goal setting. It has been effective across clinical contexts [58-63] including for behavior change [64,65].

NKF is recruiting, training, and supporting mentors for involvement in the study. The mentors will receive study-specific training in addition to standard peer mentor training offered by NKF. Peer mentor training will be divided into 10 self-paced training modules, with one live, internet-based training session for role plays and mentor skill assessment. Training will include information on: (1) the role of the peer mentor; (2) hemodynamic stability; (3) listening and communication skills, including motivational interviewing techniques; (4) sharing experiences and strategies; (5) confidentiality and boundaries; and (6) program logistics such as using multimedia tools, intervention fidelity, and record keeping. After mentors have completed all the training modules, they will be matched with ≥1 mentees who have consented to participate in the program as part of the intervention at their facility.

Figure 3. Theory-based model of behavior change for patient intervention. IDH: intradialytic hypotension.

XSL•FO
RenderX

Table 1. Interactive education modules for patient intervention.

Topic	Content	Behavioral goals
Getting enough dialysis	• How dialysis makes patients feel better • Importance of removing fluid and preventing fluid overload	• Attending dialysis sessions for the full length of time • Understanding benefits of attending lengthened or supplemental dialysis sessions as needed • Identifying values that will help with goal setting
Feeling better with less salt or sodium	• Why people on dialysis need a low-sodium diet • How to read a food label • Examples of low and high sodium foods	• Maintaining a diet that is low in sodium • Tracking sodium intake
Making fluid restrictions work for you	• Why people on dialysis need to limit fluid intake • Ways to decrease thirst and track fluid intake	• Maintaining a level of fluid intake that will optimize interdialytic weight gain • Becoming aware of usual interdialytic weight gain • Tracking fluid intake • Discussing symptoms of fluid overload with the dialysis team • Discussing the need for longer or extra sessions if experiencing fluid overload symptoms
Feeling better on dialysis and having easier sessions	• Strategies to prevent low blood pressure and other symptoms of fluid removal • Steps to correct low blood pressure • Why it is helpful to check blood pressure at home	• Recognizing symptoms of IDH[a] • Reporting IDH symptoms and episodes to staff • Tracking blood pressure at home • Notifying staff of changes in true body weight
Getting more involved in your care	• Patient roles and responsibilities as a member of the health care team • Roles and responsibilities of other dialysis team members	• Actively participating in decisions with providers regarding fluid removal targets, ultrafiltration rates, and treatment times • Asking questions of the dialysis team relevant to session stability • Share concerns related to health and care, emotional well-being, and upcoming procedures with the dialysis team

[a]IDH: intradialytic hypotension.

Approaches to Encouraging Participation and Retention for Patient Intervention

Although participant retention is an issue in virtually any trial, patients on hemodialysis are likely to experience fatigue, pain, and other symptoms; thus, there is a greater than average risk of patients not completing the intervention. Therefore, we will offer incentives [61] for both mentors and mentees to encourage completion of all 5 peer mentoring sessions. Mentors will receive US $100 per patient with whom they work and US $15 for completion of the peer mentoring satisfaction survey. Mentees will receive a total of US $120 for completing the entire mentoring program and peer mentoring satisfaction survey. Although mentors will be paid upon completion of the mentoring sessions, mentees will be paid on a per-session basis at an escalating rate (US $10 for session 1, US $15 for session 2, US $20 for session 3, US $25 for session 4, and US $50 for session 5 and completion of the satisfaction survey).

In addition, we will use several general evidence-based retention strategies: issuing reminders before a scheduled mentoring session [66], monitoring satisfaction with the study [67] via the planned peer mentoring survey (Multimedia Appendix 3 provides the survey instruments), and keeping the response burden for patient data collection very low [68].

Data Collection

For aim 1 and 2 activities, most of the data used in this study are already routinely documented within the electronic health record of participating hemodialysis facilities. Additional information gathered during this study will be minimal because of the study's pragmatic nature.

Primary Outcome

Our primary outcome is hemodialysis session stability, specifically IDH, which is measured every session using blood pressure cuffs worn by patients. The primary indicator of IDH, based on direct blood pressure measurements after the start of the session, will be sitting systolic blood pressure (SBP) falling below 100 mm Hg (using the lowest SBP during the session) if starting SBP ≥100 mm Hg.

Secondary measures of IDH based on direct blood pressure measures will include the lowest (minimum) valid SBP below 100 mm Hg during the session if starting SBP is ≥100 mm Hg; the number of SBP measurements <100 mm Hg (using raw blood pressure measures, time of blood pressure measurement, and starting SBP) if the starting SBP is ≥100 mm Hg; and whether the sitting SBP falls below 90 mm Hg (using the lowest SBP during session) if starting SBP ≥100 mm Hg.

Justification of Selection of Primary Outcome

IDH is linked to symptoms such as cramping, dizziness, vomiting, fainting, and fatigue [4,12,13,69] and increased risk of other outcomes important to patients including cardiovascular disease [70], hospitalization [71], and mortality [72-74]. IDH is a top-10 priority outcome (of 33 ranked) for patients on hemodialysis [75]. Patients express concern about the receipt of insufficient hemodialysis or administration of fluids in cases of IDH [69].

XSL•FO
RenderX

There is a lack of consensus on IDH definitions; however, for the purposes of this study, we use the threshold of SBP <100 mm Hg. As documented in the literature, a drop in SBP to <100 mm Hg is associated with a higher probability of patient-reported negative symptoms [76]. Even in asymptomatic events, intervention at this threshold has the potential to prevent repetitive multi-organ tissue ischemia [77] and further decline to dangerously low levels of SBP <90 mm Hg [71,72]. A lower threshold (eg, SBP <90 mm Hg or the occurrence of symptoms or clinical interventions) would not be appropriate for this study as we aim to prevent organ damage and negative patient experiences [5].

Secondary Outcomes

The patient-centered secondary outcomes are described in the following subsections.

Interdialytic Weight Gain

Facilities record this measure of fluid gain between hemodialysis sessions by measuring the difference between patients' pre- and posthemodialysis weights at each hemodialysis session. This outcome is important to patients as high fluid gains are linked to symptoms such as bloating and shortness of breath [78]. High fluid gains are associated with fluid overload, which is a leading cause of hospitalizations in patients on hemodialysis [79,80]. High fluid gains are also associated with mortality risk, particularly from cardiovascular causes [81,82]. Interdialytic weight gain is a top-20 priority outcome (of 33 ranked) for patients on hemodialysis [75].

Hemodialysis Adherence

Facilities routinely collect data on hemodialysis adherence [83]. We will use 3 measures: number of minutes of prescribed hemodialysis time missed per week, number of missed sessions per week, and total missed session time.

Patient Symptoms

Symptoms during the hemodialysis session are a priority outcome for patients [84]. Symptoms such as severe fatigue and cramping are reported in 50% and 30% of hemodialysis sessions, respectively [4]. We will create a patient symptom burden measure combining symptom frequency and severity for each of the following symptoms that are often indicative of IDH, if they occur during or after the hemodialysis session (not prehemodialysis): nausea, vomiting, abdominal pain, dizziness, muscle cramps, headache, chest pain, shortness of breath, palpitations, diaphoresis, and blurred vision. Patients may report symptoms to the dialysis team or nurses to assess symptoms at each hemodialysis session and document them at that time. We will also add the symptoms listed on the Kidney Disease Quality of Life survey to the patient symptom burden measure. We will also calculate the proportion of sessions with each symptom using date and time of session.

More than 40% of patients feel that they have not fully recovered even after returning home after hemodialysis [4]. As an indicator of both fatigue and energy and hemodialysis-free time, this is one of the most important outcomes to patients on hemodialysis (first and fourth of 33 ranked) and more important to patients than to health care providers [75,85]. Therefore, two additional questions will be answered in the electronic health record documentation during the midweek hemodialysis session for all patients in the study:

1. After your last dialysis session, how long did it take you to recover enough to do the things you normally do on a nondialysis day?
2. Did the patient make a request today regarding their fluid removal goal?

The first question was created in consultation with the dialysis provider's patient advisory committee and our study's patient partners and builds on past research [86]. Responses to this question will also be used as a secondary outcome for patient symptoms alone and in combination with the patient symptom burden measure described earlier.

Health-Related Quality of Life

This important patient-reported outcome [87] will be measured before and after the intervention. Health-related quality of life is a longer-term measure that reflects symptom patterns and other key life dimensions, including physical functioning, emotional well-being, pain, and energy levels [88]. The suffering represented by low health-related quality of life predicts outcomes that matter to patients, including hospitalization [89] and mortality [89,90].

We will use the 36-item Kidney Disease Quality of Life (KDQOL-36 version 1) [91,92], which has good internal consistency based on α scores [92]. This instrument is required annually for all patients on hemodialysis in the United States [93]. The KDQOL results will be provided twice for each patient from the following surveys: (1) the latest survey within 12 months before the start of the study intervention and (2) the earliest survey within 12 months after the start of the intervention.

Hospitalizations

We will gather these data from the facility's records for all patients within the study period. Hospitalizations represent a period of heightened symptoms and lost functioning among patients; patients describe hospitalizations as extremely distressing, and they are a top-21 priority outcome for patients on hemodialysis (of 33 ranked) [75].

Secondary analyses of these data will assess hospitalizations by cause using hospital discharge diagnosis (eg, fluid-related or cardiovascular causes, COVID-19), number of hospitalizations per patient, and length of hospitalization.

Mortality

This has been provided as a key example of a patient-centered outcome [87] and will be gathered from the facility's patient records.

Aims 1 and 2: Supplementary Data Collection

Practice Patterns Survey

In keeping with the precedent set by the International Dialysis Outcomes and Practice Patterns Study [94], in which several of our team members were involved, we will use practice patterns [94] surveys (Multimedia Appendix 4). These will be

XSL•FO
RenderX

delivered at all study facilities during the facility preparation period before the intervention starts and again at the end of the 24-week intervention period. These surveys will also serve as manipulation checks [95] that will allow us to determine whether practice changes occurred at intervention sites while not occurring at the no intervention sites. Accordingly, the survey results will allow us to assess whether the interventions worked as intended. Surveys will be provided to both the nurse manager and the medical director.

Peer Mentoring Satisfaction Survey

After the 5 mentoring sessions, both mentees and mentors will receive a satisfaction survey (Multimedia Appendix 3). The results will be analyzed to identify mentees' experiences with the multimedia educational modules and peer mentoring and the mentors' experiences with the digital tools, training, and support. We will share the aggregate results with NKF so that they can make program adjustments if needed.

Aim 3: Data Collection for Assessment of Intervention Implementation

Aim 3 activities will seek to identify variation in implementation approaches adopted within different study facilities and to characterize differences in intervention acceptance and workflow integration. These analyses will help with understanding any potential differences in intervention effects between sites and with identifying and responding to any emergent implementation challenges throughout the trial. We will collect implementation data in all intervention facilities. Data collection activities will not require additional meetings; study staff at University of Michigan will gather data from provider intervention training parts 2 and 3 (10 facilities) and operations committee meetings (15 facilities). No audio or video recordings will be made of any of the meetings or sessions.

At the provider intervention training sessions, UM study staff will take descriptive field notes. The study staff will inform attendees that they will take notes, the purpose of the notes, and that comments made during meetings may be tied to a staff member's role; however, staff names will not be recorded. The field notes will document the following:

1. Staff questions during the sessions.
2. Staff members' stated reactions to the interventions.
3. Discussions in which the staff talk about their plans for, and experience with, integrating the provider intervention into their workflows.

To assess usability of the checklist and patient intervention technologies, we will analyze use data, with attention to compiling the following metrics: (1) time spent on each page, (2) number of abandoned checklist sessions and videoconferencing or patient education module sessions, and (3) pages and click-through patterns preceding abandonment. We will present and discuss these data in operations committee meetings. We will also record any staff comments and concerns about the checklist.

The operations committee meeting agendas will also include a small number of questions directly related to study intervention implementation (Multimedia Appendix 5). UM study staff will record answers in descriptive field notes. These questions will be for facility staff, and study staff will ask them after patient representatives have left the meeting.

Data Analysis

Statistical Power

We calculated the statistical power for the study for the primary outcome of hemodialysis session stability. We assumed that a minimum of 60 patients on hemodialysis will be observed for at least 60 hemodialysis sessions and the primary outcome will be the proportion of unstable sessions, which we treat as a continuous variable. We assume that these proportions among patients in a facility are normally distributed with mean 0.20 in the control group and mean between 0.16 and 0.17 in the intervention group (a difference *d* of 0.034-0.043), with SD (or *sigma*) assumed to be in the range of 0.08-0.10. We conservatively assume 60 patients per facility (ie, a total of 60 × 20 facilities=1200 patients). The power calculation is robust to changes in number of patients (m), as the calculation of K (number of clusters) only increases by ~1 if m is increased to 90 [96]. We assume the intraclass correlation coefficient for hemodialysis facilities to be 0.10. We also assumed a significance level of 0.05 in all calculations. If the SD is as large as 0.10, we can detect a difference of 0.043 (ie, 20% vs 16%) with 81% power. In other words, if the smallest variance estimate is correct (sigma=0.08), we have 91% power to detect a 4% difference and 80% power to detect a 3% difference (Table 2).

Table 2. Power to detect difference in intradialytic hypotension (IDH) rates. The power is shown to detect a difference in IDH rates (D) between groups with at least (k) number of facilities, assuming 2 possible SDs (sigma).

Detectable IDH rate difference, D	SD, sigma	Number of facilities, k	Power, %
0.034	0.08	10	80
0.034	0.10	10	61
0.040	0.08	10	91
0.043	0.10	10	81

Overall Analytical Approach

Our 2 × 2 factorial trial is designed to answer the following four treatment comparison questions (Table 3):

1. Provider education versus no provider education (assumes no interaction between the interventions)

Cells ([A+B] vs [C+D])–*F* test comparison

XSL•FO
RenderX

2. Peer mentoring versus no peer mentoring (assumes no interaction between interventions)

Cells ([A+C] vs [B+D])–*F* test comparison

Note that all data will be reused in the comparisons for 1 and 2. This shows a key advantage of the 2 × 2 design: it allows testing 2 interventions for the "price of one." Furthermore, if an interaction is observed (question 4 below), then the effect of one intervention can be estimated at each level of the other intervention.

3. Comparative effectiveness of provider education alone versus peer mentoring alone

B versus C–*F* test comparison. The head-to-head comparison of the magnitude of effect for the 2 interventions is actually comparing only the interventions alone, in the absence of the other ones.

4. Are there synergistic or antagonistic effects between the provider education and peer mentoring interventions?

The purpose of this test is to determine whether the effect of one intervention differs depending on the presence of the other intervention. The test compares:

- Cells ([A−C]−(B−D)]–*F* test comparison to examine the effects of provider education intervention with and without the presence of the patient activation intervention.
- This is equivalent to ([A−B]−[C−D]), which examines the patient activation intervention with or without provider education.

Table 3. A 2 × 2 factorial trial design with facility and patient sample sizes for treatment comparisons.

	Patient activation intervention, number of facilities (number of patients)		Total, number of facilities (number of patients)
	Yes	No	
Provider education			
Yes	A—5 (300)	B—5 (300)	10 (600)
No	C—5 (300)	D—5 (300)	10 (600)
Total	10 (600)	10 (600)	20 (1200)

This interaction test will provide power to detect strong synergistic or antagonistic effects. It is a statistically efficient approach valuable for studying health care interventions, where rigorous evaluation is typically expensive [97].

Aim 1 Analyses

For aim 1, the outcome is a dichotomous measure of hemodialysis session stability. This outcome will be collected through digitally recorded blood pressures in all hemodialysis sessions of all patients at each facility who have not opted out of the study during the study period. For the continuous outcome measure of the proportion of unstable sessions, we will use linear mixed models to compare individuals in facilities in the 2 treatment arms to individuals in the nonintervention facilities. Random effects for facility clustering will be accounted for using the MIXED procedure in SAS (SAS Institute). As a sensitivity analysis, we will also examine hemodialysis session stability as a dichotomous (yes or no) variable and analysis will be carried out on the longitudinal data set using logistic regression with a random effect for both patients and facilities, using the GLIMMIX procedure in SAS. The random effects will model the correlations among the measurements at each level.

Three secondary analyses are planned for this aim. The first will test the treatment effects in a similar model but adding adjustment for any covariates found to be unbalanced between treatment groups in preliminary analyses. The next secondary analysis will test the interaction between the 2 interventions to detect a possible synergistic or antagonistic effect. The third will be a secondary analysis of patient proportion with IDH before versus after the intervention phase to test whether the intervention effects are maintained. The basic analysis is a paired comparison of percentage of IDH before versus after the intervention phase begins, with adjustments for length of intervention phase (24 wks) and follow-up phase (12 wks).

In additional sensitivity analyses, we will examine the effect of patient compliance and noncompliance rates (ie, the percentage of patients who accept peer mentoring and checklist adherence for provider intervention) on the results. The sensitivity analyses aimed to assess the robustness of the conclusions based on the analyses of the primary outcome, specifically to determine whether the findings hold under different methods of defining the primary outcome. Thus, we will conduct sensitivity analyses for the secondary measures of session instability described in *Data Collection* section. As part of this, because we will know the dates and causes of hospitalizations and death by cardiovascular- or fluid-related causes, we will identify those events that took place on days in which dialysis was administered. Accordingly, we will conduct a sensitivity analysis of the primary outcome of dialysis session stability both with, and without, those events on dialysis days included. For the primary outcome analyses, we will also conduct a sensitivity analysis without the sessions of patients who begin that session with a sitting predialysis SBP of 100 to 110 mm Hg and whether the sitting SBP falls below 90 mm Hg (using the lowest SBP during session) if starting SBP ≥100 mm Hg.

Aim 2 Analyses

Aim 2 incorporates 6 secondary outcome measures, which we will analyze at the individual level and summarize at the facility level. The interdialytic weight gain, symptom and quality of life analyses, based on continuous outcome measures, will be carried out using mixed models (the MIXED procedure of SAS). Note that the quality of life analyses will be based on data from 2 time points, one before intervention and one during the intervention, rather than session-specific data as analyzed for

XSL•FO
RenderX

the other outcomes. Analyses of missed or shortened hemodialysis sessions will use logistic regression for longitudinal data. Analyses of hospitalizations and mortality will use logistic regression for the individual-level data. As part of these models, we will test IDH-related variables (eg, recent IDH and frequency of IDH in the past month) as potential predictors. In addition, we will conduct as-treated analyses for the peer mentoring intervention whereby only patients who received peer mentoring are compared with patients in the other treatment arms, with adjustment for the same factors as in the intent-to-treat analyses.

Aim 3 Analyses

Field notes compiled from provider training sessions 2 and 3, as well as the operations committee meetings, will be used to identify and understand barriers to implementing the interventions. Using NVivo (QSR International) qualitative data analysis software, we will also analyze data thematically [98] to identify and explain the types of implementation barriers and facilitators. We will use these qualitative analyses as supplementary explanations as we seek to explain the results of the trial, especially if there are differences in effectiveness between facilities implementing the same interventions. If necessary, modifications will be made while the trial is ongoing.

Heterogeneity of Treatment Effects and Mediation Analyses

The primary analysis will examine average treatment effects, but we will also examine the heterogeneity of treatment effects (HTE) on IDH rate for a variety of covariates, particularly those that are characterized by differential outcomes among patients on hemodialysis. Covariates of interest include demographics such as age, race [99], level of education [99], literacy, presence of comorbidities, and heart rate variability. Supporting these HTE analyses, greater benefits from peer mentoring for African Americans were found in a trial conducted by our advisory partner, the Michigan branch of the NKF [34]. Depending on the sample size obtained for each of the covariates of interest, either a subgroup analysis or an analysis including interaction terms will be used to examine HTE. Only two-way interactions between the treatment indicator and each of the covariates will be analyzed.

The second part of these analyses aims to identify mechanisms of action for the interventions, such as changes in patient or practitioner behavior and session characteristics; these changes in behavior will identify important pathways for improvement in reducing IDH. However, these analyses are not intended to be used for causal inferences. Each potential mediator (Textbox 2) will be tested separately, without adjusting for other mediators, although associations between mediators can be assessed separately for improved interpretation.

XSL•FO
RenderX

Textbox 2. Potential mediators of dialysis session stability.

Patient-level variables

- Patient session instability prevention behavior
- Fluid management practice patterns
- Number and categories of medications patient is taking
- Fluid adherence (interdialytic weight gain)
- Dialysis adherence
- Patient symptoms (burden and recovery time)
- Hospitalizations for cardiovascular or fluid-related causes
- Quality of life

Session level variables

- Treatment time delivered
- Average session ultrafiltration rate
- Use of cool dialysate
- Use of sodium modeling
- Use of ultrafiltration modeling
- Ultrafiltration variability for the whole session, or until intradialytic hypotension incident
- Sitting-to-standing change in systolic blood pressure (SBP)
- Starting SBP
- Slope of changes in SBP over the whole session, or until intradialytic hypotension incident
- Values and times of lowest and highest SBP readings during session
- Patient request regarding fluid removal
- Fluid adherence (interdialytic weight gain)
- Previous achievement of postdialysis target weight
- Previous session instability

Results

This study began enrolling participants in early 2020 but was paused during the COVID-19 pandemic. The study began in May 2022, and the first facilities began enrolling patients in January 2023. Intervention start dates will be staggered such that 4 facilities (1 from each intervention arm) start at once, while the next 4 facilities will begin preparation to join the study. The first 8 facilities will complete the intervention and follow-up data collection period in November 2023. The remaining 12 facilities will begin on a staggered timeline with follow-up data collection ending in November 2024.

Discussion

Principal Findings

The enhancement of the hemodynamic stability of hemodialysis is a critical concern for clinicians owing to study findings about the problem of hemodialysis-induced cardiovascular harm [20,100] and owing to vociferous calls for reform in fluid management practices in hemodialysis care [101-104]. A consensus statement from Medical Directors of United States hemodialysis facilities reflects this concern [22].

However, with a lack of clear guidance regarding hemodynamic stability enhancement, approaches to hemodynamic stability in hemodialysis care are variable. The current practice includes educating patients regarding appropriate fluid intake, individualized treatment targets and fluid removal goals, regular monitoring and assessment during dialysis treatments, regular medication reviews, intervening as IDH emerges, and management of emergent symptoms. However, there are also wide facility-level variations in IDH rates, demonstrating the ability of practice patterns to influence cardiovascular session stability. For instance, IDH prevalence varied between 11.1% and 25.8% in a study of 13 US facilities [11]. In that study, it was demonstrated that facility was also a significant predictor of IDH with odds ratios between 0.608 and 1.468 after adjustment for patient characteristics.

Although the high prevalence of dialysis instability demands change, hemodialysis providers lack critical guidance for preventing IDH in usual practice. Our evidence-based approach contends that to prevent unstable hemodialysis sessions, optimal fluid management must be at the forefront of typical care practices. In line with a growing body of evidence, we support gentle adjustment of posthemodialysis target weights and prolongation of treatment time prescriptions, regular assessment

XSL•FO
RenderX

of patient fluid volume status, lower UFR (preferably <10-12 mL/kg/hr), and early intervention if a patient begins to show signs of instability. We do so while continuing to emphasize lower interdialytic weight gain and a low-sodium diet to reduce thirst, and thus fluid intake [83,105-109]. We also promote use of interventions such as use of cool dialysate, blood pressure medication review, and evaluation of patients for home dialysis, as appropriate (Figure 1). To facilitate this fluid management–focused practice, our intervention translates successful patient safety interventions and patient behavior interventions from inpatient and chronic disease care settings, respectively, to the outpatient hemodialysis context.

Novelty of This Study

Although checklists for patient safety have been growing in popularity in health care organizations in the United States and internationally, they have primarily been used in inpatient settings, particularly surgery [110-112] and critical care [113,114]. However, a recent trial on a checklist for hemodialysis care infection control [115,116] and another recent pilot in Canada [117] illustrated that hemodialysis care is an outpatient context that is well suited for checklist implementation. When combined with staff training, our novel application of checklists to hemodialysis care makes it an innovative and promising approach to care improvement.

Patient involvement in safety is encouraged by national and international stakeholder organizations [118-121]. Patient involvement is particularly promising in the context of efforts to improve hemodialysis session stability because patients already make daily decisions such as how much sodium and fluid to consume and whether to shorten or skip hemodialysis sessions—often without realizing the corresponding cardiovascular and hemodynamic stability implications. However, few studies to date have examined the potential for patient involvement in the prevention of hemodialysis session instability as a complication of hemodialysis care [119,122].

Outside hemodialysis care, practices designed to encourage patient involvement in the prevention of health care complications have seen mixed success in producing behavior change [123]. This is likely because of lack of education and support in prior initiatives [124-126]. Furthermore, prior efforts have been rarely grounded in validated theories of behavior change [123], relying instead on simple information provision, such as personalized care records [127] and verbal or written instruction [128-130]. Rarely have interventions explicitly used health behavior change theory, a component of our evidence-based intervention that increases its likelihood of success. Furthermore, although multimodal engagement strategies have been advocated [131], no intervention trial has examined the potential for patients to assist each other in preventing health care complications.

Supporting a peer-based approach to promoting hemodialysis session stability, there has been growing interest in peer-based health care approaches as trials have shown benefits in health outcomes [125-128] and behavior [129-131]—including complex health behaviors relevant to IDH, such as diet change [128,132]. Therefore, through an innovative application of peer mentoring, we aim to support the cardiovascular and hemodynamic stability of hemodialysis by helping patients become more actively engaged in treatment and self-care decisions that affect their cardiovascular well-being. We will address patients' frequent lack of information to help them meaningfully participate in hemodynamic stability–related decisions such as fluid removal targets, session length, and frequency. Our preliminary studies showed that some patients already try to influence their treatment targets and speed to reduce distressing symptoms and that patients with ESKD share strategies for making hemodialysis more tolerable [132]. Trained peer mentors are in an excellent position to provide this information systematically and in a manner that is accessible, actionable, and influential. Thus, our innovative approach meets important patient needs while enhancing the likelihood of success in mobilizing patients to engage in behaviors that will increase hemodialysis session stability.

Study Limitations

The study is being conducted in the United States in collaboration with one large hemodialysis facility chain. Although this may limit generalizability, we note that hemodialysis care in the United States is predominately provided by 2 large facility chains, one of which is a study partner. This study partner has >2000 facilities, which suggests the potential for substantial reach if the intervention proves successful. Study facilities were stratified by region and county poverty level, ensuring representation of facilities from 4 US regions and varied patient populations in the study. Furthermore, this study, as with other pragmatic trials, is dependent on care providers' data entry as part of routine care. In an effort to support completeness of study data, some training of staff in data collection will be undertaken as part of the facility staff onboarding process. This study will leverage a robust data infrastructure used for ongoing clinical trials.

Conclusions

The effects of provider and patient education on patient-centered clinical outcomes will be analyzed, and the findings will be used to inform further improvements in patient care. Improving the hemodynamic stability of hemodialysis sessions is a critical concern for clinicians and patients, and educating providers and patients is predicted to lead to improvements in patient health outcomes and quality of life.

Acknowledgments

This work is funded by the Patient-Centered Outcomes Research Institute (Research award IHS-1503-27848).

Abstract

Background: According to Europe’s Beating Cancer Plan, the number of cancer survivors is growing every year and is now estimated at over 12 million in Europe. A main objective of the European Commission is to ensure that cancer survivors can enjoy a high quality of life, underlining the role of digital technology and eHealth apps and tools to achieve this.

Objective: The main objective of this study is the development of a user-centered artificial intelligence system to facilitate the input and integration of patient-related biopsychosocial data to improve posttreatment quality of life, well-being, and health outcomes and examine the feasibility of this digitally assisted workflow in a real-life setting in patients with colorectal cancer and acute myeloid leukemia.

Methods: A total of 60 patients with colorectal cancer and 30 patients with acute myeloid leukemia will be recruited from 2 clinical centers: Universitätsmedizin der Johannes Gutenberg-Universität Mainz (Mainz, Germany) and IRCCS Istituto Romagnolo per lo Studio dei Tumori “Dino Amadori” (IRST, Italy). Psychosocial data (eg, emotional distress, fatigue, quality of life, subjective well-being, sleep problems, and appetite loss) will be collected by questionnaires via a smartphone app, and physiological data (eg, heart rate, skin temperature, and movement through step count) will be collected by a customizable smart wrist-worn sensor

XSL•FO
RenderX

device. Each patient will be assessed every 2 weeks over their 3-month participation in the ONCORELIEF study. Inclusion criteria include patients with the diagnosis of acute myeloid leukemia or colorectal cancer, adult patients aged 18 years and older, life expectancy greater than 12 months, Eastern Cooperative Oncology Group performance status ≤2, and patients who have a smartphone and agree to use it for the purpose of the study. Exclusion criteria include patients with a reduced cognitive function (such as dementia) or technological illiteracy and other known active malignant neoplastic diseases (patients with a medical history of treated neoplastic disease are included).

Results: The pilot study started on September 1, 2022. As of January 2023, we enrolled 33 patients with colorectal cancer and 7 patients with acute myeloid leukemia. As of January 2023, we have not yet started the data analysis. We expect to get all data in June 2023 and expect the results to be published in the second semester of 2023.

Conclusions: Web-based and mobile apps use methods from mathematical decision support and artificial intelligence through a closed-loop workflow that connects health professionals and patients. The ONCORELIEF system has the potential of continuously identifying, collecting, and processing data from diverse patient dimensions to offer health care recommendations, support patients with cancer to address their unmet needs, and optimize survivorship care.

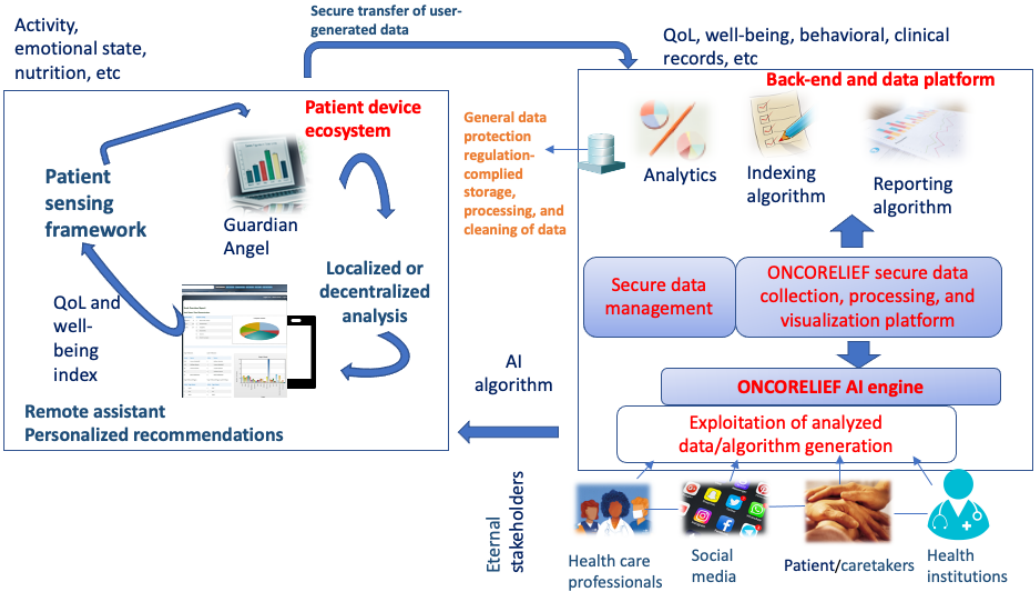
Introduction

Background

Cancer is the second leading cause of death worldwide, and 10 million deaths in 2020 were attributed to cancer [1]. In 2020, a total of 2.7 million people in the European Union were diagnosed with cancer, and another 1.3 million people lost their lives to it, including over 2000 young people [2].

According to the Europe's Beating Cancer Plan, the number of cancer survivors is growing every year and is now estimated at over 12 million in Europe [3]. The Europe's Beating Cancer Plan aims to ensure that patients with cancer, survivors of cancer, their families, and caregivers can enjoy a high quality of life (QoL), highlighting the role of digital technology and eHealth app and tools to achieve this objective. In the last decade, there has been an increasing use of eHealth (ie, the broad use of health information and communication technologies and networks to enhance patient-centered care delivery) in the delivery of patient-centered cancer care [4,5]. Among the tools that have been used are smartphone apps, wearable devices, SMS text messaging, and internet-delivered interventions [5]. However, there has been little use of artificial intelligence (AI) in psycho-oncology research.



ONCORELIEF is a European project funded by EU Horizon 2020 (grant 875392) whose main objective is the development of a user-centered AI system to facilitate the input and integration of patient-related biopsychosocial data to improve posttreatment QoL, well-being, and health outcomes. Measurable parameters include patient-reported outcomes about their unmet needs (eg, emotional distress, fatigue, sexual problems, and sleep quality), physiological data monitored by a wearable device (eg, heart rate and skin temperature), and demographic and health status data from medical records. This objective is achieved by establishing a workflow that connects health professionals and patients by means of assisting digital solutions.

Concept and Study Architecture

The way that the connection between health professionals and patients is done is presented in Figure 1, which illustrates the concept and architecture of ONCORELIEF with its 5 technological components: the Guardian Angel app, the back-end and data platform, the Big Data and AI engine, the QoL and well-being index, and the sensing framework.

XSL•FO
RenderX

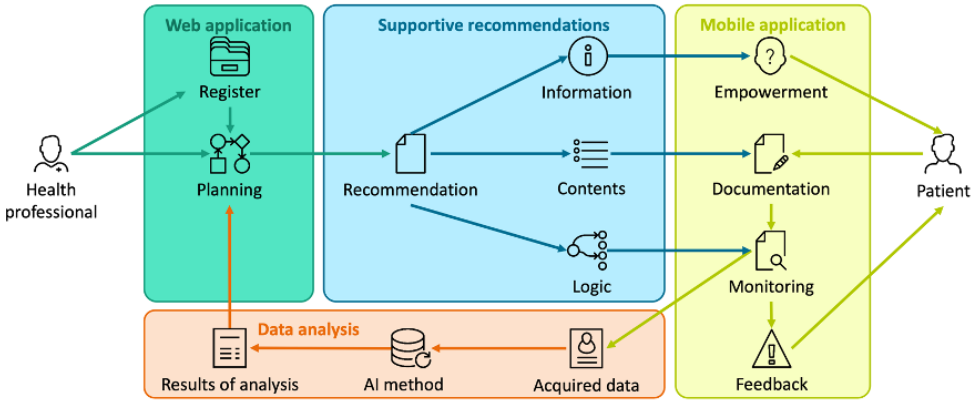


Figure 1. ONCORELIEF concept and architecture. The 5 main technological components of ONCORELIEF are the Guardian Angel—this is an app, compatible with portable devices operating with iPhone operating system and Android built upon the AI models generated by the ONCORELIEF platform; the back-end and data platform—this is where all the data are collected, processed, and used to deliver the services of the ONCORELIEF platform; the Big Data and AI engine—this resides on top of the back-end platform and exploits the insight derived from the analyses of the data as well as it is responsible for the interaction with the users of the Guardian Angel; the QoL and well-being index—this is used to monitor the QoL and well-being status and progress of the different users; and the sensing framework—this is the unobtrusive and pervasive, wearable, and embedded sensing ecosystem of the patient for data collection. AI: artificial intelligence; QoL: quality of life.

Novelty of the Study

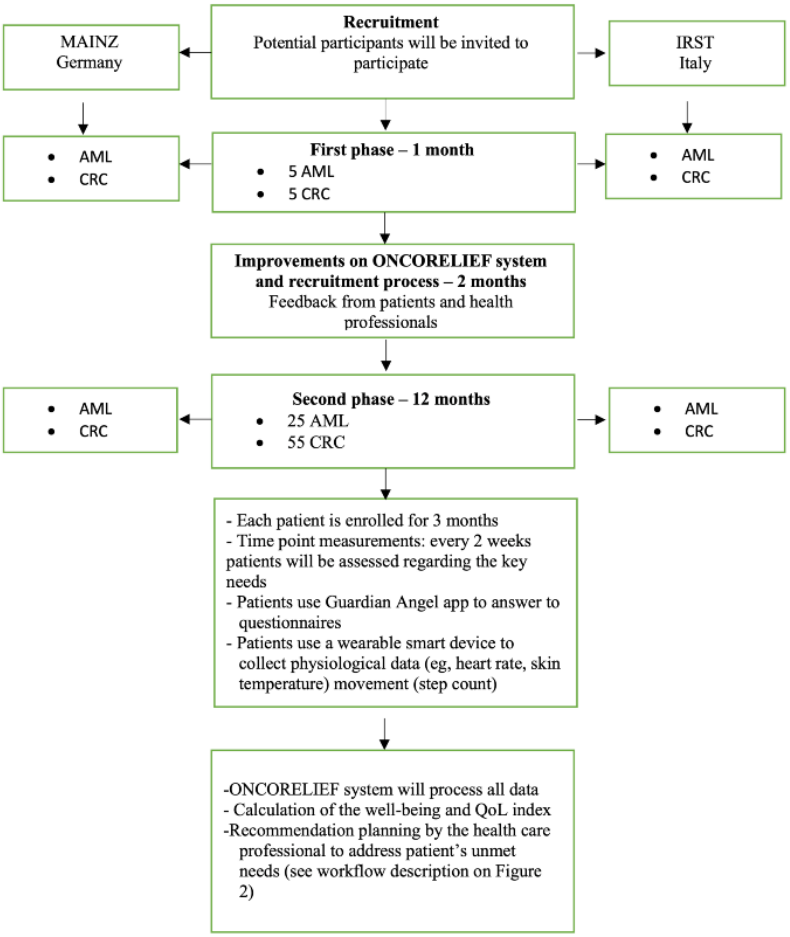
A main innovation of ONCORELIEF is that all data will run on a digitally assisted workflow of posttreatment supportive patient care supported by an AI system (see Figure 2) [6]. This workflow comprises the planning of supportive recommendations with a web-based app by the health professional, the documentation and monitoring of recommendations with a mobile app by the patient, and analyzing the AI-based data of the achieved progress as preparation for the next planning step.

Figure 2. General AI solution approach with the core components and main information flows. The thick arrows indicate the main process steps of the approach. (Icons: Line icons [iconsmind.com] and Windows 8 icons [icons8.com]). AI: artificial intelligence.

The specific realization of this approach depends on the circumstances of the application scenario, such as the preferred level of detail of the recommendations, the information contents of the acquired data, and the amount of reference data available for the training of AI methods. The realization would feature a provision of suitable supportive recommendations by the register, adequate concepts for their documentation and monitoring, and an appropriate selection of AI methods for data analysis. In this sense, the ONCORELIEF pilot study features text-based informative recommendations, the documentation of recommendation outcomes with standardized health questionnaires and vital parameter data measured with wearable sensor devices, and a data analysis with methods from statistics and statistical learning such as automated classification and artificial neural networks, respectively.

The ONCORELIEF pilot study is designed with the aim to examine the feasibility of this digitally assisted workflow in a real-life setting on 2 quite different types of cancer: colorectal cancer and acute myeloid leukemia. These represent cancers with different biological characteristics, different treatment pathways, and specific patient needs [7-10]. In this paper, we describe the study protocol of a multicenter pilot study. There

XSL•FO
RenderX



are four key questions to be examined: (1) It is feasible to assess the unmet needs of patients with cancer, after-treatment, through questionnaires included in a smartphone app (ie, Guardian Angel)? (2) It is feasible to collect physiological (eg, heart rate) and behavioral (eg, movement through step count) data from a wearable smart device connected with the app? (3) It is feasible to generate, with the support of AI, a composite and ongoing QoL and well-being Index that indicates continuously the balance of met and unmet needs of patients with cancer? (4) It is feasible to deliver timely recommendations for patients based on patients' data inputted from the Guardian Angel app and a wearable device?

Methods

Study Design

This 2-group pilot study is aimed to evaluate the feasibility of the ONCORELIEF system in real-life clinical settings for patients with colorectal cancer and acute myeloid leukemia. It will run in two phases: (1) a prepilot phase is a 1-month training of the entire system. A total of 10 patients (5 with acute myeloid leukemia and 5 with colorectal cancer) will be enrolled and provided with the ONCORELIEF digital tools (ie, the Guardian Angel app and the wearable device). Based on the feedback of patients and health professionals, improvements will be made to the entire system over a period of 2 months. (2) The second phase will last 12 months (see Figure 3).

Figure 3. The flow of patients throughout the study. AML: acute myeloid leukemia; CRC: colorectal cancer; IRST: Istituto Romagnolo per lo Studio dei Tumori; QoL: quality of life.

Clinical Centers

The study will be conducted in 2 clinical centers: Universitätsmedizin der Johannes Gutenberg-Universität Mainz (Mainz, Germany) and IRCCS Istituto Romagnolo per lo Studio dei Tumori "Dino Amadori" (IRST, Italy).

Study Participants

Inclusion criteria include (1) patients with the diagnosis of acute myeloid leukemia or colorectal cancer, (2) adult patients aged 18 years and older, (3) life expectancy greater than 12 months, (4) Eastern Cooperative Oncology Group performance status [11] ≤2, and (5) patients who have a smartphone and agree to use it for the purpose of the study.

Exclusion criteria include (1) patients with a reduced cognitive function (such as dementia) or technological illiteracy and (2) other known active malignant neoplastic diseases (patients with a medical history of treated neoplastic disease are included).

Recruitment and Enrollment

Figure 3 describes the flow of patients throughout the study. All patients will be treated and monitored for their disease according to the local clinical practice, and no changes in

XSL•FO
RenderX

treatment or follow-up will be decided based on participation in this study. At IRST Italy, patients in follow-up at clinical sites for acute myeloid leukemia or colorectal cancer disease and those considered eligible by the study oncologists will be invited to participate in this research. The oncologist will inform patients of the aims and procedures of the study. At Mainz, patients are prescreened by the treating health care professional (HCP) for eligibility and are introduced to the study by the HCP during their regular clinic visits. If the patient is interested, the HCP will give the patient's name and the time of the next clinic visit to the study coordinator or study nurse. At the patient's next visit, the study coordinator will meet the patient and enroll the patient by following the enrollment procedures.

All patients will be informed that the participation is voluntary and that they are allowed to interrupt their participation whenever they want and for any reason. This will not prejudice the patient's subsequent care. Patients will also be informed about relevant data protection and privacy legislation. A written, signed, informed consent form from the patient must be obtained before study entry. After signing informed consent, patients will be registered into ONCORELIEF electronic data capture system. Only deidentified data will be collected, including the data collected by the app or wearable device. Each patient will be assigned a unique alphanumerical ID, and only clinical site staff will have access to patients' personal data and reidentification key. The anticipated total number of recruited patients will be 30 acute myeloid leukemia and 60 colorectal cancer for the 2 study phases. Therefore, for the pilot phase, an additional 25 patients with acute myeloid leukemia and 55 patients with colorectal cancer will be enrolled in total across clinical sites. Mainz will attempt to recruit about two-third of the patients, that is, up to 20 patients with acute myeloid leukemia and up to 40 patients with colorectal cancer. IRST is expected to recruit 20 patients with colorectal cancer (1 site in Italy, IRST IRCCS) and 10 patients with acute myeloid leukemia. However, due to the COVID-19 health crisis, fewer patients are coming to the clinic and the number might have to be adjusted. Patients are enrolled for 3 months.

Demographic, Medical, and Treatment Data

The clinical variables regarding medical and treatment data will be obtained from the patient's medical records. The following data will be recorded for each patient at study entry through an electronic data capture system: (1) demographics include age, gender, weight, educational background, occupation, and family status; (2) medical and medication history include relevant medical and medication history and acute myeloid leukemia or colorectal cancer history including date of diagnosis, type, treatments, and disease status at study entry; (3) baseline conditions (comorbidities and symptoms) assessment; (4) history of oncological treatments and any residual toxicity relating to prior or current treatment; (5) performance status (Eastern Cooperative Oncology Group); and (6) physical examination.

Instruments and Measures

Wearable Device and the Sensing Framework

The sensing infrastructure is an essential part of the ONCORELIEF ecosystem due to its role in providing and managing the data flow for all patients. The sensing framework describes the parameters that can be obtained from the wearable multisensor device as well as the ways to connect to them and encompasses four fundamental elements: (1) the whole set of smart sensors in the wearable device that includes sensors relevant both to the physiological parameters as well as to behavioral data (step count), (2) the patient's smartphone ONCORELIEF mobile app (the patient-centered Guardian Angel app) (3) interim sensor data storage and further processing (AI algorithms for stress level based on heart rate variability parameters), and (4) ability of real-time (or almost real-time) data transmission from the wearable device via the Guardian Angel mobile app to the ONCORELIEF cloud.

The customizable smart wrist-worn sensor device developed by a partner of this project, MCS Datalabs, is equipped with diverse sensors. It is able to monitor vital data (optical heart rate = pulse rate and oxygen saturation by photoplethysmography and skin temperature) and motion data from a 3D accelerometer (step count as an output of the sensor). The wrist-worn device is configured and customized to meet the defined data and security requirements.

Psychosocial Instruments

Before the selection of the instruments for measuring patient needs, we selected the key needs that should be assessed for each type of cancer. The aim of this selection was to reduce the number of needs as much as possible to diminish the patients' burden and make it possible to assess these needs through the Guardian Angel app and from the wearable. We started by identifying all needs documented in the scientific literature for acute myeloid leukemia and colorectal cancer, which resulted in a first list of needs. Next, the ONCORELIEF clinical partners (IRST and Mainz) filtered the needs based on the following criteria: (1) is it a common need (ie, affecting >10% of patients with the corresponding condition)? (2) can patients or caregivers self-report this need? (3) does the need have "intensity levels" or "grades" (1-5, or 1-10, or so on) or is it just "binary" (yes or no)? (4) is there more than one potential intervention available for this need? (5) could potential interventions bring noticeable improvement within the period of the pilot? (6) could this need be related to urgent care with action that needs to be taken in a very short timeframe? (7) is there a high risk from using AI (or training AI) for this need? (8) is this need a "must-have" patient need? From the app of these criteria resulted a final list of key needs presented in the first column of Table 1. Some needs are common to both cancers (anxiety, depression, fatigue, and subjective well-being) and others are specific, as shown in Table 1. Each patient will be assessed every 2 weeks over the 3-month participation in the ONCORELIEF study.

XSL•FO
RenderX

Table 1. Patient key needs and questionnaires.

Patient needs	Questionnaire	Description
Anxiety	Hospital Anxiety and Depression Scale (HADS) [12-14]	HADS is a 14-item measure designed to assess anxiety and depression. This study focuses only on the 7 items of anxiety (HADS-A). Each item is endorsed on a Likert-type scale (0-3), and the score obtained ranges from 0 to 21.
Depression	Patient Health Questionnaire-9 (PHQ-9) [12-14]	The PHQ-9 is the 9-item depression module from the full PHQ. The PHQ-9 score can range from 0 to 27, since each of the 9 items can be scored from 0 (not at all) to 3 (nearly every day).
Fatigue	Brief Fatigue Inventory (BFI) [15-17]	BFI is a 9-item measure to assess the subjective report of cancer-related fatigue severity and the impact of fatigue on daily functioning. BFI uses an 11-point scale (0="no fatigue" to 10="fatigue as bad as you can imagine") to measure each specific symptom.
Appetite loss	EORTC-QLQ C30[a] [18]	Assessed by the appetite loss item from EORTC-QLQ C30. In the past week, have you lacked appetite? (from 1=not at all to 4=very much).
Subjective well-being	World Health Organization Well-Being Index (WHO-5) [19]	WHO-5 is a generic global rating scale measuring subjective well-being. Each of the 5 items is scored from 5 (all of the time) to 0 (none of the time). The raw score ranges from 0 (absence of well-being) to 25 (maximal well-being).
Lack of sexual interest (only acute myeloid leukemia)	EORTC-SHQ-C22[b] [20]	The EORTC SHQ-C22 is a 22-item scale designed to assess the physical, psychological, and social aspects of sexual health in patients with cancer and survivors of cancer. Each item is scored a 4-point Likert scale (not at all to very much).
Sleep problems (only acute myeloid leukemia)	Insomnia Severity Index (ISI) [21-23]	The ISI is composed of 7 items that evaluate sleep problems (the last item evaluates the level of distress caused by the sleep problem). Each of these items is rated on a 5-point Likert scale (not at all to extremely), and the time interval is "in the last 2 weeks." Total scores range from 0 to 28, with high scores indicating greater insomnia severity.
Sore mouth (only acute myeloid leukemia)	EORTC-OH15[c] [24]	The EORTC-OH15 assesses oral health quality of life in patients with any type of cancer. It has 15 items, containing one 8-item OH-QoL[d] scale, 3 single items (sticky saliva or mouth soreness or sensitivity to food or drink), and two 2-item contingency scales regarding use (yes or no) and problems with dentures and reception of (yes or no) and satisfaction with information.
Colitis (only colorectal cancer)	EORTC-QLQ-CR29[e] [25]	The European Organization for Research and Treatment of Cancer developed the colorectal QoL module as an adjunct to the generic EORTC QLQ-C30. This module consists of 4 scales and 19 individual items.
Hand-foot syndrome (only colorectal cancer)	EORTC-QLQ CIPN20[f] [26]	The EORTC QLQ-CIPN20 is the common method for determining chemotherapy-induced peripheral neuropathy symptoms.
Neuropathy (only colorectal cancer)	EORTC-QLQ CIPN20	Same as previous scale.

[a]EORTC-QLQ C30: European Organization for Research and Treatment of Cancer Core Quality of Life questionnaire.

[b]EORTC-SHQ-C22: European Organization for the Research and Treatment of Cancer Sexual Health Questionnaire.

[c]EORTC-OH15: European Organization for the Research and Treatment of Cancer—Oral Health Questionnaire.

[d]QoL: quality of life.

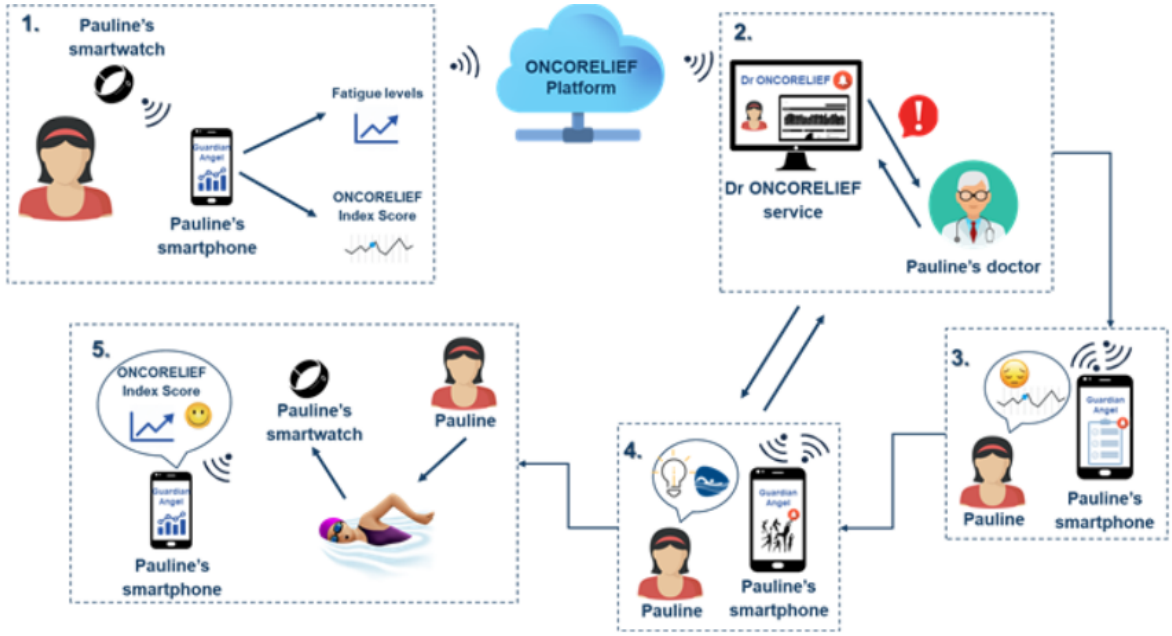
[e]EORTC-QLQ-CR29: European Organization for Research and Treatment of Cancer—colorectal quality of life module.

[f]EORTC-QLQ CIPN20: European Organization for Research and Treatment of Cancer Quality of Life Questionnaire—Chemotherapy-Induced Peripheral Neuropathy 20-item scale.

The selection of the instruments for measuring the psychosocial needs described in Table 1 was based on three criteria: (1) sound reliability and construct validity, (2) reduced number of items, and (3) have already been translated and validated into Italian and German.

Measurement of the QoL and Well-being Index

The QoL and well-being composite index has a hierarchical structure of three levels: (1) global, (2) domains, and (3) needs. The first level represents the total QoL and well-being score. The second level includes 3 different need domains (emotional distress, psychophysiological, and physical). For example, the "emotional distress" domain includes the needs "depression" and "anxiety." See Table 2 that presents the grouping of needs into domains and the instruments to assess the needs for each type of cancer, acute myeloid leukemia and colorectal cancer.



XSL•FO
RenderX

Table 2. Domains and key needs assessed for each type of cancer.

Domain	Acute myeloid leukemia needs	Colorectal cancer needs
Emotional distress	• Depression • Anxiety	• Depression • Anxiety
Psychophysiological	• Sleep • Fatigue • Lack of sexual interest	• Fatigue
Physical symptoms	• Sore mouth • Appetite loss	• Colitis • Appetite loss • Peripheral neuropathy • Hand-foot syndrome
Well-being	• Well-being	• Well-being

The different scores at each level will provide a set of metrics that will allow to identifying and monitoring QoL and well-being of patients with cancer. This multilevel approach will provide information about what domain or domains (eg, emotional distress) related with patient needs (eg, depression, anxiety) must be improved or to identify differences by gender, type of cancer, and country at the 3 levels. The global index results from averaging the scores of each domain, which are based on the scores obtained in each patient's key needs. The QoL and well-being global score is converted on a 0-1000 scale and will allow a qualitative appreciation, which will range between 400 (very poor) and 900 or higher (very good). Clinical and psychosocial recommendations coming from the ONCORELIEF system are analyzed and decided by the health professional and are focused on specific needs rather than the overall score. However, it is expected that a positive change in specific unmet needs will be reflected positively on the QoL and well-being index global score. Below we describe a user scenario illustration based on a fictitious case (see Figure 4) as an example of how the ONCORELIEF digitally assisted workflow may hopefully work in a real-life setting.

Figure 4. Pauline case illustration.

User Scenario Illustration

Shortly after Pauline was diagnosed with stage 2 colorectal cancer, she had surgery followed by chemotherapy as adjuvant treatment. She accepted the opportunity to use the ONCORELIEF Guardian Angel app, although she didn't particularly like the idea of entering much data into an app. Over time, the Guardian Angel app, having connected with her smart device, identified patterns, which had been correlated with the early onset of fatigue in patients like Pauline: she napped more than before and was less active. Additionally, her ONCORELIEF QoL and well-being global score had dropped from 700 to 500. Her HCP got notified of these patterns through the ONCORELIEF service and, after some consideration, sent a message to the patient. When Pauline got notified the next day, she read the accompanying text and realized from the color coding on her app that her QoL and well-being index score had dropped further, and upon further investigation, she read that it was 500 because of early fatigue and some mild depressive symptoms. It then occurred to her that this may have been the

XSL•FO
RenderX

reason behind her low motivation and her reluctance to get up and go to work in the morning. She gave consent for her new information to be shared with her HCP and was provided with a few minutes' worth of reading material, which made her feel somewhat better since she realized this is relatively common and not a huge cause of concern. Her HCP, after viewing the report on Pauline's responses as well as her recent history via ONCORELIEF, gave a recommended intervention: gradual exercise increase and get support from psycho-oncology services. The HCP agreed and soon enough Pauline had the recommendation on her Guardian Angel app. She felt OK but not great—but then read that the exercise coach would motivate her based on her achievements but also that her exercises would be tailored to her unique needs and preferences. The accompanying content offered a variety of exercises: since she had not had an ostomy surgery and did not have a stoma bag, she could also swim in the local pool, and she liked that idea. Pauline started tracking her swimming sessions simply with a couple of taps at a time. The psycho-oncologist assessed Pauline's depressive cognitions and beliefs and her lack of motivation and pleasure in doing daily activities and suggested some stress management skills to cope with depression. After a few weeks, both Pauline and her HCP could see her ONCORELIEF Index QoL and well-being score increasing slowly but steadily to 700.

Ethics Approval

The protocol, informed consent, and any accompanying material provided to the patient were submitted to the ethical board of IRST (CEROM, Comitato Etico della Romagna, case number Prot. 8528/2021) and Mainz (Ethik-Kommission der Landesärztekammer Rheinland-Pfalz, case 2021-16122) for review. The pilot study was approved by both ethical boards. Any modifications made to the protocol, informed consent, or material provided to the patient after receipt of the Ethics Committee approval must also be submitted by the investigator to the committee in accordance with local procedures and regulatory requirements. It is the responsibility of the investigator to obtain written informed consent from each subject prior to entering the trial or, where relevant, prior to evaluating the subject's suitability for the study.

The investigators will ensure that this study is conducted in full conformity with the current revision of the Declaration of Helsinki (last amended 64th WMA General Assembly, Fortaleza, Brazil, October 2013), with relevant regulations and with the ICH Guidelines for Good Clinical Practice E6 (R2), and other relevant local legislation.

Results

The ONCORELIEF project started in January 2020 and will end in June 2023. The pilot study started on September 1, 2022. As of January 2023, we enrolled 33 patients with colorectal cancer and 7 patients with acute myeloid leukemia. As of January 2023, we have not yet started the data analysis. We expect to get all data in June 2023 and expect the results to be published in the second semester of 2023.

Discussion

Principal Findings

The main objective of ONCORELIEF is the development of a user-centered AI system to facilitate the input and integration of patient-related biopsychosocial data to improve posttreatment QoL, well-being, and health outcomes. We hope that this project will be feasible and will provide patients and health professionals with a valuable tool to improve the holistic rehabilitation of patients with cancer. There has been increasing use of eHealth tools in health care in general [5] and in patients with cancer in particular [4,27,28], but the main innovation of ONCORELIEF is that all data of patients with cancer will run on a digitally assisted workflow of posttreatment supportive patient care supported by an AI system. The core concept of the ONCORELIEF proposal is based on the collection of biopsychosocial patient data to provide patient-centered care and better support services to patients with cancer and survivors of cancer. ONCORELIEF will enable identifying, collecting, harmonizing, modeling, and eventually processing and analyzing data from diverse channels and domains, using Big Data and AI techniques to develop services and features that will be offered to all cancer stakeholders, with the aim to serve them with a continuous monitoring and assistance app, toward increasing the awareness of their QoL and well-being status. The overall output of ONCORELIEF has the potential to provide insights for HCPs and caregivers, as well as for patients, and to deliver recommendations toward more effective psychosocial support. Patients may be more motivated to improve their health and hasten their way back to normal, through the adoption of healthy lifestyles and stress management skills. The power of ONCORELIEF lies on a holistic model of health, capturing ongoing data from diverse sources (eg, patient-reported outcomes through a smartphone app, physiological signals from a wearable smart device, and demographic and medical data from health records) involving the biological, psychological, and social dimensions of the patient with the potential to offer the patient just-in-time recommendations to cope with the unmet needs and challenges of the cancer journey.

Strengths

The strengths of the study are as follows: the platform and patient-assessment profile are continuously updated and is available 24/7, the study has the potential of less demand of medical consultations since ONCORELIEF gives support to the patient all the time, and the study contributes to better clinical outcomes.

Limitations

The limitations of this study are resistance from some patients who are not familiar with digital devices, eHealth tools and procedures are not yet integrated into hospitals' data evaluation and recording systems, and platforms and systems such as ONCORELIEF may emerge as extra tools that can be felt as complications in the day-to-day life of HCPs.

Abstract

Background: Cancer survivors represent one of the fastest growing populations in the United States. Unfortunately, nearly 1 in 3 survivors experience anxiety symptoms as a long-term consequence of cancer and its treatment. Characterized by restlessness, muscle tension, and worry, anxiety worsens the quality of life; impairs daily functioning; and is associated with poor sleep, depressed mood, and fatigue. Although pharmacological treatment options are available, polypharmacy has become a growing concern for cancer survivors. Music therapy (MT) and cognitive behavioral therapy (CBT) are evidence-based, nonpharmacological treatments that have demonstrated effectiveness in treating anxiety symptoms in cancer populations and can be adapted for remote delivery to increase access to mental health treatments. However, the comparative effectiveness of these 2 interventions delivered via telehealth is unknown.

Objective: The aims of the Music Therapy Versus Cognitive Behavioral Therapy for Cancer-related Anxiety (MELODY) study are to determine the comparative effectiveness of telehealth-based MT versus telehealth-based CBT for anxiety and comorbid symptoms in cancer survivors and to identify patient-level factors associated with greater anxiety symptom reduction for MT and CBT.

Methods: The MELODY study is a 2-arm, parallel-group randomized clinical trial that aims to compare the effectiveness of MT versus CBT for anxiety and comorbid symptoms. The trial will enroll 300 English- or Spanish-speaking survivors of any cancer type or stage who have experienced anxiety symptoms for at least 1 month. Participants will receive 7 weekly sessions of MT or CBT delivered remotely via Zoom (Zoom Video Communications, Inc) over 7 weeks. Validated instruments to assess anxiety (primary outcome), comorbid symptoms (fatigue, depression, insomnia, pain, and cognitive dysfunction), and health-related quality of life will be administered at baseline and at weeks 4, 8 (end of treatment), 16, and 26. Semistructured interviews will be conducted at week 8 with a subsample of 60 participants (30 per treatment arm) to understand individual experiences with the treatment sessions and their impact.

Results: The first study participant was enrolled in February 2022. As of January 2023, 151 participants have been enrolled. The trial is expected to be completed by September 2024.

Conclusions: This study is the first and largest randomized clinical trial to compare the short- and long-term effectiveness of remotely delivered MT and CBT for anxiety in cancer survivors. Limitations include the lack of usual care or placebo control

XSL•FO
RenderX

groups and the lack of formal diagnostic assessments for psychiatric disorders among trial participants. The study findings will help guide treatment decisions for 2 evidence-based, scalable, and accessible interventions to promote mental well-being during cancer survivorship.

Introduction

The Burden of Anxiety During Cancer Survivorship

With advances in oncology care, the number of cancer survivors in the United States is expected to increase dramatically and exceed 22 million by the end of this decade [1]. A meta-analysis identified anxiety as one of the most common mental health issues faced by cancer survivors [2]. Compared with the general population, cancer survivors experience higher rates of anxiety [2-5], and up to one-third of them experience clinically meaningful anxiety symptoms [3,5-9]. Characterized by restlessness, muscle tension, and worry that is difficult to control, anxiety is a highly disruptive symptom associated with poor sleep [10], depressed mood [11-13], and fatigue [14-17]. Anxiety also contributes to poor treatment adherence [18-20] and increased health care expenditures [21,22]. As a primary driver of poor quality of life among cancer survivors [23-26], anxiety is an important issue to address in this rapidly growing population.

Although pharmacological treatment options for anxiety are available [27], polypharmacy is a growing concern among cancer survivors [28-31]. Compared with the general population, cancer survivors have much higher rates of polypharmacy, with 64% taking ≥5 unique medications [30]. One-third of survivors receive at least 1 psychotropic medication (eg, anxiolytics and antidepressants), and nearly 1 in 6 survivors report using ≥2 classes of psychotropic medications [31]. Psychotropic polypharmacy is associated with poor quality of life, impaired physical and mental functioning, financial toxicity, and higher risk of side effects and drug interactions [31]. These challenges of polypharmacy highlight the need for nonpharmacological treatment options for anxiety during cancer survivorship.

Cognitive Behavioral Therapy: An Effective First-Line Treatment for Anxiety

Cognitive behavioral therapy (CBT) is an evidence-based, nonpharmacological intervention delivered by licensed mental health professionals [32,33]. The American Society of Clinical Oncology (ASCO) [27] and the National Comprehensive Cancer Network (NCCN) [34] recommend CBT for treatment of anxiety in patients with cancer. Informed by the cognitive behavioral model of anxiety, CBT focuses on the relationship between thoughts, behaviors, and emotions and how thoughts and behaviors can exacerbate or reduce anxiety [35-37]. The therapeutic components of CBT consist of psychoeducation on anxiety, relaxation techniques, cognitive restructuring, and strategies for planning activity engagement and managing realistic worries [38,39]. Meta-analyses demonstrated moderate to large effects of CBT on anxiety symptoms in patients with cancer and cancer survivors relative to control conditions, with effect sizes ranging from 0.42 to 1.10 [40-43]. CBT is widely considered an effective first-line treatment for anxiety in people affected by cancer [27,34].

Despite the established effectiveness of CBT, studies have demonstrated that 20% to 25% of CBT participants fail to complete a full treatment course [44,45] and 37% do not achieve clinically meaningful improvements in anxiety symptoms [46,47]. Furthermore, social stigma surrounding psychotherapy exists in some demographic groups and cultures, and research shows that underserved racial or ethnic groups are more likely than White patients to delay, avoid, or drop out of mental health treatments [48,49]. These challenges of CBT highlight the importance of studying other nonpharmacological treatments that are not only effective but also culturally acceptable to diverse cancer survivors.

Music Therapy: An Evidence-Based Anxiety Treatment With Increasing Availability at Cancer Centers

Music therapy (MT) is a nonpharmacological, evidence-based intervention in which board-certified music therapists engage patients in personally tailored experiences with music to achieve therapeutic goals [50]. These experiences range from music-guided relaxation to more active forms of musical engagement, including singing and improvising music [50]. The social-cognitive processing model of emotional adjustment in cancer is one of several possible models that informs the use of MT for anxiety management in cancer survivors [51]. Supported by empirical studies [52,53], this model conceptualizes the cancer treatment journey as a disruptive, trauma-like experience that must be cognitively processed in a supportive social context for healthy emotional adaptation to occur [51,52]. A growing body of research demonstrates the capacity of MT to influence these social-cognitive processes central to anxiety. Interactive music experiences have been shown to build social connections and promote a sense of belonging [54-56]. Prior studies also suggest that MT provides novel, creative outlets (eg, through songwriting) to cognitively process past traumatic experiences that may otherwise be difficult to verbalize [57,58]. In addition to its social-cognitive effects, musical engagement has been shown to modulate brain regions (ie, amygdala) [54] and biological systems (ie, hypothalamic-pituitary-adrenal axis [59-61] and autonomic nervous system [62-65]) responsible for emotional regulation

XSL•FO
RenderX

and implicated in anxiety and mood disorders [66-69]. Importantly, ethnographic and phylogenetic research has identified music as a defining characteristic of humankind across many cultures worldwide [70,71]. The multicultural presence of music supports the potential of MT to resonate with a diverse population of cancer survivors.

MT has a growing evidence base for cancer symptom management [72-75] and is recommended by ASCO [76], NCCN [34], and the Society for Integrative Oncology [77,78] as a treatment option for anxiety in cancer populations. A recent Cochrane review (81 trials, N=5576) found that MT was associated with a large reduction in anxiety symptoms compared with usual care [79]; MT is also offered at approximately 75% of the National Cancer Institute (NCI)–designated Comprehensive Cancer Centers and 55% of community-based cancer programs [80]. Owing to its growing evidence base and availability, MT represents a promising alternative to CBT for the treatment of anxiety.

Digital Transformation of Health Care During COVID-19: A Timely Opportunity to Improve Access to Mental Health Resources

In the past 2 decades, the percentage of US adults who use the internet has increased from 52% to 90% [81]. Approximately 59% to 79% have access to home broadband internet services [81] and 37% use smartphones as their primary access to the internet [82]. Cancer centers across the country are increasingly leveraging digital technology to monitor and manage symptoms remotely [83]. The COVID-19 pandemic accelerated these digital trends, and the use of videoconferencing for telehealth services increased by 8700% at the peak of the pandemic [84].

Although key disparities in digital access and literacy remain [85], the widespread adoption of videoconferencing offers a promising platform for reducing barriers to mental health services. Therapists have successfully used videoconferencing to deliver MT remotely to military populations [86-90] and patients with autism [91]. Therapists have also used videoconferencing to deliver MT services to inpatient [92,93] and oncology settings [94]. At the outset of the pandemic, the American Music Therapy Association and other MT professionals rapidly developed and implemented telehealth guidelines and resources to facilitate the telehealth-based delivery of MT services to patients isolated at home [92,95]. Many music therapists have shifted their clinical practices to web-based platforms [96,97]. There is also an extensive body of research (>100 trials) on internet-delivered CBT interventions [98,99], and studies have consistently demonstrated that CBT delivered remotely is as effective and acceptable as in-person treatments for anxiety [100]. Thus, both MT and CBT are equipped for the digital health care landscape, with unique potential for scalability to reduce barriers to mental health services.

Gaps in the Evidence: Treatment Dilemmas Facing Patients and Clinicians in the New Digital Health Care Landscape

Although CBT is widely considered a first-line treatment for anxiety, not all individuals are able to complete a full treatment course [44,45] or achieve meaningful improvements in their symptoms [46,47]. People may also be reluctant to pursue CBT because of the sociocultural stigma surrounding psychotherapy in different groups and communities [48,49]. For individuals who do not respond or do not wish to pursue CBT, evidence is lacking on whether MT is an effective, noninferior treatment alternative to CBT.

To inform treatment decision-making, the American Psychological Association, in its resolution on the Recognition of Psychotherapy Effectiveness, has called for “continued and further research on the comparative effectiveness” of CBT and other psychotherapeutic interventions [101]. Furthermore, as health care continues to undergo rapid digital transformation, there is a critical need for additional research into telehealth interventions. Although CBT research has compared remote delivery versus traditional in-person formats, few studies have compared telehealth-based CBT with other telehealth interventions, such as MT [98,100]. In their systematic review of digital health interventions for cancer survivors, Harris et al [83] emphasized that “one size may not fit all” and there is a “need to identify who is most likely to benefit from digital interventions.” Comparative effectiveness research on different telehealth-based treatments (ie, CBT vs MT) is essential to guide timely and patient-centered decision-making and help patients and clinicians navigate this new digital health care landscape.

The Music Therapy Versus Cognitive Behavioral Therapy for Cancer-Related Anxiety Trial: Study Aims and Hypotheses

The Music Therapy Versus Cognitive Behavioral Therapy for Cancer-related Anxiety (MELODY) trial seeks to address the following aims:

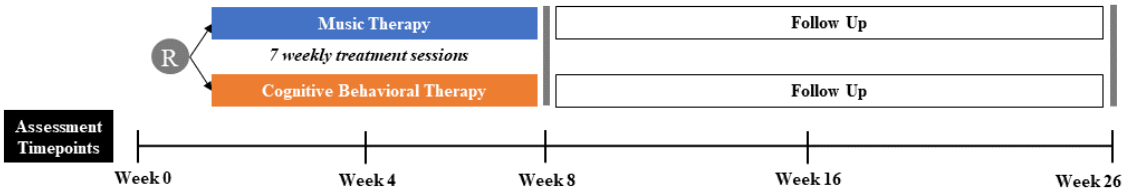
The primary aim is to determine the comparative effectiveness of telehealth-based MT versus telehealth-based CBT for anxiety and comorbid symptoms in cancer survivors.

- *Hypothesis 1(a)*: MT will be noninferior to CBT in treating anxiety symptoms among survivors at week 8 (end of treatment) and week 26 (long-term follow-up).
- *Hypothesis 1(b)*: Compared with CBT, MT will be associated with significantly greater improvement in fatigue co-occurring with anxiety.
- Exploratory hypothesis: Survivors may have unique experiences with MT and CBT for anxiety during cancer survivorship.

The secondary aim is to identify patient-level factors associated with greater anxiety symptom reduction after MT and CBT.

- *Hypothesis 2*: Specific sociodemographic characteristics (eg, age, sex, race, and education) or psychological attributes (ie, expectancy) will be associated with treatment response to MT or CBT.

Methods



Study Design

The MELODY study is a 2-arm, parallel-group, pragmatic randomized clinical trial that aims to compare the effectiveness

XSL•FO
RenderX

of MT versus CBT for anxiety and comorbid symptoms in a diverse and heterogeneous sample of 300 cancer survivors (Figure 1). This study will be conducted at the Memorial Sloan Kettering Cancer Center (MSK), an NCI-designated Comprehensive Cancer Center, as well as the Miami Cancer Institute (MCI) and Drexel University. These sites were chosen in part for their potential to help recruit a diverse study population. Interventions will be delivered weekly via Zoom (Zoom Video Communications, Inc) over 7 weeks. Study assessments will be administered at baseline and at weeks 4, 8, 16, and 26. This study will be conducted in accordance with the Consolidated Standards of Reporting Trials (CONSORT) guidelines for nonpharmacological interventions [102], the reporting guidelines for music-based interventions [103], and the National Institutes of Health Protocol Template for Behavioral and Social Sciences Research [104]. This study has also been registered at ClinicalTrials.gov (NCT05215353).

Figure 1. Study schema.

Ethics Approval

The study was approved by the institutional review board (IRB) at MSK on December 22, 2021 (IRB: 21-516). MSK serves as the IRB of record for both MCI and Drexel University.

Eligibility Criteria

The eligibility criteria were designed to be broad and consistent with a pragmatic design while ensuring participant safety and scientific rigor. Participants are eligible if they are English- or Spanish-speaking, are aged ≥18 years, have a prior cancer diagnosis of any type or stage, are free of oncological disease, have a score of ≥8 on the anxiety subscale of the Hospital Anxiety and Depression Scale (HADS), report anxiety symptoms lasting at least 1 month, and have access to Zoom and a quiet or private location. Participants will be excluded if they had completed active cancer treatment (eg, surgery, radiation, and chemotherapy) less than 1 month before enrollment; however, participants receiving maintenance hormonal or targeted therapies will be allowed to enroll. Participants will also be excluded if they have active suicidal ideation, bipolar disorder, schizophrenia, or substance abuse; have a score of ≥10 indicative of cognitive impairment on the Blessed Orientation-Memory-Concentration; or received a treatment course of ≥7 MT or CBT sessions for anxiety symptoms within the last 6 months.

Recruitment

This study will use a multimodal recruitment strategy that comprises population-based methods, clinician referrals, and community outreach and engagement, which are described as follows:

1. Population-based methods: MSK and MCI patient databases will be queried to identify survivors who meet basic eligibility criteria. MSK catchment areas include urban and suburban locations in New York, Long Island, and New Jersey, whereas MCI catchment areas include urban and suburban locations in South Florida with access to a large Hispanic population. Drexel University investigators will query the Pennsylvania Cancer Registry to identify potential participants from rural populations. A recruitment letter will be sent to the potential participants identified on these databases and registries. The recruitment letter will introduce the study and include instructions for interested persons to contact the study team.
2. Clinician referrals: potential participants will also be identified and referred by clinicians at MSK, MCI, or other health care settings. To facilitate referrals, the study team will educate clinicians about the study, focusing on those who care for cancer survivors.
3. Community outreach and engagement: information about the study will also be posted on social media outlets, ClinicalTrials.gov, and public-facing websites. The study team will also present the study at scientific conferences, cancer survivorship support groups, community organizations, and other patient advocacy groups.

The goal of this multimodal approach is to enroll a diverse sample that includes traditionally underrepresented sociodemographic groups. The recruitment strategies were developed jointly by the study team and the patient and stakeholder advisory board, which includes patient advocates, cancer survivors, community leaders, and clinical stakeholders. Diverse study representation will facilitate careful exploration of the differences between participant subgroups to inform personalized decision-making.

Once interested and potentially eligible participants are identified, the research staff will schedule them for an initial screening visit. If participants meet the basic eligibility criteria, they will then be scheduled for a telehealth visit with a study clinician to confirm their eligibility. If a participant is deemed eligible, the research staff will explain the study procedures and request informed consent. Once consent is obtained, the participants will complete the baseline assessments.

Randomization

After completing the baseline assessments, participants will be randomized using MSK's secure computer system that ensures full allocation concealment. Randomization will be 1:1 (MT:CBT) using randomly permuted blocks of random length, which are stratified by study site, current anxiety medication use (yes or no), and preferred language (English or Spanish).

XSL•FO
RenderX

The principal investigator and biostatistician will be blinded to treatment assignments.

Interventions

Treatment Course

Study participants will receive 7 weekly 60-minute MT or CBT sessions over the first 7 weeks. All sessions will be delivered remotely through Zoom's Health Insurance Portability and Accountability Act (HIPAA)–compliant, encrypted, and passcode-protected videoconferencing software. Although the duration of these types of treatments may vary in real-world settings, this study will match the MT and CBT groups for patient-therapist contact time to ensure rigorous comparative effectiveness comparison.

MT Protocol

MT will be delivered by board-certified music therapists. The MT protocol is based on the neuroscience of music [54,105], the social-cognitive processing model [51,52], the scientific literature on MT [72], and the clinical and research experience of the study team [106]. Healthy psychological adjustment during cancer survivorship requires the processing of feelings and thoughts related to one's cancer journey in a supportive context [51,52]. Therefore, the intervention protocol is structured to build patient-therapist rapport and allow for greater emotional expressivity and deeper cognitive processing. Guided by the social-cognitive processing model [51,52], the first few sessions will focus on building a trusting relationship with the therapist, whereas the later sessions will focus on the cognitive processing of cancer-related experiences and current fears, worries, and hopes, using playlist creation and songwriting as an outlet for reflection, expression, and meaning making. Research also suggests that patients prefer receptive modes of engagement during their initial exposure to MT [75,107]. As such, the early sessions will focus on receptive techniques (eg, music-guided stress management), and the later sessions will progress to more active MT techniques (eg, songwriting). The protocol includes homework activities in between sessions to promote self-management skills (eg, the use of music-guided deep breathing), strengthen social connections (eg, sharing meaningful songs with loved ones), provide outlets for cognitive processing (eg, writing or reflecting on themes for song lyrics), and serve as transitions to the subsequent sessions.

CBT Protocol

The CBT protocol is based on the scientific literature [32,33] and the clinical and research experience of the study team [108]. CBT therapists will include licensed social workers because they are the most commonly employed mental health providers in cancer care and, therefore, reflect the real-world practice and implementation of CBT in oncology settings [109]. Informed by the cognitive behavioral model of anxiety, CBT focuses on addressing the thoughts and behaviors that exacerbate or reduce anxiety [35-37]. The protocol consists of psychoeducation on anxiety, relaxation techniques, cognitive restructuring, and strategies for planning activity engagement and managing realistic worries [38,39]. These components target the somatic symptoms of anxiety (eg, muscle tension) as well as the thoughts (eg, "What if my next scan is bad?") and behaviors (eg, excessive symptom monitoring) that trigger and exacerbate anxiety. Once identified, these problematic thoughts and behaviors are replaced by thoughts and behaviors that prevent and reduce anxiety. Each session will follow a consistent format that includes an overview of the session content, review of the homework exercise from the prior session, information on a new skill for managing anxiety, discussion of the upcoming homework exercise, and a plan for completing the exercise before the next session. Patients will receive a workbook with materials for each session and homework activities that promote practice of the skill learned during the session.

Interventionist Training and Treatment Fidelity

All interventionists will be trained about the specific research protocol and educated on the importance of adherence to the protocol methods. The interventionists will be either English speaking or bilingual in English and Spanish. The training of study interventionists will include didactic information on anxiety in cancer survivors and review of intervention materials. Interventionists will be provided with ongoing supervision over the course of the trial. During the trial, the CBT and MT sessions will be recorded and stored on secure, encrypted MSK servers. To ensure that study therapists adhere to the treatment protocol, document treatments appropriately, and maintain fidelity to the core functions of the intervention, the session recordings for the first 2 patients seen by a therapist will be reviewed. The review of session recordings will be based on treatment fidelity checklists outlining the core intervention components. If a therapist adheres to at least 80% of the treatment fidelity checklist items, then subsequent fidelity monitoring will be reduced to 2 randomly selected session recordings per patient. Deviations from the MT or CBT protocols will be discussed with study therapists during supervision meetings, and strategies will be suggested to minimize the number of deviations. Therapists who fail to adhere to at least 80% of the treatment fidelity checklist items will be retrained. Similar treatment fidelity strategies have been successful in other MT [106] and CBT trials [108,110] of patients with cancer conducted by the study team.

Study Assessment Procedures

Overview

Patient-reported outcomes (Table 1) will be completed on the web using Research Electronic Data Capture (REDCap; Vanderbilt University) [111]. Participants will also have the option to complete these study assessments on paper or over the telephone with research staff. Study assessment materials will be available in English or Spanish. Patient-reported outcome measures for anxiety, comorbid symptoms, and quality of life have been validated in Spanish [112-117]. Where needed, Spanish translation of other assessments took place in standard forward and reverse translation.

Table 1. Summary of patient-reported outcomes.

Primary or secondary	Name of outcome	Validated instrument	Time points (weeks)
Primary	Anxiety	HADS[a]	0, 4, 8, 16, and 26
Secondary	Depression	HADS	0, 4, 8, 16, and 26
Secondary	Fatigue	BFI[b]	0, 4, 8, 16, and 26
Secondary	Insomnia	ISI[c]	0, 4, 8, 16, and 26
Secondary	Pain	BPI[d]	0, 4, 8, 16, and 26
Secondary	Cognitive dysfunction	FACT-Cog[e]	0, 4, 8, 16, and 26
Secondary	Quality of life	PROMIS–Global Health[f]	0, 4, 8, 16, and 26
Secondary	Treatment expectancy	METE[g]	0 and 8
Secondary	Treatment preference	Treatment preference Scale	0 and 8
Secondary	Music reward	BMRQ[h]	0
Secondary	Mental health stigma	SSRPH[i]	0
Secondary	Generalized anxiety disorder	GAD-7[j]	0

[a]HADS: Hospital Anxiety and Depression Scale.

[b]BFI: Brief Fatigue Inventory.

[c]ISI: Insomnia Severity Index.

[d]BPI: Brief Pain Inventory.

[e]FACT-Cog: Functional Assessment of Cancer Therapy–Cognitive Function.

[f]PROMIS–Global Health: Patient-Reported Outcomes Measurement Information System–Global Health.

[g]METE: Mao Expectancy of Treatment Effects.

[h]BMRQ: Barcelona Music Reward Questionnaire.

[i]SSRPH: Stigma Scale for Receiving Psychological Help.

[j]GAD-7: Generalized Anxiety Disorder 7-Item Scale.

Anxiety

The primary outcome is severity of anxiety symptoms, as assessed using the HADS anxiety subscale. The reliability, validity, and factor structure of this 7-item subscale has been established in patients with cancer with a Cronbach α of .83 [118,119]. A score of ≥8 indicates the presence of anxiety symptoms. Research has identified a minimal clinically important difference (MCID) of 1.7 points [120]. The HADS anxiety subscale will be administered at baseline and at weeks 4, 8, 16, and 26.

Comorbid Symptoms and Quality of Life

Given that anxiety is strongly associated with depressed mood [11-13], fatigue [14-17], insomnia [10], pain [121], and cognitive dysfunction [122], these comorbid symptoms will be assessed using validated instruments. Depressive symptoms will be assessed using the HADS depression subscale (Cronbach α=.79) [118,119]. Fatigue will be assessed using the Brief Fatigue Inventory (BFI), a 9-item scale that has been validated in cancer populations with a Cronbach α of .96 [123]. Insomnia symptoms will be assessed using the Insomnia Severity Index [124], a 7-item instrument validated in cancer populations with a Cronbach α of .90 [125]. Pain severity and pain-related interference will be assessed using the Brief Pain Inventory (BPI). The BPI has been demonstrated to be a reliable, valid, and responsive measure with a Cronbach α of .77 to .91 [126]. Cognitive difficulties will be assessed using the Functional Assessment of Cancer Therapy–Cognitive Function (FACT-Cog), version 3, a 37-item questionnaire with 4 subscales (perceived cognitive impairments, impact on quality of life, comments from others, and perceived cognitive abilities). The FACT-Cog is a reliable instrument validated in cancer populations with a Cronbach α of .89 [127]. The FACT-Cog instrument will only be administered to participants who reply "YES" to the following question at baseline: "Are you experiencing difficulties with memory, concentration, or other cognitive abilities?" As anxiety is a key determinant of quality of life in cancer survivors [23-26], the Patient-Reported Outcomes Measurement Information System–Global Health (PROMIS–Global Health) will also be administered. This validated measure contains 2 domains related to quality of life: mental health (Cronbach α=.86) and physical health (Cronbach α=.81) [128]. These measures will be administered at baseline and at weeks 4, 8, 16, and 26.

Treatment Expectancy

The Mao Expectancy of Treatment Effects (METE) is a 4-item instrument originally developed as the Acupuncture Expectancy Scale to measure outcome expectancy. It has demonstrated validity and reliability (Cronbach α=.82) and is correlated with patient self-reported efficacy and satisfaction [129-131]. Prior research has also demonstrated that outcome expectancy is

XSL•FO
RenderX

associated with treatment response [129,132,133] and can, therefore, help inform personalized treatment decisions. The score ranges from 4 to 20, with higher scores indicating greater expectancy of benefit. This measure has been adapted for the MELODY study to assess patient expectancy of MT and CBT. The METE will be administered at baseline before receiving treatment. It will also be administered at week 8 to explore whether the expectancy changes after the treatment process.

Treatment Preference

As participants may have different preferences toward mental health treatment based on health beliefs or prior experiences with interventions, they will be asked at baseline whether they prefer MT or CBT or none [134]. Their preferences will also be assessed at week 8 to explore whether preferences change after their experiences with either MT or CBT.

Music Reward

Prior research has demonstrated variability in how people derive reward and pleasure from music, which may affect their experience with MT [135]. Therefore, the Barcelona Music Reward Questionnaire will be administered at baseline to assess the level of reward associated with music. This instrument has been validated with a Cronbach α of .92 [135].

Stigma of Receiving Psychological Help

In some groups and cultures, there is stigma associated with mental health needs, which may affect treatment experiences [48,49]. Therefore, the Stigma Scale for Receiving Psychological Help will be administered at baseline. This instrument has been validated (Cronbach α=.72) in different cultures to assess the stigma associated with receiving psychological health from mental health providers [136,137].

Covariates

Sociodemographics (eg, age, sex, race or ethnicity, and education) and other relevant clinical characteristics (eg, cancer type, stage, treatment history, and time since cancer diagnosis) will be collected at baseline. The Generalized Anxiety Disorder 7-Item Scale (GAD-7) will also be administered as a diagnostic screen for generalized anxiety disorder at baseline [138]. The use of medications prescribed for anxiety (eg, antidepressants, anxiolytics, hypnotics, and sedatives) will be tracked using weekly medication diaries at weeks 0, 8, and 26.

Semistructured Interviews

It may be difficult to capture the impact of MT and CBT using quantitative measures alone. Methodological experts recommend mixed methods approaches to understand patient experiences with health interventions [139-141]. Thus, qualitative method specialists will conduct 45-minute, semistructured individual interviews over the phone at week 8 (end of treatment). To reach thematic saturation from interviews, the research team will purposively sample 30 survivors in each treatment arm to be interviewed (N=60), aiming for balance across age, sex, race, ethnicity, and treatment response. Interviews will be conducted shortly after the intervention period to enhance the recall of personal experiences during therapy sessions. Interviews will be conducted using a semistructured guide that covers the following topics: (1) acceptability: treatment satisfaction, usefulness of the intervention, barriers and facilitators to session attendance, and adherence to and engagement with between-session assignments; (2) impact on anxiety symptoms and coping: perceived benefits and harms of the intervention on anxiety and comorbid symptoms, how one copes with stress and anxiety, integration of learned skills into daily life, and plans for maintaining anxiety management skills; (3) digital literacy and experience: views toward technology, comfort level with telehealth, and transfer of acquired digital skills to other aspects of daily living; and (4) unexpected experiences: unanticipated benefits, harms, or insights from engaging with the interventions. The interview guide will include flexibility in asking probing questions to enable participants to elaborate on their experiences. All the interviews will be audio-recorded and transcribed for thematic analysis.

Analytical Approach

General Description

Analyses will be conducted using the intention-to-treat principle (ie, participants will be analyzed according to their randomly assigned treatment group regardless of dropout or treatment adherence status). Given that CBT is widely recognized as a first-line therapy for anxiety, the study team opted to test the noninferiority of MT to CBT, with the goal of understanding whether MT can be an appropriate treatment option for patients who lack CBT access or do not wish to pursue CBT. To provide complementary information for treatment decision-making, the study team will also test which intervention is superior for addressing fatigue and other symptoms co-occurring with anxiety. For all specific aims, the main analytical tool will be a linear mixed-effects model (LMM) because the primary outcome (anxiety) and secondary outcomes (fatigue, depression, insomnia, pain, cognitive dysfunction, and health-related quality of life) are repeated continuous outcomes over time [142]. This statistical procedure takes into account within-subject correlations from repeated measurements in the same subjects and allows the estimation of between-group differences without necessitating the exclusion of participants with missing data. The general template of each LMM will model the outcome as a function of the treatment arm and assessment time (categorical), controlling for the randomization stratification variables (baseline anxiety medication use, preferred language, and study site) and including a subject-specific random intercept. The general LMM template will be tailored to test the specific aim hypotheses by adding interaction terms (eg, time-by-intervention) and additional covariates of interest to the model and by reparametrizing the assessment time variable to focus on specific contrasts.

Aim 1—Hypotheses 1(a) and 1(b)

Outcome measure trajectories will be plotted by randomization arm over time. Each outcome measure will be summarized at each assessment time by treatment arm using descriptive statistics. Comparisons between randomization arms with respect to changes in symptom outcomes will be based on specific coefficients from time-by-arm interactions added to the general LMM template described above in the *General Description* section. Specifically, the model will include all time points (categorical) at which the outcome was assessed (baseline and

XSL•FO
RenderX

weeks 4, 8, 16, and 26), and the time-by-arm interaction will include multiple coefficients corresponding to the time-by-arm interaction at each discrete postbaseline time point. However, statistical inferences will focus on the interaction coefficients at 8 and 26 weeks, which are interpreted as the differences between arms in change from baseline to 8 and 26 weeks, respectively. For hypothesis 1(a), the 2 primary end points are HADS anxiety score changes at 8 weeks and 26 weeks. On the basis of the LMM coefficients for the time-by-arm interaction at weeks 8 and 26, 2 tests will be performed to determine whether MT is noninferior to CBT at reducing the HADS anxiety subscale score within a noninferiority margin of 0.35 SD for both comparisons. The noninferiority of MT to CBT will be tested at a significance threshold of $P<.025$ for each comparison, controlling the overall type I error at $P=.05$ for the primary end point comparisons. For hypothesis 1(b), a similar LMM evaluating BFI scores over time will be used to test whether the MT arm had significantly greater improvement in fatigue (BFI score) compared with the CBT arm at weeks 8 and 26. In contrast to the primary end point noninferiority comparisons, these tests will be superiority tests. For other comorbid symptoms (eg, depression and insomnia) and quality of life, the methods described for hypothesis 1(b) will be used to compare the treatment arms. Given that a small number of cancer survivors may experience disease recurrence during the 26-week study, sensitivity analyses will be performed, excluding those individuals who experienced a recurrence during the study period. These sensitivity analyses will not replace the primary analysis.

Aim 2—Heterogeneity of Treatment Effect

An essential part of patient-centered care is recognizing that not all patients will respond to treatments the same way. As such, exploratory, hypothesis-generating heterogeneity of treatment effect (HTE) analyses will be conducted to identify patient-level factors associated with treatment response to either MT or CBT by incorporating 6 relevant variables (sex, race, ethnicity, education, outcome expectancy, and time since cancer diagnosis) and variable-by-intervention interaction terms in the mixed-effects model described above in the *Aim 1—Hypotheses 1(a) and 1(b)* section. These 5 exploratory LMM-based analyses will be guarded against inflated type I error owing to multiple testing by adjusting the variable-by-intervention interaction *P* values for the false discovery rate [143,144]. This type of subgroup analysis, although patient centered, may need to be interpreted with caution and cannot replace the primary analyses. The evaluation and reporting of HTE analyses will be based on the approach proposed by Kent et al [145]. However, recognizing other factors may also contribute to treatment responses, the study team will also apply Bayesian [146,147] and machine learning [148,149] methods, which can identify HTE and subgroups based on multiple variables simultaneously and are potentially more powerful than traditional univariate methods.

Qualitative Analyses

All interviews will be transcribed verbatim and imported into MAXQDA 2022 (VERBI Software) for analysis. The semistructured interviews will be analyzed using theoretical thematic analysis procedures as per the guidelines by Braun and Clarke [150,151]. Such an analysis is aimed at identifying patterns driven by an a priori theoretical framework or research questions. Themes will be identified using a semantic approach in which themes are derived from "the explicit meaning of the data and the analyst is not looking for anything beyond what a participant has said" [150]. Two coders will code the interview transcripts. To ensure the trustworthiness of the analysis, the primary coder will code each transcript, whereas the secondary coder will code 30% of the transcripts. Coding discrepancies will be resolved through discussion until consensus is reached. The codes will then be organized into categories, reviewed, and subsequentially organized into broader themes. Interviews from each treatment arm will be analyzed separately and then compared for convergence and divergence. The themes will be linked to patient-reported outcomes to explore whether specific themes vary according to the magnitude of change in the HADS anxiety score. To augment the HTE analyses, the study team will also explore whether qualitative themes differed by subgroup (eg, sex, race, ethnicity, education, outcome expectancy, and time since cancer diagnosis) within each treatment group.

Missing Data

As the only certain way to avoid biases from missing data is to collect complete data [152], the study team will strive to minimize missing observations by using study procedures that reduce participant burden. Participants who experience difficulties completing assessments on the web will have the option to complete assessments on paper or over the telephone with the research staff. Participants with time constraints or other barriers to completing outcome assessments will be given the option to complete only the primary outcome, that is, the HADS scale. Participants who withdraw from treatments will be encouraged to continue completing the outcome assessments. Reasons for withdrawal will be recorded for those who completely withdraw from the study. Given that missing data are inevitable in a prospective study, sensitivity analyses will be performed to assess the impact on the results of adjusting for patient disease progression or death, and analytical strategies that are as robust as possible to data losses will be applied. The study team will first explore whether missingness is associated with observed variables (eg, randomization arm and baseline outcome measures) by comparing patients with complete and incomplete data. Notably, the LMMs described previously will include patients with incomplete data under the missing at random assumption. However, the exploration of the data may deem the missing at random assumption to be inappropriate. Multiple imputation and pattern mixture models are well-established methods for addressing these issues [153,154]. Sensitivity analyses will be performed to evaluate the robustness of the LMM results by refitting the models after imputing the missing week 8 and week 26 outcomes using multiple imputation.

Sample Size and Power

The sample size is based on the primary hypothesis that MT is noninferior to CBT for anxiety reduction at weeks 8 and 26. Two tests will be performed to determine whether MT is

XSL•FO
RenderX

noninferior to CBT at reducing HADS anxiety at weeks 8 and 26, each with a noninferiority margin of Cohen *d*=0.35 SD for both comparisons. These comparisons will be based on the LMM coefficients for the time-by-arm interaction at weeks 8 and 26; however, the power calculation is based on 2-sample *t* tests of differences between the arms in their change scores. Therefore, the power estimate is conservative, that is, in the LMM-based analysis, there will be slightly higher power than the power calculation presented below, with all other assumptions held constant. Assuming 150 participants are randomized to each arm, 15% attrition, and a 1-sided significance threshold of *P*=.025 (controlling the overall type I error at 0.05 for our 2 primary end point comparisons), there will be 80% power to find MT noninferior to CBT with respect to the HADS anxiety subscale scores at weeks 8 and 26 within a noninferiority margin of Cohen *d*=0.35 SD.

The noninferiority margin was informed by a large study that used multiple rigorous methods to empirically estimate a difference of 1.7 points as the MCID for the HADS scales [120]. In preliminary data from CBT recipients with baseline HADS anxiety subscale scores ≥8, the SD for the HADS anxiety subscale score was 4.2 at week 8 [110]. In addition, in a large acupuncture trial of cancer survivors, among 159 patients with baseline HADS anxiety subscale scores ≥8, the HADS anxiety subscale score SD was 4.0 during follow-up [155,156]. On the basis of these studies, it is assumed that the HADS anxiety subscale score SD will be approximately 4.2. Dividing the raw-score MCID of 1.7 points by 4.2 yields a standardized difference, that is, Cohen *d*=0.40. The noninferiority margin of Cohen *d*=0.35 SD is smaller than the standardized MCID (Cohen *d*=0.40) of the HADS anxiety subscale; as such, the noninferiority margin and statistical approach will find MT to be noninferior to CBT only if MT is not meaningfully worse than CBT.

Regarding the sample size for the qualitative analyses, the number of participants required to draw meaningful conclusions from semistructured interviews is determined by saturation, that is, the point at which existing themes are fully understood and no new themes emerge through further data collection [157]. Prior research has indicated that thematic saturation can typically be obtained with <15 interview participants, although these findings were based on relatively homogeneous samples [158]. Given that this study is enrolling a more heterogeneous population, the plan is to conduct 30 interviews in each treatment arm to better capture the diverse perspectives.

Results

The MELODY study was funded by the Patient-Centered Outcomes Research Institute in July 2021. The IRB at MSK approved the study protocol in December 2021. The first study participant was enrolled in February 2022. As of January 2023, a total of 151 participants have been enrolled. Enrollment is expected to be completed by February 2024, and data collection is expected to be completed by September 2024.

Discussion

Cancer survivors represent one of the fastest growing populations in the United States [1]. Unfortunately, nearly 1 in 3 survivors experience anxiety symptoms as a long-term consequence of cancer and its treatment [3,5-9]. Although pharmacological treatment options are available, polypharmacy has become a growing concern for cancer survivors [28-31]. CBT is an established first-line treatment for anxiety [32,33,159], but not all individuals respond or wish to use CBT [45,47-49]. Although MT has a growing evidence base for anxiety in cancer populations [72-75], it remains unclear how MT compares with CBT as a treatment alternative. The MELODY study will address this evidence gap by determining the comparative effectiveness of telehealth-based MT and telehealth-based CBT for anxiety in cancer survivors. This study will intentionally support enrollment access for racially and ethnically diverse populations of English- or Spanish-speaking survivors from urban, suburban, and rural settings to improve the generalizability of the findings and to inform future efforts to reduce the disparities in survivorship care. By focusing on telehealth-based interventions, this study will capitalize on the accelerating digital trends in health care and society at large, helping patients and clinicians to navigate a growing array of remotely delivered care options.

Despite its novelty and strengths, the MELODY study has some limitations. First, the study lacks a usual care or waitlist control group and therefore cannot control for Hawthorne effects or regression to the mean; however, both MT [72-75] and CBT [40,43,160] have demonstrated effectiveness for anxiety symptoms in cancer populations. Second, although the study participants are screened for the presence of generalized anxiety disorder, they do not undergo a formal diagnostic interview for psychiatric disorders. Third, this study focuses on treating anxiety symptoms rather than an anxiety disorder. However, cancer care guidelines are often based on symptom severity rather than psychiatric diagnoses [161]. Furthermore, research indicates that anxiety symptoms are associated with poor quality of life and other problematic outcomes in cancer populations, even if symptoms do not meet the criteria for an anxiety disorder [23,162]. Thus, by focusing on symptoms, this study will align closely with clinical guidelines and enroll more patients who could potentially benefit from interventions.

In conclusion, the MELODY study is the first and largest randomized clinical trial to compare the short- and long-term effectiveness of remotely delivered MT and CBT for anxiety symptoms in cancer survivors. This trial has the unique potential to produce timely findings on 2 evidence-based, scalable, and accessible interventions to promote mental well-being during cancer survivorship.

Abstract

Background: Individuals with disabilities living with chronic health conditions require self-management programs that are accessible, sustainable, inclusive, and adaptable. Health coaching is an effective approach to promoting behavior change in self-management. Health coaching combined with telehealth technology has the potential to improve the overall quality of, and access to, health services.

Objective: This protocol outlines the study design for implementing the My Health, My Life, My Way intervention. The study will assess the feasibility, acceptability, and preliminary efficacy of the intervention for people with disabilities and optimize it.

Methods: The My Health, My Life, My Way study is a 4-arm randomized controlled trial evaluating the delivery of a 6-month intervention involving telecoaching, inclusive educational content, and technology access for 200 individuals with chronic conditions and physical disabilities. This study uses the engineering-inspired multiphase optimization strategy (MOST) framework to evaluate intervention components and assess whether a combination or lack of individual elements influences behavior. Participants will be randomized to 1 of 4 study arms: scheduled coaching calls and gamified rewards, no scheduled coaching calls and gamified rewards, scheduled coaching calls and flat rewards, and no scheduled coaching calls and flat rewards.

Results: The My Health, My Life, My Way study was approved by the institutional review board of the University of Alabama at Birmingham, and recruitment and enrollment will begin in May 2023. Data analysis is expected to be completed within 6 months of ending data collection. This clinical trial protocol was developed based on the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) 2013 statement.

Conclusions: The My Health, My Life, My Way study will help to optimize and improve our understanding of the feasibility and efficacy of a web-based self-management program for people with physical disabilities and chronic conditions. More specifically, My Health, My Life, My Way will determine which combination of interventions (coaching calls and gamification) will result in increased participation in self-management programming. The My Health, My Life, My Way intervention has the potential to become a scalable and novel method to successfully manage chronic conditions in people with disabilities.

Introduction

Background

The Centers for Disease Control and Prevention (CDC) defines chronic diseases as conditions that last ≥1 year and require ongoing medical attention or limit activities of daily living or both. In the United States, 6 in 10 adults are reported to have at least 1 chronic condition, whereas 4 in 10 adults are reported to have ≥2 chronic conditions [1]. The prevalence statistics of these individual conditions, which include diabetes, heart disease, and stroke, present an even more disturbing picture; for example, diabetes affects 12.2% of the overall American adult population and 25.25% of the population aged >65 years [1,2]. Similarly, approximately 1 in 3 deaths in the United States are attributed to heart disease, stroke, and other cardiovascular diseases [3]. In 2020, the CDC identified chronic diseases as the leading causes of death and disability as well as the leading drivers of annual health care costs of US $3.5 trillion [1].

Although physical disabilities increase the risk of developing chronic conditions, the inverse also occurs [4,5]. In fact, chronic conditions are the leading causes of disability [1]; for example, a report on the top causes of disability among adults in the United States found arthritis, heart conditions, and diabetes among the top 6 causes of disability [6]. This bidirectional relationship between disabilities and chronic conditions is indeed well documented. Diabetes is associated with a substantial increase in the risk of mobility disability [4]. Among older participants with diabetes (aged ≥60 years), diabetes was correlated with a 2- to 3-fold increased odds of not being able to perform each task of walking one-fourth of a mile, climbing stairs, or doing housework among both men and women [2]. In brief, chronic conditions and disability exist in a tightly knit closed loop, with the onset of any of these factors exposing the individual to increased risk for the other.

Current science has enabled multiple approaches to managing chronic disease conditions [7,8]. Approximately two-thirds of chronic disease management is conducted in primary care settings globally, whereas approximately one-fifth is conducted in community-based settings [9]. An extensive review of 145 chronic disease management studies notes that self-management support is the most frequently used intervention approach and the most effective strategy [7]. A meta-analysis specifically focused on chronic disease self-management strategies for diabetes, hypertension, and osteoarthritis spanning 53 randomized controlled trials concludes that these programs are indeed effective for people with diabetes or hypertension [10].

Within these programs, multiple approaches have been used to implement self-management programs. Health coaching is one of the most common and cost-effective mechanisms of delivering self-management programming [11-13]. Health coaches are health care professionals who are trained in relevant areas of focus based on the disease or condition being managed. Positive aspects of health coaching include removal of barriers and increased retention with human interactions that support individualized interventions. Health coaching can be conducted either synchronously or asynchronously, which further allows individualization to meet participant needs. However, health coaching has 2 challenges—resources and availability of time spent with participants—both of which affect the scalability of health coaching [14]. In addition to health coaching, gaming features incorporated into telehealth interventions have the capability to promote adherence and compliance and warrant adoption in disability-related self-management programs. Such features include obtaining points, participating in challenges or competitions, social communication, and person-centered customizations such as avatars. There is broad appeal to incorporating gaming elements into self-management programs for individuals with physical disabilities [15].

Although self-management programs are effective for behavior change in managing health conditions, individuals with physical disabilities who also experience chronic conditions lack inclusive and accessible self-management programming to positively affect their own behavior change. People with disabilities experience barriers that are different from those experienced by people without physical disabilities, including nutritional and dietary concerns, as well as barriers to physical activity (PA) participation. More specifically, these barriers include lack of accessible environments, appropriate equipment (eg, wheelchair accessibility), and low health literacy and knowledge [16-19]. As there are few studies evaluating the impact of self-management programs on individuals with physical disabilities, there is a demand to provide and optimize holistic self-management programming to those with physical disabilities who also experience chronic conditions.

In the goal to improve chronic disease management for people with disabilities, we propose the development of an inclusive telecoaching self-management program. To make the telecoaching approach sustainable and scalable, artificial intelligence techniques are used to reduce the time that health coaches spend communicating with each participant.

Objectives

This study is structured to serve as the optimization phase of the multiphase optimization strategy (MOST) framework and involves efficient randomized experimentation to estimate the effectiveness of individual intervention components and identify the optimal intervention package to improve the primary outcome, health-related quality of life after 6 months [20,21]. We will specifically focus on the physical functioning and emotional well-being subscale scores. The feasibility and acceptability of the My Health, My Life, My Way intervention will also be studied. This study protocol has been developed by using the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) 2013 statement [22]. It has been registered at ClinicalTrials.gov (NCT05481593).

Methods

Study Overview

Coaching Calls

Telehealth programs provide several advantages for individuals who want to improve their overall health and promote positive behavior change [23]. A substantial advantage of such programs is scalability or widespread availability, which allows participants to engage domestically or internationally. Many of these programs use human-to-human interactions to deliver web-based content to their clients or patients. In addition, some programs now implement artificial intelligence in conjunction with human interactions; for example, certain health care industries use chatbots to provide satisfactory and engaging interactions. A chatbot is a software platform that mimics human interaction with individuals using text or voice capabilities across different technologies, such as computers and smartphones. Within the literature, there is an acceptable level of satisfaction with using chatbot technology [24,25]. Because of the perceived benefits of telehealth programs using human interactions as well as web-based chatbots, it is necessary to evaluate whether scheduling coaching calls are necessary for successful self-management of chronic conditions. Each study arm in this project will incorporate either scheduled coaching calls or no scheduled coaching calls. Those receiving scheduled coaching calls will receive weekly calls with trained health coaches. Although individuals not receiving coaching calls will not have regular contact with a health coach, these participants can still contact health coaches using texting, chatting, or calling to initiate on-demand communication with the health coaching team.
