Our group previously used qualitative methods to assess barriers and facilitators to a coprimary outcome for this study: SI-IVC administration [32]. The data from this qualitative study and a systematic review of barriers to NMIBC guideline compliance [12] were used to identify intervention functions and behavior change techniques (BCTs) using the theoretical domains framework, as suggested in the implementation science literature [29,30,33].

Conclusions from systematic reviews and expert groups about improving effectiveness of audit and feedback were used to inform the design of the feedback and education. For example: "feedback may be more effective when baseline performance is low [16]"; "if the source is a supervisor or colleague [16]"; "it is delivered in both verbal and written formats [16]"; "it includes both explicit targets and an action plan [16]"; and "process of care measures are more positively influenced by feedback than outcome of care [26]." In addition, adding education to feedback may enhance the effectiveness of audit and feedback and so this strategy will be adopted [17]: "audit and feedback interventions will be more effective when recommendations related to the audit and feedback are based on good quality evidence" [18] and if it "creates opportunity to learn [18]."

The design of the feedback is further informed by Brehaut et al's [34] "15 suggestions for optimising effectiveness" of practice feedback interventions, the Clinical Performance Feedback Intervention Theory [31], and Colquhoun et al's [18] "Theory Informed Hypotheses" for improving effectiveness of audit and feedback.

Finally, the study steering group applied the APEASE (Affordability, Practicability, Effectiveness and Cost-effectiveness, Affordability, Side-effects, Equity) [29] criteria to the possible BCTs. This process highlighted suitable BCTs and feedback and education components detailed in Table 1.

The performance feedback will take the form of a web-based feedback dashboard that will be freely available at any time to those given access as well as a report of the individual cases that make up their performance outcomes and other components. The components of the feedback dashboard are described in Table 1 and Figure 3 and displayed in Figure 4.

The study team or lead investigator will receive an email detailing the feedback and education intervention. They will be asked to forward the email and feedback and education dashboard access to all the surgeons at their site and present and discuss the feedback at a departmental meeting. The lead investigator must then complete a survey about how the feedback and education were used and disseminated at their site and any specific changes they have made (Figure 3).

Table 1. Feedback and education intervention components, behavioral change techniques, theories, and mode of delivery.

Component	Description	Behavior change technique [30] or audit and feedback effectiveness theories or evidence	Mode of delivery
Performance feedback			
1. Peer-comparison graphs	• "Rate of achievement" scatter graphs displayed at both the site and surgeon level. All sites and surgeons are displayed but are anonymous, only current site data points are labeled with anonymous unique ID. Filterable by tumor grade.	Social comparison (6.2), "for those with a mastery goal orientation" feedback will be more effective if it involves comparison to others [18].	Web-based data dashboard, accessed via link in feedback email with site-specific passcode.
2. Performance statement	• The site's level of achievement, the average level of achievement, the target, and whether they are considered above or below an explicit target. This is based on the experience of the Scottish Quality Performance Indicator programme [15].	Social comparison (6.2), Explicit target given [16].	In feedback email and displayed alongside peer-comparison graphs on web dashboard.
3. Data description	• An optional pop-up box described how the graphs were generated including the description of numerator and denominator, advice on interpretation, justification of quality indicator selection, target and case selection.	Theory of trust or credibility and nature of the data [18].	An optional pop-up box alongside each peer-comparison graph in the web dashboard.
4. Action plan	• Actions specific to each behavior provided, for example, an operative recording proforma to improve documentation outcomes.	Instruction on how to perform the behavior (4.1), restructuring the physical environment (12.1), adding objects to the environment (12.5), prompts or cues (7.1).	Displayed beneath the peer-comparison graph of each quality indicator with links to either written resources or to download the operative proforma.
5. Individual case report	• The cases analyzed for each quality indicator, along with selected clinically relevant variables (eg, tumor details and operating surgeon code) can be reviewed in a filterable report, and individual database records easily entered for case review and discussion.	Theory of feedback specificity, user-guided experience, and social engagement [18].	The site-specific reports are available in the study REDCap[a] database environment, instructions about how to use are included in the feedback email and dashboard.
6. Provide feedback more than once	• The feedback dashboard is available throughout and displays live performance. Sites will be encouraged to engage with this at a departmental level regularly. Feedback email is resent encouraging ongoing feedback engagement every 2 weeks.	Provide multiple instances of feedback [34].	Same delivery method.
Education			
7. Evidence and guideline education	• Key evidence and related guidelines about why the behavior is important are summarized and links are provided to published evidence.	Information about health (5.1) and social and environmental consequences (5.2).	Provided beneath the peer-comparison graph for each of the quality indicators. Links to web-hosted publicly available resources. Accessible at any time after dashboard access is given.
8. Tutorial videos	• Evidence reviewed and practice from a center of excellence presented by an expert in the field. Operative video tutorials for practical skills provided. • The videos can be accessed at any time, and access is unsupervised. Collaborators are encouraged to review them together at departmental meeting but they may also be accessed individually.	Instruction on how to perform the behavior (4.1) and demonstration on how to perform the behavior (6.1) by a credible source (9.1).	Links to web-hosted videos provided beneath the peer-comparison graphs on the dashboard and in the feedback email. Accessible at any time after dashboard access is given.

Figure 4. Intervention and design. Web-based performance feedback and education dashboard—accessible to only sites in the intervention arm during the study. Numbers in the boxes relate to the components in Table 1.

Prospective Data Collection After Randomization

Sites will be asked to submit observational data about all consecutive eligible TURBT cases performed after they have been randomized. Sites in the feedback and education arm will only be permitted to submit cases in the prospective phase once the mid-point survey has been received. The purpose of the midpoint survey was to determine if any unprompted changes to practice or performance had been made since the site registration survey was completed and confirm that sites had disseminated the education and feedback at their site (if relevant) and assess how this had been done.

Primary Outcomes

Principles

The study will use 4 coprimary outcomes. The primary outcomes are key "surgical quality indicators" or "process measures." The outcomes were chosen through a combination of evidence, guidelines associating their performance with improved bladder cancer outcomes, expert steering group consensus, and independent external peer review. Primary outcomes were chosen to meet the following criteria: (1) They are behaviors or practices associated with the primary operation or occurring at the time of the primary operation. (2) It is possible for the surgeon to directly influence these practices. (3) They are practices recommended by professional guidelines or evidence associating them with improved outcomes. (4) They can be objectively measured through review of the standard patient record.

Coprimary outcomes were chosen because not all behaviors are applicable to all patients and no single behavior may indicate overall quality. The 4 outcomes chosen draw on experience and the outcomes used in the Scottish Quality Performance Indicator programme and work by Mariappan et al [14,15].

The intervention will be considered effective if any one of the 4 coprimary outcomes is significantly improved. "Eligible cases" and excluded cases were determined for each coprimary outcome. Eligible cases (after exclusions) make up the denominator for calculation of the proportion of cases achieving the outcome.

Quality Performance Indicator 1: The Proportion of Eligible Cases Where Detrusor Muscle Is Present in the Surgical Specimen

Rationale

International evidence-based guidelines include clear recommendations related to TURBT [5,7]. There is evidence that resection of detrusor muscle at the index TURBT is associated with reduced early recurrence rate [6,22] and

XSL•FO
RenderX

long-term mortality [25] and is more likely to be resected by experienced than inexperienced surgeons [6,22]. If detrusor muscle is not obtained, it is not possible to accurately determine the tumor stage and all of the tumor may not have been removed, which may lead to recurrence. It is accepted that detrusor muscle resection is not appropriate in all patients and is a clinical judgment. Therefore, the average rate of detrusor muscle will be used as a performance indicator.

Eligibility

All cases where the tumor maximal diameter is estimated at >5 mm by the operating surgeon.

Assessment

The outcome will be determined from the surgical pathology report.

Exclusions

Where the data for the presence or absence of detrusor muscle in the specimen are investigator-missing, the case will be excluded.

Quality Performance Indicator 2: The Proportion of Eligible Cases Where SI-IVC Is Administered Within 24 Hours of TURBT

Rationale

There is high-certainty evidence supporting the use of SI-IVC, such as Mitomycin C following TURBT. It is known that SI-IVC administration can significantly reduce the rate of NMIBC recurrence [23,35-39]. EAU and AUA guidelines recommend administration of SI-IVC within 24 hours of surgery in patients most likely to benefit [5,7].

Eligibility

All cases at sites where it is possible to give SI-IVC.

Assessment

The outcome will be determined from review of the patient record.

Exclusions

It is anticipated that a small number of sites will be unable to provide SI-IVC due to local or national service, supply, or economic restraints. These sites will be identified from the study registration survey and excluded from this indicator a priori. Cases where a patient has a documented allergy to SI-IVC will be excluded. Where this data field is investigator-missing, the case will be excluded from this outcome.

Quality Performance Indicator 3: The Proportion of Eligible Cases Where Resection Completeness Is Documented in the Operation Record

Rationale

Guidelines strongly recommend documenting the completeness of resection [5]. Using a TURBT proforma to document the surgical procedure and findings at surgery in a standardized way is associated with improved patient outcomes [15,24,40]. Completely removing all visible tumors is a core surgical principle in cancer surgery. Documentation of this is essential for subsequent multidisciplinary team meeting decisions on the management of individual patients as it determines the need for repeat resection, which can improve oncological outcomes in selected patients [41].

Eligibility

All cases included in the study.

Assessment

The outcome will be determined from review of the operation note. To achieve the indicator, a statement that the resection was either complete, incomplete, or uncertain is required. Where there is no statement of resection completeness in the operation record the indicator will be failed.

Exclusions

Where this data field is investigator-missing, the case will be excluded from this outcome.

Quality Performance Indicator 4: The Proportion of Eligible Cases Where All of the Tumor Number, Size, and Location Are Documented in the Operation Record

Rationale

Guidelines strongly recommend documenting the tumor location, appearance, size, and multifocality [5]. Tumor size and number are associated with recurrence risk and are required to risk-stratify patients according to European Organisation for Research and Treatment of Cancer (EORTC) risk categories as recommended by both AUA and EAU guidelines [5,7]. Documentation of these factors and subsequent risk stratification allows multidisciplinary team meeting decisions for individual patients, determining the need for adjuvant treatments, which determine long-term oncological outcomes. Documenting tumor location also allows appropriate assessment of recurrence and resection completeness at reresection surgeries and during cystoscopic surveillance.

Eligibility

All cases included in the study.

Assessment

The outcome will be determined from review of the official operation note. To achieve the indicator, a statement of the tumor number, size (an assessment of tumor maximal diameter and at least to a resolution of <3 cm or ≥ 3 cm [a risk category cut-off in the EAU guidelines]), and location is required. Where record of any of these 3 features is missing from the operation record, the outcome will be failed.

Exclusions

Where this data field is investigator-missing, the case will be excluded from this outcome.

Secondary Outcomes

Key Secondary Outcome: Early Recurrence Rate

Rationale

International guidelines recommend that a “check” cystoscopy be performed approximately 3 months after complete TURBT [5,7]. The rationale is that recurrence detected at this early stage

XSL•FO
RenderX

is due to surgical failure rather than disease process [6]. Therefore, the early recurrence rate represents an outcome of surgical quality.

Eligibility

All cases where a cystoscopy has been performed within 6 months of complete index TURBT or planned completion re-TURBT, or, in cases where an adjuvant treatment course is given prior to check cystoscopy, at a check cystoscopy performed within 12 months.

Assessment

The outcome will be determined from review of the patient record. Recurrence will be defined as either (1) a clinical assessment of "highly likely" recurrence where fulguration is applied, and no surgical specimen is obtained or (2) when a surgical specimen is obtained, and then histological confirmation of cancer will be required.

Exclusions

Where this data field is investigator-missing. Where muscle-invasive bladder cancer is identified in either the primary or re-TURBT pathology. Where the patient is deemed not fit or appropriate for further surveillance.

Other Secondary Outcomes

Other secondary outcomes include (1) the proportion of eligible patients in whom all applicable primary quality indicators are achieved (not all quality indicators are applicable in every patient) and the association of this composite outcome with early recurrence rate and (2) the rate of complications of grade 3 or greater, within 30 days of surgery according to the Clavien-Dindo [42] classification.

Sample Size

The intervention will be delivered to centers, and so the primary outcomes will also be measured at the center level. The only published data about intersite achievement of the listed coprimary outcomes are the Scottish Quality Performance Indicator programme covering 11 sites in Scotland. The outcome with the largest SD (SI-IVC) was used to determine the overall sample size. With mean 0.651 (SD 0.2) for SI-IVC, recruiting 172 sites (86 per arm) would give 90% power to detect a difference of 0.1 between the intervention and control groups at the 5% significance level. Where a smaller SD of 0.1 (detrusor muscle in specimen) or 0.15 (resection documenting) can be assumed, this would provide 90% power at the 5% significance level to detect differences of 0.05 and 0.075, respectively. It is possible that some sites may have missing data for 1 or more of the coprimary outcomes. Missing data will not be imputed for the primary outcomes. In that case, the site will be excluded from the analysis for that outcome. A sensitivity analysis will be performed to determine the effect of missing data in that outcome. An extensive international marketing campaign will be undertaken to ensure sample size is reached, along with endorsement of the study by the British Association of Urological Surgeons to all urology centers in the United Kingdom.

Analysis

The average rate of achievement of each of the 4 co-primary outcomes per site will be compared between sites that received education and feedback and those that did not. The primary outcomes will be analyzed using mixed effects linear regression to compare the outcome between the group that received audit, feedback, and education and the control group. The primary outcomes are the proportion of cases where the relevant outcome is obtained and measured at the site level (a continuous variable). The regression model will have fixed effects for the study arm (intervention group); audit already in place at the site before the study; and the baseline achievement of the relevant outcome. A random effect will be included for the region. Outcomes will be assessed in subgroups of low- and high-grade tumors, tumors with estimated maximum diameter of ≤3 cm or >3 cm and in single vs multiple tumors for the detrusor muscle, and intravesical chemotherapy outcomes.

The early recurrence rate is a secondary outcome. This is measured at the patient level. In this instance, the outcome is binary. A mixed effect logistic regression will be used including random effects for site and surgeon to incorporate the 2 levels of clustering. Fixed effects will be included for intervention arm and tumor variables known to be associated with early recurrence (tumor size, tumor number, grade, and stage). Patient age will also be included as a fixed effect. A second analysis will be undertaken for the early recurrence outcome at the patient level to determine if the quality indicators are associated with reduced recurrence rate regardless of performance feedback.

Secondary Analyses

This study is an observational audit with an embedded cluster randomized design and was planned so that the following factors could be analyzed for association with TURBT quality indicator achievement and early recurrence rate: (1) surgeon factors: (a) the experience of the operating surgeon in years, (b) total number of cases performed by the surgeon to date, (c) number of cases performed per month on average in the last year, and (d) a self-declared specialist interest in bladder cancer; (2) TURBT surgery performed on a dedicated TURBT list; (3) the estimated annual TURBT case volume of the site; (4) the use of en-bloc resection; (5) the use of diagnostic visual aids including: (a) photodynamic diagnosis–assisted resection, (b) narrow band imaging, and (c) Storz Professional Image Enhancement System; (6) the length of inpatient stay; (7) geographical region—continent; (8) World Health Organization health care quality and access index for the country; (9) the preexistence of a TURBT audit at the site; (10) the use of re-TURBT; (11) the use of primary adjuvant BCG or Mitomycin C; and (12) patient factors: age and sex.

Discussion

This study aims to use a distributed collaborative model to deliver a site-level web-based performance feedback intervention to improve the quality of endoscopic bladder cancer surgery. The goal is to gain incremental benefit across vast numbers of patients using a simple and cheap intervention that will amount to large absolute benefits across the population of

XSL•FO
RenderX

patients with NMIBC. We have considered previous advice from systematic reviews of previous audit and feedback interventions and used the theoretical domains framework to design the feedback intervention. We have worked closely with expert international clinical, methodological, and statistical professionals to ensure quality of study design.

The effectiveness of audit and feedback in improving professional practice varies depending on "baseline performance and how feedback is provided" as well as setting [16]. We have determined that a clinically relevant relative difference between intervention and control arms is 10% and powered this study accordingly. Electronic audit and feedback have also been found to have variable effectiveness, and a systematic review recommended closer attention to theoretical domains targeted [21]. We have done this as part of the study design. This study is unique because of its global multicenter reach and therefore aspires to power a cluster-cluster randomized controlled study design to confidently determine the effect of the intervention. The Hawthorne effect will be accounted for since we measure performance retrospectively (when the study was not known about) and then compare 2 parallel arms in the randomized study. There have been previous time-series studies of audit and feedback in TURBT surgery, which suffer from the lack of a contemporaneous control group [15,40]. To our knowledge, this will be the first randomized study of audit and feedback in TURBT surgery. Limitations of the study design include the pragmatic intervention—clinicians can choose to engage or not, and implementation at the site level is left up to local teams. The site-level intervention and analysis will limit the ability to make conclusions about the behavior of individuals. In conclusion, this study will determine if audit, feedback, and education is effective in improving professional practice in the quality of TURBT surgery and if this reduces NMIBC early recurrence rates.

Acknowledgments

We would like to acknowledge the input and expertise of our protocol external peer reviewers: Christopher Blick, Ashish Kamat, Jim Catto, Hugh Mostafid, Richard Sylvester, and John McGrath. This study was supported by the Rosetrees Trust grant CF1\100002, the Urology Foundation, Action Bladder Cancer UK, Karl Storz agreement, Photocure agreement, Medac Pharma agreement, and the British Journal of Urology International Charity. None of the study funders had any academic input to the study design analysis or reporting. This study was sponsored by British Urology Researchers in Surgical Training.

Data Availability

The data sets generated and analyzed during this study are not publicly available due to a need to maintain anonymity of the included sites as set out in the study agreement but are available from the corresponding author on reasonable request. All statistical code will be made available upon request.

Authors' Contributions

VK, KG, SML, and NB conceptualized the study. VK, KG, NB, PM, SML, LA, DC, SK, KC, MK, ED, BG, PH, GM, and JY-CT designed the study. VK, KG, NB, PM, SML, LA, DC, SK, KC, MK, ED, BG, TOB, and MN were part of study steering and endpoint adjudication committee. KG, NB, VK, and KC managed the data. KG wrote the manuscript. VK, KG, NB, PM, SML, LA, DC, SK, KC, MK, TOB, MN, ED, BG, AA, AL, TA, FG, PH, GM, and JY-CT reviewed the manuscript.

Conflicts of Interest

This study has received funding from 3 industry sources—Karl Storz, Photocure, and Medac Pharma. Funds were provided as unrestricted grants with no influence on the design, analysis, or reporting of the study. PM is a designer and chief investigator for the Scot BC Quality OPS clinical project.

Abstract

Background: Depression is highly prevalent in individuals on hemodialysis, but it is infrequently identified and remains undertreated. In this paper, we present details of the methodology of a randomized controlled trial (RCT) aimed at testing the feasibility and preliminary efficacy of a 5-week positive psychological intervention in individuals on hemodialysis with comorbid depression delivered using immersive virtual reality (VR) technology.

Objective: We aim to describe the protocol and design of the *Joviality* trial whose main objectives are 2-fold: determine the feasibility of the *Joviality* VR software through metrics capturing rates of recruitment, refusal, retention, noncompliance, and adherence, as well as end-user feedback; and assess preliminary efficacy for outcomes measures of depressive symptoms, psychological well-being and distress, quality of life, treatment adherence, clinical biomarkers, and all-cause hospitalizations.

Methods: This 2-arm RCT is scheduled to enroll 84 individuals on hemodialysis with comorbid depression from multiple outpatient centers in Chicago, Illinois, United States. Enrollees will be randomized to the following groups: VR-based *Joviality* positive psychological intervention or sham VR (2D wildlife footage and nature-based settings with inert music presented using a head-mounted display). To be eligible, individuals must be on hemodialysis for at least 3 months, have Beck Depression Inventory-II scores of ≥11 (ie, indicative of mild-to-severe depressive symptoms), be aged ≥21 years, and be fluent in English or Spanish. The *Joviality* VR software was built using agile design principles and incorporates fully immersive content, digital avatars, and multiplex features of interactability. Targeted skills of the intervention include noticing positive events, positive reappraisal, gratitude, acts of kindness, and mindful or nonjudgmental awareness. The primary outcomes include metrics of feasibility and acceptability, along with preliminary efficacy focused on decreasing symptoms of depression. The secondary and tertiary outcomes include quality of life, treatment adherence, clinical biomarkers, and all-cause hospitalization rates. There are 4 assessment time points: baseline, immediately after the intervention, 3 months after the intervention, and 6 months after the

XSL•FO
RenderX

intervention. We hypothesize that depressive symptoms and hemodialysis-related markers of disease will substantially improve in participants randomized to the VR-based *Joviality* positive psychology treatment arm compared with those in the attention control condition.

Results: This RCT is funded by the National Institute of Diabetes and Digestive and Kidney Diseases and is scheduled to commence participant recruitment in June 2023.

Conclusions: This trial will be the first to test custom-built VR software to deliver a positive psychological intervention, chairside, in individuals on hemodialysis to reduce symptoms of depression. Within the context of an RCT using an active control arm, if proven effective, VR technology may become a potent tool to deliver mental health programming in clinical populations during their outpatient treatment sessions.

KEYWORDS

virtual reality; hemodialysis; positive psychology; emotional well-being; mindfulness; depression; comorbid depression

Introduction

Background

End-stage kidney disease (ESKD) requiring hemodialysis is a taxing condition that requires difficult self-care practices (eg, multiple weekly treatment center visits) [1]. Depression is the most pervasive psychological issue in this patient population and presents a substantial added burden: one-third of individuals on hemodialysis in the United States report compromised emotional well-being [2]. Comorbid depression exacerbates disease progression and is associated with increased markers of systemic inflammation; compromised cellular immunity [3]; and adverse clinical outcomes, including lower rates of treatment adherence [4], greater hospitalization risk, and shorter survival [5]. Possible mechanisms by which depression heightens morbidity and mortality in individuals on hemodialysis include negative effects on treatment adherence, impairment of the immune system, and hampering of healthy dietary practices [6].

Few individuals on hemodialysis experiencing psychological distress are currently being diagnosed and treated [7]. Pharmacotherapy has seen limited application, given the substantial pill burden among individuals on hemodialysis and reluctance by physicians given the possibility for drug-drug interaction and low medication adherence [8]. Health care providers and patients are reluctant to add another drug to the existing regimen unless severe psychopathology (eg, suicide ideation) is evident [8]. Despite the limited uptake of antidepressant medication in people on hemodialysis, nonpharmacologic strategies to boost psychological well-being continue to be underused and understudied [9,10].

The few published trials on efficacy of psychosocial strategies to improve depressive symptoms in individuals on hemodialysis overwhelmingly focus on face-to-face delivery of cognitive behavioral therapy [10]. Although cognitive behavioral therapy shows promise in reducing symptoms of depression and improved compliance of fluid intake [11,12], this approach presents significant challenges given the complexity and intensiveness needed for deployment, which requires highly trained and skilled clinicians for appropriate delivery and multiple in-person communications.

Rationale for the Study

There is a critical need to identify practical, well-accepted, sustainable, and cost-effective strategies to reduce depressive symptoms and increase levels of psychological well-being in individuals on hemodialysis considered at risk. Fittingly, there has been a proliferation of programs that promote psychological assets and resilience, with the recognition of the importance of focusing on individual-level strengths and human flourishing—instead of solely focusing on negative psychological indicators, deficits, and emotional pathology [13,14]. Evidence shows that positive psychological assets (eg, optimism, positive affect, life meaning, and purpose) are uniquely related to better emotional and physical well-being, independent of the effects of negative emotion [15-21]. A meta-analysis of 25 positive strengths-based interventions targeting constructs such as gratitude, happiness, and optimism found a medium effect size for relief of depressive symptoms (median r=0.26), with stronger effects seen for phenotypes of participants with current depressive symptoms [22,23]. Published studies comparing positive psychology interventions with treatment as usual show effectiveness and durability similar to those of traditional psychotherapy or pharmacotherapy [22].

Accompanying expanded focus on strengths-based approaches is an increase in the use of technology to deliver these interventions that explicitly target boosting of positive emotions and factors of resilience. Testing remote distribution options (eg, mobile phone apps) for strengths-based interventions provides evidence of their efficacy and cost-effectiveness. Advantages of web-based delivery options include generally lower cost, easier dissemination, more consistent fidelity to the intervention protocol through automation that counteracts going off script, and greater accessibility in settings with Wi-Fi availability [24,25]. Comparative effectiveness trials document similar effect sizes for internet-based psychotherapy compared with traditional face-to-face approaches, with high patient satisfaction when rating these high-technology platforms [26,27]. Barriers to entry associated with traditional in-person forms of therapy may be bridged using web-based platforms that offer low-threshold and convenient at-home alternatives.

XSL•FO
RenderX

A participative technology that has rarely been used in individuals on hemodialysis is fully immersive 3D virtual reality (VR), although recent evidence in other clinical populations hints at its promise as an effective therapeutic tool [28]. VR is an evolving technology that presents an immersive experience to transport users to fictitious yet realistic and lifelike environments. Users wear a head-mounted display (HMD) or headset that recognizes physical motion (eg, head movement and remote control) to navigate VR (3D) worlds, which can replicate realistic settings or complex science fiction environments [29]. A meta-analysis confirms the utility of VR for pain reduction when pooling 11 trials that included individuals experiencing varied pain-inducing therapies or complaints (ie, burn injuries and wound redressing, postsurgical pain, and complex dental procedures, among others) [30]. This is the question that remains: "How might VR technology be used in individuals on hemodialysis to decrease procedural pain and discomfort and simultaneously deliver strengths-based programming to address the pervasive psychological distress experienced in this patient population?"

Hypothesis and Objectives

To answer the question of the utility of VR in individuals on hemodialysis, we describe the design for a randomized controlled trial (RCT) that tests whether VR is a viable interface to deliver an evidence-based positive psychological intervention as a means to boost emotional well-being and reduce symptoms of depression in individuals on hemodialysis. VR has the benefit of allowing individuals on hemodialysis to digitally travel to multiple settings across the globe and briefly leave the confines of the clinic, which may offer further salutary benefits.

Specifically, we describe the design and protocol for testing our VR-based *Joviality* software, intended to decrease depressive symptoms and boost psychological well-being in individuals on hemodialysis. This study details the methodology of a prospective, 2-arm, parallel RCT that is set to launch in the June of 2023 and that has the following aims: to (1) evaluate the acceptability and feasibility of a 5-week positive psychological intervention, delivered using a VR platform, through the consideration of rates of recruitment, refusal, retention, noncompliance, and adherence, as well as end-user feedback; and (2) test the preliminary efficacy of our VR-based positive psychological intervention in comparison with that of an active control arm on outcomes of depressive symptoms, psychological well-being and distress, quality of life, treatment adherence, clinical biomarkers, and all-cause hospitalizations in individuals on hemodialysis at 3 and 6 months after the intervention. At trial conclusion, we expect that our software will have high system usability with superior performance, offering an enjoyable and positive end-user experience, and that participants in the *Joviality* treatment arm will show significant improvements in psychological well-being, treatment adherence, and hospitalization rates.

Methods

Overview and Study Design

This study describes the design and protocol of a 2-arm RCT, inclusive of both groups requiring use of an HMD: (1) VR-based *Joviality* positive psychological intervention, an immersive program that teaches 8 different skills to boost positive emotion with focused lessons on noticing of positive events, positive reappraisal, gratitude, acts of kindness, and mindful or nonjudgmental awareness, among others; and (2) sham VR [31], which consists of 2D wildlife and nature-based videos with inert background music. This prospective trial plans to recruit and enroll study participants from the University of Illinois Hospital Outpatient Dialysis Center, DaVita Kidney Care, and Nephrology Associates of Northern Illinois and Indiana. Both arms will be exposed to the virtual environments intraprocedurally during regular hemodialysis treatment sessions (ie, 3 times per week for 25- to 30-minute immersive sessions on each occasion). After the 6-month assessment period, participants in the control arm will be given access to the *Joviality* software.

Randomization procedures will use the web-based REDCap (Research Electronic Data Capture; Vanderbilt University) system, with 1:1 allocation across trial arms. Block randomization will occur among varying block sizes of 4, 6, and 8, with stratification by sex, depressive symptom severity, and recruitment site. The randomization procedure will be generated by our lead statistician (RD) and implemented by the project director (GM), who will actively participate in intervention delivery. However, the project director will not be involved in survey assessments to ensure safeguards against the risk of bias. Research staff conducting survey assessments will be blinded on assignment across intervention arms. Enrolled participants will also be blinded to randomization assignment, with a generic description of the VR content as *VR travel* and identification as either *groupA* or *groupB*.

Ethics Approval

This VR-based trial has been approved by the institutional review board of the University of Illinois Urbana-Champaign and the University of Illinois Chicago (19190). Following requirements for an ethics approval process, all study-related documents (eg, recruitment flyers and consent forms) conform to specific language approved by the lead institutional review board, inclusive of its content, elements, and wording.

Trial Registration and Guidelines

The trial has been registered a priori at ClinicalTrials.gov (NCT05642364). The clinical trial will follow published CONSORT (Consolidated Standards of Reporting Trials) guidelines, along with auxiliary standards of the CONSORT 2010 statement for social and psychological interventions (CONSORT-SPI 2018) [32].

Staff Training, Data Collection, and Participation

Research staff and coinvestigators will be required to undergo human participants research training by completing the National Institutes of Health Human Research Protection Training module or the Collaborative Institutional Training Initiative program. Survey data will be collected using Health Insurance Portability and Accountability Act (HIPAA)–compliant server software, with each enrollee assigned a unique identifier to ensure privacy and confidentiality. All enrollees will provide written informed consent. Enrollees of both trial arms will be compensated for

XSL•FO
RenderX

their time and participation. They will receive US $120 for participation in trial activities, specifically, for the completion of all survey assessments (US $30 for baseline assessment and US $30 for each follow-up measure).

Sample Size

We estimated sample size requirements of a 2-arm RCT to evaluate whether our VR-based positive psychological intervention will result in clinically meaningful improvements in depressive symptoms compared with an active control. The following operational characteristics were assumed: (1) medium Cohen effect size of d=0.35, (2) a within-participant correlation of depressive symptoms over time (P=.60), (3) a 1-sided type I error probability of 0.10 [33], and (4) a statistical power of 85% [34]. This approach yields an estimated sample size requirement of 34 participants per study arm under equal allocation. Assuming an attrition rate of 20%, an updated estimation produces a sample size of 34 / 0.8 = 42 participants per study arm.

Study Setting, Participants, and Eligibility

Trial participants must meet the following inclusion criteria: (1) on hemodialysis for at least 3 months before trial enrollment, (2) a Beck Depression Inventory-II (BDI-II) score of ≥11 [35], (3) age ≥21 years, (4) sufficient visual and audio acuity to enable immersion in the VR world, and (5) fluent in English or Spanish. Participation is restricted to individuals with a BDI-II score of ≥11 because this indicates elevated depressive affect and represents a group that may procure most benefit from the intervention (ie, greatest possible effect size) through targeting of psychological well-being and resilience. Women are eligible independent of pregnancy status. The exclusion criteria include (1) unavailable for study period; (2) cognitive impairment denoting dementia [36]; (3) diagnosis severely limiting life expectancy (eg, metastatic cancer); (4) physical limitations restricting use of an HMD (eg, facial injury); and (5) a history of epilepsy, seizures, or vertigo.

Recruitment and Enrollment

Potentially eligible patients will be recruited in person by approaching them in the waiting room of the clinic before or during regularly scheduled hemodialysis sessions and at other suitable times during the patient consult or treatment period. Patients will also be remotely recruited through telephone calls made by research staff through contact information extracted from electronic medical records (EMRs). Research staff will also distribute flyers and brochures (chairside) to individuals on hemodialysis during regular clinic visits. Once full eligibility is determined and the patient expresses willingness to enroll in the trial, they will be provided a copy of the informed consent form for their signature. After submitting the signed informed consent form and before randomization, enrollees will complete the baseline assessment consisting of REDCap interviewer-led surveys.

Intervention Arm: VR-Based Joviality Positive Psychological Intervention

The VR *Joviality* software architecture and content were built by the University of Illinois Urbana-Champaign Center for Innovation in Teaching & Learning, as led by the digital art director (KS) and principal investigator (RH). Adapted from the web-based course developed by Cohn et al [25], that is, *Developing Affective Health to Improve Adherence*, the original text-based curricula were transposed into a VR software system (ie, Unity [Unity Technologies]) using agile design principles, including brainstorming, storyboarding, designing, testing, and refining, thus transforming textual content into an interactive 3D environment. Finally, software design features have integrated an interface to easily modify the language in which content is presented (ie, English vs Spanish).

The 3D VR software, called *Joviality*, is a strengths-based positive psychological intervention that consists of a skills-based curricula to boost positive emotion and foster individual-level characteristics of resilience and grit. Our multicomponent 5-session intervention teaches the following eight skills: (1) noticing positive events, (2) amplifying positive events, (3) gratitude, (4) behavioral activation, (5) mindfulness, (6) positive reappraisal, (7) personal strengths, and (8) acts of kindness (Table 1). The skills are presented sequentially, starting with noticing of positive events in daily life and ending with the benefits of volunteerism and carrying out of acts of kindness. Only 1 new lesson is made available each week. Successive curricular content is unlocked only after all assigned weekly activities have been completed. Once the lessons are unlocked, participants can revisit prior lessons as a refresher or if they enjoyed a particular previous module.

Each skill is taught in a distinctive virtual environment using the Meta Quest Pro (October 2022 release date). The delivery of intervention content will require VR use for no more than 30 minutes during each hemodialysis session (ie, 30-minute sessions thrice weekly)—this will deter social isolation because patients will have ≥3 hours remaining to interact with neighboring patients and staff. VR immersion will only occur chairside when patients are already sedentary and in a seated position during regularly scheduled hemodialysis treatment. Table 1 details the weekly curricular content and the VR setting in which each lesson is delivered. As noted previously, end users on hemodialysis will be able to select whether the curricular VR content is presented in English or Spanish based on their preference and fluency.

As part of *Joviality*, end users begin each lesson in a virtual lobby outfitted with lounge furniture, flatscreen television, and an instructional green wall where they sequentially select curricular lessons (Figure 1). Skill 1 takes place in a Japanese garden with lush greenery, wildlife, and a waterfall, where end users learn about positive events while snapping virtual photographs using head gaze movement. During skill 2, end users are transported to an art gallery where they participatively display the photographs they took while at the Japanese garden. The lesson on gratitude takes place in an outdoor patio where end users receive didactic instructions, view 2D videos augmenting curricular content, and visit 3D environments to appreciate nature and wildlife. Skills 4 and 5 are situated in a greenhouse, garden, or beach environment where end users play interactive games reinforcing lessons on behavioral activation, mindfulness, and meditation. The remaining lessons take place in the main lobby space. Across all lessons, VR environments

XSL•FO
RenderX

present didactic instructions and interactive games and quizzes, along with 2D videos throughout.

Table 1. Joviality positive psychology curricular content and lessons.

Week and title	Description	Virtual reality environment
Week 1		
Noticing positive events	Recognizing and focusing on positive events in life	Japanese garden
Amplifying positive events	Capitalizing on positive events and making the events more vivid and longer lasting	Museum gallery
Gratitude	Practicing thankfulness and appreciation of life, positive circumstances, and family or friends	Outdoor patio
Week 2		
Activation	Breaking out of the harmful spirals that worsen emotions	Greenhouse
Week 3		
Mindfulness and meditation	Paying attention and developing nonjudgmental awareness of one's thoughts, feelings, and physical sensations in the present moment	Meditation garden and private beach
Week 4		
Positive reappraisal	Understanding positive reappraisal and that reappraisal can substantially increase positive emotions in the face of stress, particularly when the silver lining is identified	Lobby and neighborhood bus stop
Personal strengths	Recognizing and enhancing a unique set of personal strengths, talents, skills, and positive qualities	Lobby
Week 5		
Acts of kindness	Understanding the positive effects on mental and physical health when engaging in kind acts, volunteerism, and helping others	Lobby

Figure 1. Scenes across Joviality modular lessons.

Control Arm: Nonimmersive Sham VR

Participants randomized to the control arm will receive a rigorous placebo, based on the clinical trial guidelines of the VR Clinical Outcomes Research Experts panel [37], that consists of 2D nonimmersive visual content displayed on the HMD [28,38]. Footage of wildlife and nature-based settings are visually displayed as part of the sham VR with inert music that is unlikely to promote high levels of relaxation or distraction. The sham VR experience has very passive features such that it mimics viewing content on a large flatscreen television. Passive viewing during the sham VR experience rotates content using 20 different videos and has a duration time that is matched to that of *Joviality* over the 5-week intervention period. The delivery of the sham VR content will use the same VR hardware (ie, Meta Quest Pro) as that of the intervention arm to further promote the blinding of end users and research staff.

Study Outcome Measures

The VR-based randomized trial has 4 assessment time points: baseline (T0), immediately after the intervention (T1; five weeks after baseline), follow-up 1 (T2; three months after the intervention), and follow-up 2 (T3; six months after the intervention). Figure 2 provides a visual of the design and timeline of survey measures. Staff collecting baseline and follow-up data (interview assessors), will be blinded to intervention assignment of enrollees and will not be involved in randomization procedures or any aspects of intervention delivery.

Figure 2. Joviality trial timeline and flowchart. VR: virtual reality.

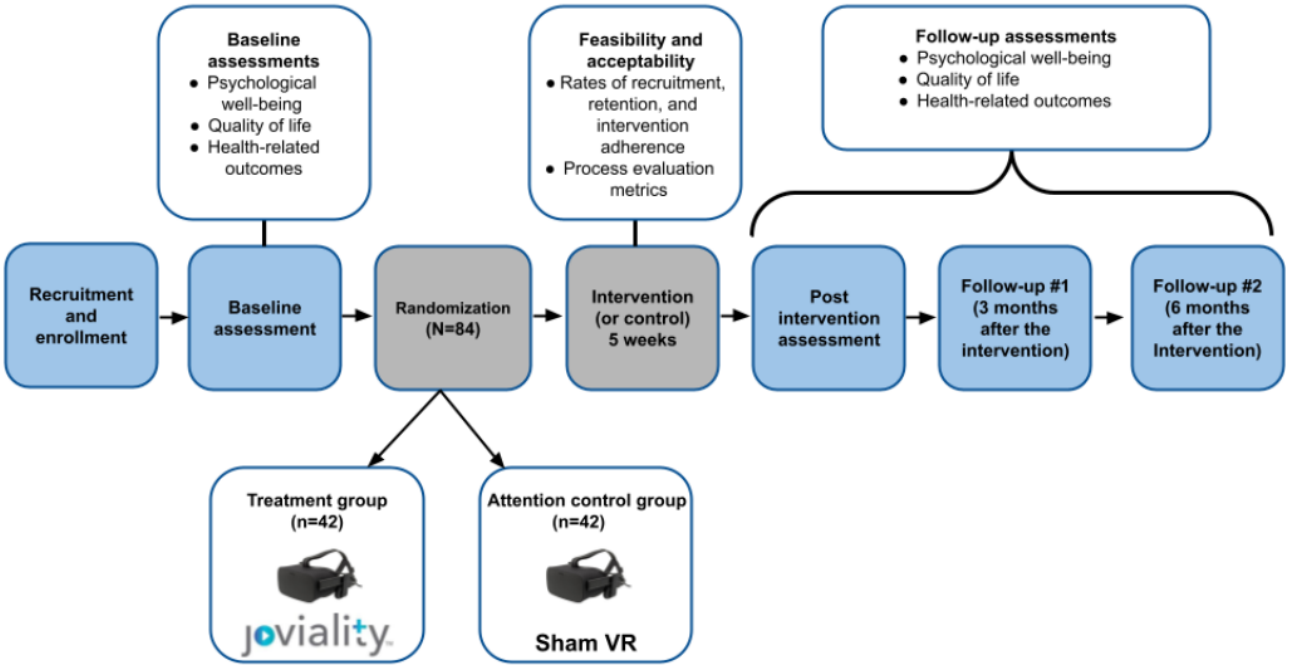

Table 2 details the primary, secondary, and tertiary outcomes of the RCT, along with process evaluation metrics. The primary outcome testing efficacy targets depressive symptoms, as measured by the BDI-II [35]. The PROMIS (Patient-Reported Outcomes Measurement Information System) [39,40] computer adaptive test for depressive symptoms will serve as an additional measure to triangulate the findings of the BDI-II. The central construct serving as our main secondary outcome is psychological well-being, inclusive of its hedonic, evaluative, and eudaimonic domains. Specific domains of psychological well-being will be assessed using PROMIS adaptive measures, including life satisfaction, positive affect, life meaning and purpose, and self-efficacy for managing emotions in the context of a chronic condition [39,40]. PROMIS measures have undergone psychometric testing and show high levels of reliability and validity [41]. Additional measures of psychological well-being include optimism using the 7-item State Optimism Measure [42]; emotional vitality, as measured using select items of the General Well-Being Schedule [43,44]; and the 10-item Flourishing Index, which broadly captures "a state in which all aspects [health and well-being] of a person's life are good" [45]. PROMIS measures will also be used to assess anxiety levels [39,40], along with use of the Perceived Stress Scale [46].

The tertiary measures focus on quality of life, treatment adherence, and disease-related outcomes. First, we will assess self-reported quality of life using the 24-item Kidney Disease Quality of Life-Short Form [47]. Data extracted from the EMR, triangulated through interviews with enrollees or proxies, will be used to document the number of dialysis sessions missed and the total number of hospitalizations, with details on cause and length of stay. EMR data will also be used to capture the following biomarkers: urea reduction ratio, serum albumin concentration, blood urea nitrogen concentration, creatinine concentration, calcium phosphate product, and interdialytic weight gain (% Δ kg per day). We will also capture the etiology of chronic kidney disease via EMR data and self-reported information from enrollees.

Data on relevant covariates will be collected. These will include demographic factors, medical comorbidities [48], and medication use. The EMRs will be used to collect data on age, date of birth, sex, height, and weight. Surveys will be used to collect information on annual household income, educational attainment, marital status, health insurance status, employment, nativity status and number of years in the United States, and country of origin. The Charlson Comorbidity Index [48] will be used to extract codes of the International Classification of Diseases, Tenth Revision (ICD-10), from EMRs, inclusive of the following 18 conditions: myocardial infarction, congestive heart failure, peripheral vascular disease, cerebrovascular disease, dementia, chronic pulmonary disease, rheumatic disease, peptic ulcer, mild liver disease, diabetes without chronic complications, diabetes with chronic complications, hypertension, hypercholesterolemia, hemiplegia or paraplegia, any malignancy (including lymphoma and leukemia, except malignant neoplasm of the skin), moderate-to-severe liver disease, metastatic solid tumor, and AIDS or HIV. Medication use will be extracted by research staff through the review of

XSL•FO
RenderX

medication lists using EMR data. Interview assessors will review the medication list with study participants to verify its accuracy and note any errors or inconsistencies.

We will also collect feasibility and process evaluation metrics (Table 3). Finally, we will extract information from the Meta Quest Pro across patient end users, inclusive of accelerometer data, eye tracking, and visual scanning of pupils, along with facial expressions.

Table 2. Joviality measures of feasibility and metrics testing efficacy.

Measure	Time frame	Type	Source
Psychological well-being			
Beck Depression Inventory-II	In the past 2 weeks	Primary outcome	REDCap[a]
PROMIS[b] computer adaptive tests			
Depression	In the past 7 days	Secondary outcome	REDCap
Anxiety	In the past 7 days	Secondary outcome	REDCap
General life satisfaction	N/A[c]	Secondary outcome	REDCap
Positive affect	In the past 7 days	Secondary outcome	REDCap
Life meaning and purpose	N/A	Secondary outcome	REDCap
Self-efficacy for managing chronic conditions—managing emotions	Right now	Secondary outcome	REDCap
Perceived Stress Scale	In the last month	Secondary outcome	REDCap
State Optimism Measure	Right now or present moment	Secondary outcome	REDCap
Emotional vitality (via General Well-Being Schedule)	In the last month	Secondary outcome	REDCap
Flourishing Index	In the past days	Secondary outcome	REDCap
Quality of life: 24-item Kidney Disease Quality of Life-Short Form	N/A	Tertiary outcome	REDCap
Health-related outcomes			
Interdialytic weight gain (% Δ kg per day)	N/A	Tertiary outcome	EMR[d] or MyChart (EPIC Systems Corporation)[e]
Dialysis sessions missed	N/A	Tertiary outcome	EMR or MyChart (EPIC Systems Corporation)
All-cause hospitalizations	N/A	Tertiary outcome	EMR or MyChart (EPIC Systems Corporation)
Kidney-related biomarkers: urea reduction ratio, serum albumin concentration, blood urea nitrogen concentration, creatinine concentration, calcium phosphate product, and hemodialysis etiology	N/A	Tertiary outcome	EMR or MyChart (EPIC Systems Corporation)
Feasibility and process evaluation: VR[f] utility and usability			
Simulator Sickness Questionnaire	N/A	Feasibility	REDCap
Igroup Presence Questionnaire	N/A	Feasibility	REDCap
System Usability Scale	N/A	Utility	REDCap

Table 3. Joviality trial metrics of feasibility and acceptability.

Measure	Description	Target
Recruitment and refusal	Measured by the proportion of potential enrollees who were approached for recruitment but decided not to enroll	N/A[a]
Retention	Defined as completing all postintervention assessments, categorized as a binary outcome (yes or no), %	≥75
Adherence	Measured by the proportion of the intervention completed (eg, number of virtual reality environments viewed out of the total possible available across skill lessons in the intervention), %	≥75
Acceptability	Measured by whether a participant would recommend Joviality to other individuals on hemodialysis (ranging from 0=definitely not to 10=definitely yes)	≥8.0

[a]N/A: not applicable.

Planned Analyses

Aim 1: Software Testing and Quality Assurance

Before deploying the *Joviality* VR software among patient end users, the software will be tested by the digital art director (KS) and visual media designer (DF) to ensure that the experience aligns with the original intentions of the research team and to ferret out accessibility or usability concerns. The software will also be tested for performance to ensure that the equipment can run the software without dropping frames or lagging, which can lead to motion or simulation sickness in participants on hemodialysis. User testing will also inform software editing. End users will have the option to experience the final content and audio of the VR environment in English or Spanish.

Aim 2: Acceptability and Feasibility

Key metrics to assess acceptability and feasibility are as follows: (1) recruitment rates, (2) refusal rates, (3) retention rates, and (4) noncompliance and adherence rates (Table 3). A mixed methods approach will be used to assess acceptability through consideration of participants' subjective ratings of the intervention content and modality of delivery and whether it was deemed enjoyable, understandable or clear, and beneficial, along with the measurement of motion sickness, system usability, and end-user perspectives on being fully present in the 3D virtual space. This will be accompanied by open-ended qualitative inquiry on overall thoughts across VR environments and associated content.

Aim 3: Testing of Intervention Effects

Participants will complete survey measures at 4 time points: baseline, immediately after the intervention (5 weeks after baseline), 3 months after the intervention, and 6 months after the intervention. Our exploratory aim will test intervention effects on depressive symptoms, positive psychological well-being (eg, optimism and positive affect) and distress, quality of life, disease-related biomarkers, missed hemodialysis treatment time (in minutes), and rates of hemodialysis sessions missed and hospitalizations.

Central Hypothesis

Our central hypothesis is that our VR-based intervention will lead to postintervention improvements in depressive symptoms, emotional well-being, quality of life, and treatment adherence, along with reduced hospitalization rates and improvements across multiple clinical biomarkers. We will use repeated measures analysis of covariance to compare mean differences in depressive symptoms between the control and intervention arms as measured at baseline and follow-up, that is, immediately after the intervention at 5 weeks, and at 3 months and 6 months after the intervention. Analyses will be adjusted for baseline outcome values to account for the regression to the mean effect and to improve statistical power. To be precise, the average postrandomization effect in the VR-based intervention will be compared with the average postrandomization effect in the active control group. We will also implement an intention-to-treat approach. Multiple imputation procedures will be used across missing values to ensure inclusion of all observations, particularly those resulting from participants who withdraw, are lost to follow-up, or do not complete all assessments. Furthermore, sensitivity analyses will be implemented via the application of mixed effects models, assuming that data are missing at random. The independent variables include a time variable t (t=T0, baseline; T1, immediately after the intervention at 5 weeks; T2, six months after the intervention; and T3, six months after the intervention), a dummy variable k (k=1 if VR-based intervention condition and k=0 if active control arm), and baseline score of dependent variables. Unbalanced variables (mean differences across treatment arms) will be adjusted for, if necessary. Similar analyses will be repeated when examining outcomes of psychological well-being, quality of life, disease-related biomarkers, dialysis treatment adherence, and hospitalization rates.

At the individual level, we will calculate reliable change indices (RCIs) for each participant, as per Jacobson and Truax [49]. The RCI addresses whether the changes that participants experience are statistically reliable by comparing pre-post change with the reliability of the measurement instrument. RCI scores are calculated as follows:

$$RCI = x_2 - x_1 / SE_{diff} \quad \textbf{(1)}$$

where x_1 represents a participant's baseline score and x_2 represents a participant's postintervention score, and SE_{diff} represents the SE of the difference between the 2 scores. RCI scores of >1.96 (approximately 2 SDs from the mean difference) are considered to be reliable [49]. We will present the percentage of participants who experienced reliable change for scores across the measures of interest. RCIs will also be expressed as percentage change from baseline by dividing the RCI score by the baseline score and multiplying by 100. At the sample level, we will conduct 1-tailed paired sample t tests to determine the magnitude of pre-post changes across the main outcomes of interest at each time point. In addition to reporting nominal P

XSL•FO
RenderX

values, we will implement a false discovery rate approach to accommodate potential inflation of type I error rate owing to multiple comparisons. Furthermore, 95% CIs will be constructed to report meaningful differences between the groups, even if statistical difference is not achieved.

Sex as a biological variable will be addressed in exploratory analyses by tabulating disaggregated data by sex and via sex-stratified analyses of the main outcomes.

Results

This RCT testing our *Joviality* software is funded by the National Institute of Diabetes and Digestive and Kidney Diseases through the funding period lasting from September 1, 2021, to July 31, 2024. The first 18 months of the funding period were dedicated to software development and the final build of the 3D immersive experience. The recruitment of patients on hemodialysis is scheduled to commence in June 2023. Participant recruitment is projected to end in December 2023, with the commencement of data analysis and submission of results for peer review in 2024.

Discussion

Overview

A dialysis treatment session is an ideal time for the delivery of strength-based interventions to boost psychological well-being because it constitutes a 3- to 4-hour window where patients are a captive audience [50], particularly because the lengthy treatment session is often described by patients as a wasteful and monotonous experience in a sterile environment. VR not only offers interactive technology to deliver much needed strengths-based interventions, but it also has the added advantage of allowing individuals on hemodialysis to digitally travel outside the clinical walls and into more relaxing and enjoyable settings. It has become evident that large-scale dissemination and scalability of face-to-face delivery of psychosocial interventions by trained clinicians are difficult, given the limited resources, unequitable health care access, and lack of bilingual practitioners, which makes the use of technology a particularly viable and attractive modality.

Our protocol provides the description of an RCT that adapts and tailors VR technology for use in a clinical population that encounters special needs and challenges. Our team of engineers has designed an intuitive system that requires simple head movement for interactability and that incorporates user-friendly features and an interface for adults with limited technology-based experience [51]. The trial sets the stage for fully immersive technologies in individuals with ESKD aimed at promoting positive emotional and physical health outcomes. Our trial is a preliminary step toward the design of patient-centered interactive VR technologies where patients are given autonomy to select their avatar, language, setting of choice, and much more. This, of course, would be accompanied by future integration of artificial intelligence to autonomously modify and predict end-user preferences for aesthetics, VR content, and travel locations.

VR technology has largely been exploited in video gaming and simulation training with clinicians and military personnel [52]. More recently, VR technology has been used in clinical settings with patients experiencing high-level pain and psychological phobias with favorable results [30,53]. In a randomized trial with patients with burn injuries aged 5 to 18 years, significantly lower pain scores were reported among those engaged in VR gaming while their wounds were being redressed [29]. In individuals with severe phobias, a systematic review found VR exposure therapy to be just as effective as in vivo therapies, particularly for cases of acrophobia (the fear of heights), claustrophobia, and blood injection phobia (the fear of injection exposure), with significant reductions in levels of fear, anxiety, and avoidance [54]. Other successful use cases with meta-analytic evidence include VR in palliative care [55], physical therapy and rehabilitation [56], and cognitive functioning (eg, memory and attention) [57].

In the context of hemodialysis, gamification techniques have focused primarily on nonimmersive gaming devices (eg, *Nintendo Wii*), which overlooks the advantages of fully immersive technologies where end users are teleported to artificial environments to interact with 3D virtual content. As VR technologies continue gaining traction in health care, it is important to decipher the mechanism involved and identify the active ingredients. Theorized pathways on the impacts of VR on health may include (1) cognitive distraction through appealing stimuli, (2) decreased autonomic parameters and healthful physiological responses, (3) targeted induction of body movement and physical activity, and (4) the delivery of evidence-based programming. Much research remains to be conducted to fully understand the role of VR in health care and the mechanisms at play. However, certain considerations should be kept at the forefront, including accessibility across the spectrum of socioeconomic backgrounds, so that immersive technology does not further widen the chasm of health disparities in the United States and abroad.

Our previous work, using the largest cohort of Hispanic or Latino adults, that is, the Hispanic Community Health Study/Study of Latinos, found a positive association between psychological well-being and ideal cardiovascular health in adults with early-stage chronic kidney disease [58]. Each unit increase in positive affect was associated with higher odds of ideal cardiovascular health across multiple indicators. There is no doubt that accumulating evidence documents the merit and healthful benefits of positive emotions and psychological assets in the context of disease-related stress and trauma. As such, this VR-based trial is also a call for greater focus on the strengths and factors of resilience that individuals with ESKD possess, with a focus on programming that will further amplify these positive attributes.

Potential Limitations and Conclusions

Despite the innovativeness and strengths of this RCT, a few limitations should be noted. First, the inclusion criteria capturing elevated symptoms of depression will use the self-report BDI-II survey measure and will not rely on a more precise clinical diagnosis. Nonetheless, the BDI-II has been widely tested in individuals on hemodialysis and has documented satisfactory

XSL•FO
RenderX

psychometric properties to suggest a higher likelihood of clinical depression. Generalizability of the results may be restricted if recruitment fails to enroll individuals on hemodialysis who are averse to the use of technology or if those with severe depression are reluctant to engage with research staff, thus selectively reducing enrollment rates. It is also possible that the VR content may lead to relaxation that induces sleep, a possibility that our engineering team has contemplated. Thus, triggering design features have been incorporated to alert research staff and end users if prolonged inactivity in the VR space is detected. Finally, given the small targeted enrollment goal, we may not have the power to explore mechanisms through which VR exerts protective effects (if any), nor will it be possible to fully test important effect modifiers of the intervention (eg, race, ethnicity, and socioeconomic status).

In conclusion, we seek to examine whether VR is an effective platform to deliver a positive psychological intervention in individuals on hemodialysis with comorbid depression to improve emotional well-being and clinical health outcomes. If successful, VR headsets could be salient clinical tools in hemodialysis clinics in the United States and abroad. Our VR-based approach could become the new evidence-based tool that clinics house and adopt to improve mental health outcomes in individuals on hemodialysis, with the added potential benefit of improving treatment adherence and healthy longevity.

Acknowledgments

This work is funded by the National Institute of Diabetes and Digestive and Kidney Diseases (5 R01 DK129594-02).

Data Availability

This paper presents details of the protocol and design for a randomized controlled trial testing virtual reality in the context of hemodialysis; as such, this study does not generate or analyze an associated data set, making data sharing nonapplicable. Once the protocol is implemented and data are made available, we will use a National Institutes of Health–approved data repository to share derived data in a deidentified format and follow rigorous procedures to ensure protection of the privacy, rights, and confidentiality of human research participants. Finally, the public will have access to the detailed protocol and general findings of the trial (when available) at ClinicalTrials.gov (NCT05642364).

Abstract

Background: Social anxiety symptoms are highly prevalent among adolescents and are associated with poor quality of life and low psychosocial functioning. If untreated, social anxiety often persists into adulthood and increases the risk for comorbid disorders. Therefore, early interventions for social anxiety to prevent negative long-term consequences are critical. However, adolescents rarely seek help and often avoid face-to-face psychotherapeutic interventions due to the perceived lack of autonomy and anonymity. Thus, online interventions represent a promising opportunity to reach adolescents who have social anxiety but do not seek help yet.

Objective: This study aims to evaluate the efficacy, moderators, and mediators of an online intervention developed to reduce social anxiety in adolescents.

Methods: A total of 222 adolescents aged 11-17 years with subclinical social anxiety (N=166) or with a diagnosis of social anxiety disorder (N=56) are randomly assigned to the online intervention or a care-as-usual control group. The 8-week guided online intervention is based on the Cognitive Model of Social Phobia and evidence-based online interventions for social anxiety adapted to the specific needs of adolescents. The care-as-usual group will be given access to the online intervention after the follow-up assessment. Participants are assessed at baseline, at 4 and 8 weeks post intervention, and at 3-month follow-up assessment on the primary outcome, that is, social anxiety, on secondary outcomes (eg, level of functioning, fear and avoidance, general anxiety, depression, quality of life, self-esteem, and negative effects of the intervention), on potential moderators (eg, therapy motivation, therapy expectancy, and satisfaction with the intervention), and potential mediators (eg, therapeutic alliance and adherence to the intervention). Data will be analyzed based on an intention-to-treat approach and both groups (intervention and care-as-usual) will be compared at each assessment time point. Furthermore, potential mechanisms of change and generalization of intervention effects on daily life are assessed using an ecological momentary assessment procedure that includes items on maintaining mechanisms of social anxiety, social context, and affect. Participants are prompted 3 times a day during the first 8 weeks of the study and again for 2 weeks following the follow-up assessment.

Results: Recruitment is ongoing; initial results are expected in 2024.

Conclusions: Results are discussed considering the potential of online interventions as a low-threshold prevention and treatment option for adolescents with social anxiety and in light of current advances in dynamic modeling of change processes and mechanisms in early intervention and psychotherapy in adolescents.

Introduction

Adolescence marks a crucial timespan for the development of social anxiety disorder (SAD) with the peak of onset between 13 and 15 years. Prevalence rates in adolescents meeting SAD criteria range from 12% to 36%. Additionally, 16% of adolescents report subclinical levels of social anxiety [1-5]. The burden of disease on adolescents with SAD or subclinical social anxiety is considerable, including poor quality of life, low psychosocial functioning [6-8], and high risk of persistence into adulthood and of developing comorbid mental disorders [9-12]. Promising strategies to prevent or diminish these detrimental effects of SAD include low-threshold early interventions that are delivered online.

Online interventions might be especially appealing to adolescents as [3,13-15] they experience higher stigma regarding seeking and accepting help than adults [16,17], particularly those with social anxiety [13]. Low help-seeking behavior results in few adolescents receiving adequate treatment. This is exacerbated by the lack of available psychotherapeutic services for adolescents worldwide [14,15]. Thereby, online interventions bear the promise to offer adolescents help at a low threshold and with high confidentiality [16].

Meta-analyses have generally supported the efficacy of online interventions in adolescents [17]. These online interventions primarily targeted anxiety and depressive symptoms based on cognitive behavioral therapy (CBT). They have been demonstrated to be superior to passive control conditions (eg, waitlist) and equally efficacious to active control conditions (eg, face-to-face CBT) [18]. Notably, face-to-face interventions targeting several anxiety disorders simultaneously are less efficacious in patients with SAD than other anxiety disorders [19-22]. This emphasizes the need for interventions specifically targeting symptoms of social anxiety such as those proposed in the Clark and Wells or Heimberg model [22,23]. Face-to-face trials imply that the Cognitive Model of social anxiety by Clark and Wells [24] also applies to adolescent samples [25-27]. Online interventions targeting social anxiety in adolescents showed large effects compared to passive (ie, waitlist [28,29]) and active control conditions (ie, online support [30]) but, unlike the face-to-face trials, was equally efficacious compared to a generic CBT program for anxiety [29]. These results are promising but need to be interpreted cautiously as some studies primarily focused on a small sample size with older adolescents with speech anxiety [28] or reported high dropout rates in the study and low adherence rates to the online intervention [29]. Poor engagement with online interventions is a known issue [17]. Human support in the form of guidance (eg, sending summaries and reminders and answering questions) can enhance adherence to and effects of online interventions in adult samples [31,32]. So far, there is no conclusive evidence about adolescents; nevertheless, initial studies suggest that guidance is generally accepted and beneficial for adherence and efficacy [33-36].

Since levels of social anxiety and the incidence of SAD increase during adolescence [37], it is important to detect and treat first signs of SAD as early as possible to prevent the development of a full-blown disorder and address associated high rates of psychosocial impairments early on [8]. Most prevention efforts for anxiety disorders have been delivered as universal programs [38]. Indicated prevention offered to individuals already experiencing elevated, subclinical levels of social anxiety below the diagnostic threshold is still relatively scarce, although may be experienced as more satisfying and less resource-intensive than universal programs [38]. Accordingly, studies suggest that indicated prevention carried out in schools [39] or online [40] can produce small but beneficial effects in adolescent samples. As for interventions addressing social anxiety specifically, an online game to improve social skills [41] and an online cognitive bias modification training [42] were shown to be efficacious in adolescents.

Based on these findings, online interventions may be helpful for adolescents with subclinical social anxiety and with SAD, but our understanding of the mechanisms of change underlying these interventions in adolescent samples is still limited [43].

One method of identifying mechanisms of change is to derive them theory-based and examine them as mediators [43]. Possible mechanisms of change for social anxiety may be the hypothesized maintaining factors of SAD derived from the Cognitive Model (eg, automatic thoughts, self-focused attention, safety behavior, pre-, and postevent processing [24]). In correlational and experimental studies, these factors were positively associated with a higher level of social anxiety [44-47]. However, mediation analysis inherently implies a temporal order of the relationship between the intervention, mediators, and the outcome. Therefore, these variables must be assessed longitudinally ideally at multiple times such as in ecological momentary assessment (EMA) [43,48-50]. Previous intervention studies in adolescents including EMA have mostly assessed global social anxiety, momentary social context, and affect but missed to assess individual maintaining factors [51,52]. As EMA captures events as they occur at the moment, this method thereby minimizes memory bias, incorporates contextual information from participants' natural environment, and accounts for variability in answering behavior [43,48]. This allows to assess mediators of change and the efficacy in participants' daily lives and extends the knowledge about intervention benefits to their natural and variable contexts [53]. Eventually, this information may add valuable input to improve interventions in the future.

Further efforts to optimize treatments and outcomes involve the modeling of mental disorders as a network of symptoms to identify central treatment targets [54]. According to the network

XSL•FO
RenderX

perspective, a mental disorder is best understood as a complex system of dynamically interacting symptoms [55]. Central symptoms (eg, fear of humiliation) of such a network are supposed to spread quickly by activating other strongly interrelated symptoms, while bridging symptoms (eg, low self-esteem) may link clusters of symptoms. Both central and bridging symptoms may represent important intervention targets as they are supposed to be causally linked to other symptoms of an individual's network [55-57]. To this point, studies of cross-sectional networks have demonstrated that dysfunctional cognitions function as central symptoms and influence multiple other social anxiety symptoms, especially behavioral components such as avoidance and safety behavior in adolescents [58,59]. Examining social anxiety as networks at symptom level over the course of the intervention could add to this knowledge by exploring whether participants' network structures change from beginning to end of the intervention, in particular, by identifying relevant core and bridging symptoms as drivers of clinical change, by investigating differences in symptom networks between intervention and control group, and by studying the influence of possible moderators (eg, age, gender, and diagnostic status) on networks.

Overall, first studies suggest that online interventions have positive effects on adolescents with SAD; however, much uncertainty still exists about the efficacy of indicated prevention trials including adolescents with subclinical social anxiety. Moreover, previous research has focused mainly on the efficacy of interventions while neglecting both the mechanisms of change and the symptom-level network structure of SAD.

The primary objective of this study is to examine the efficacy of an online intervention called SOPHIE for adolescents with subclinical social anxiety or SAD compared to a care-as-usual (CAU) control group. Thereby, the name SOPHIE is derived from the German term "SOziale PHobIE" (social phobia). It is hypothesized that SOPHIE will be superior to CAU in reducing social anxiety symptoms post assessment and that the intervention effect will be maintained until follow-up assessment 3 months after intervention completion. Furthermore, it is hypothesized that SOPHIE will also have beneficial effects on secondary outcomes, such as depressive as well as general anxiety symptoms, level of functioning, self-esteem, and quality of life at post assessment and follow-up. It is further hypothesized that intervention effects will be moderated by therapeutic alliance, adherence, treatment motivation, and treatment expectation of the online intervention. Moreover, by measuring social anxiety symptoms in their natural context longitudinally, we will examine if intervention effects translate into everyday life and if the postulated maintaining factors of SAD function as mediators of change. Additionally, we intend to model the network structure of social anxiety symptoms at each time point and observe differences in networks of adolescents (eg, regarding age, gender, and severity of social anxiety).

Methods

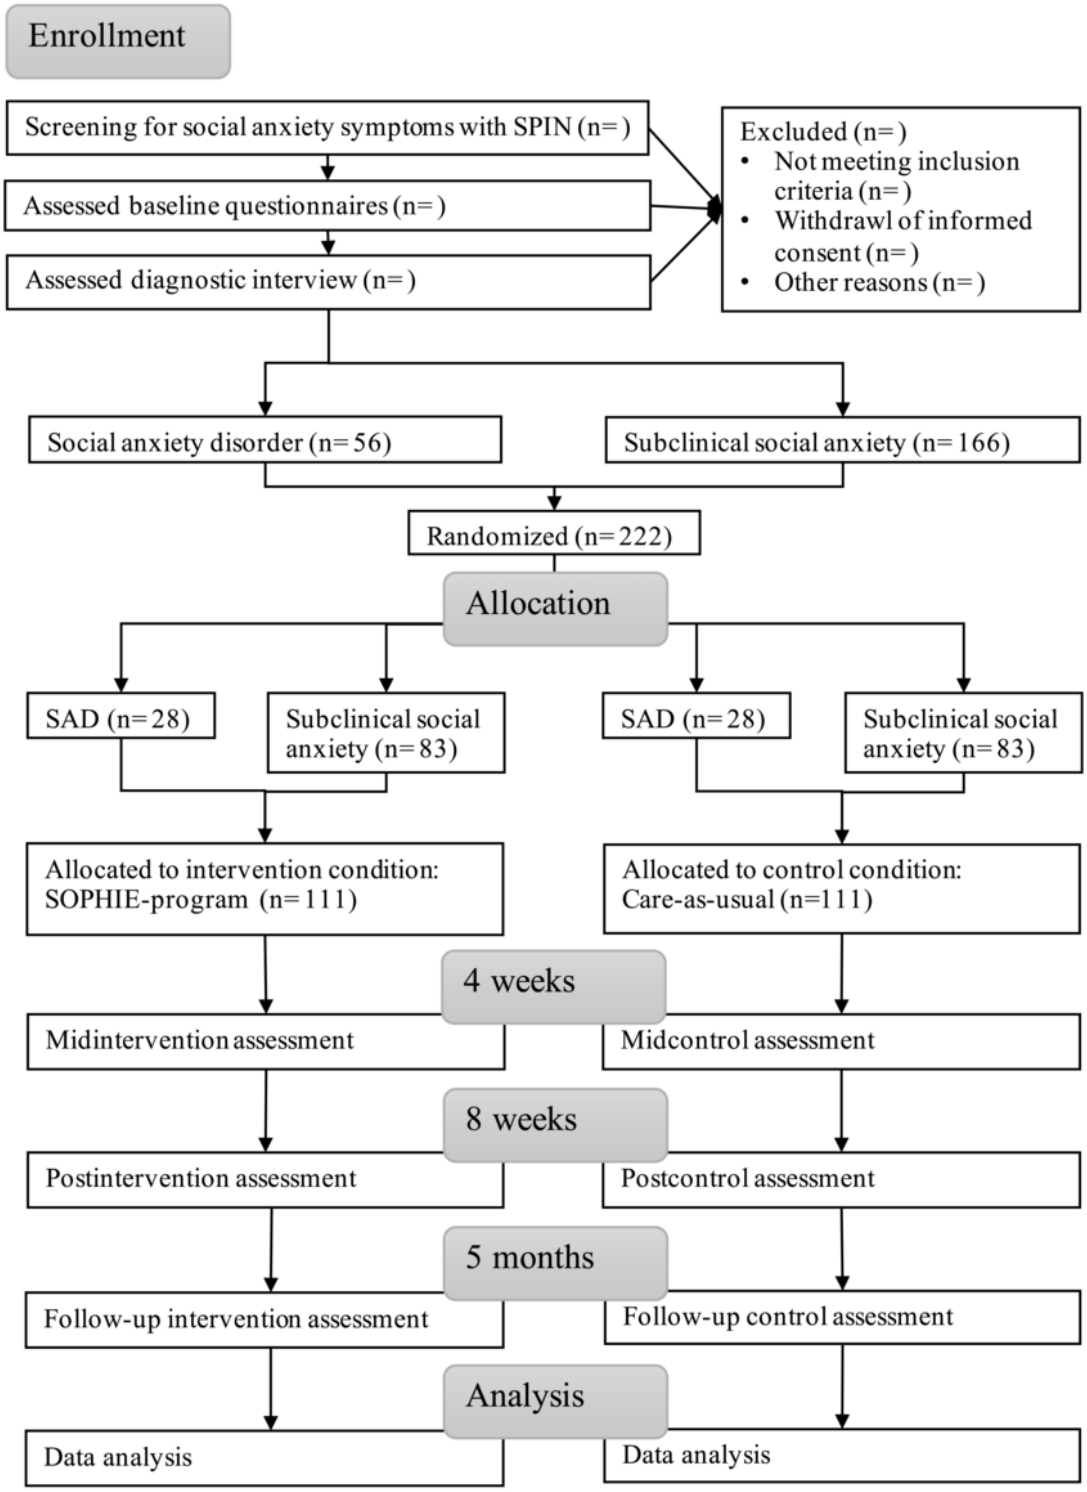
Study Design

This randomized controlled trial (RCT) investigates the efficacy of the online intervention SOPHIE for adolescents with subclinical social anxiety or a diagnosis of SAD. SOPHIE is compared to a CAU control condition in a 2×2×4 design with a 2-level between-subjects factor (2 experimental conditions: SOPHIE vs CAU), a 2-level between-subjects factor (2 diagnostic conditions: SAD vs subclinical social anxiety), and a 4-level within-subjects factor (repeated measures: baseline, midintervention at week 4, post intervention at week 8, and follow-up 5 months after randomization, ie, 3-months follow-up). All participants are additionally assessed in EMA surveys during the first 8 weeks (from baseline to postassessment) and for 2 weeks after follow-up assessment. Participants in the intervention group have additional process assessments at weeks 2 and 6 during the intervention.

Ethical Considerations

The trial was registered in ClinicalTrials.gov (NCT04782102) and was approved by the Ethics Committee of the Canton Bern in Switzerland (CEC Bern, Project ID 2020-02501). Any changes to the protocol will be submitted to the Ethics Committee. Adolescents and, if younger than 14 years, their guardians must sign the informed consent form prior to the first assessment. Adolescents and their guardians can withdraw from the study at any time. Withdrawal from the study will not be associated with any disadvantages and is fully documented and explained in the informed consent form. Data collected up to withdrawal will still be used for the planned data analyses. All details about privacy and confidentiality protection are given in *Data Management and Monitoring* subsection. Participants were not compensated for their participation in the study. However, they have the opportunity to participate in a lottery and win Netflix, BookBeat, Spotify, or Apple Music vouchers worth CHF 30 (~US $33).

Procedures



Adolescents interested to take part in the study leave their email addresses on the study website [60]. They receive the participant study information by email and are asked to provide informed consent or assent (see Figure 1 for study flow). Participants younger than 14 years provide written assent, and their parent or guardian provides written consent. Participants 14 years or older provide consent on their own. Informed consents are accepted both on paper by mail and electronically as scans via email. Once the consent forms have been received, they are printed out and stored in analog form. Afterward, potential participants are screened for eligibility. Those with a score lower than 16 on the Social Phobia Inventory (SPIN) [61,62] are not included in the study but receive immediate access to the online intervention. The cutoff of 16 was chosen in reference to a previous study that showed good discrimination between healthy and subclinical adolescents [63]. Adolescents with a SPIN score of 16 or higher receive the remaining baseline questionnaires. Subsequently, they are interviewed by trained psychology graduate students via phone to ascertain whether they fulfill the diagnostic criteria for SAD or not. Those with a current

XSL•FO
RenderX

diagnosis of SAD are assigned to the SAD group, while those with no current and no past SAD diagnosis are assigned to the subclinical social anxiety group. Training and weekly supervision of the graduate students are carried out by the first and last authors.

Participants are assigned to the intervention group or the control group by stratified block randomization to ensure that both groups are balanced regarding the diagnostic status: SAD or subclinical social anxiety. The randomization is carried out after all data collected by the diagnostic interview including diagnoses are entered into the electronic protocol form hosted on Qualtrics (Qualtrics XM) [64]. Randomization was set up before the start of the study by the first author (ie, number of groups, allocation ratio [1:1], and size of blocks). During the study, the allocation list was produced using an automated computer-generated random numbers table and was concealed from the investigators and the participants. After randomization, the intervention group receives immediate access to the online intervention.

Figure 1. SOPHIE trial flowchart. SAD: social anxiety disorder; SPIN: Social Phobia Inventory.

XSL•FO
RenderX

During study participation, all participants are reminded twice for each noncompleted questionnaire. For post- and follow-up assessments, an additional reminder is sent out. For EMA surveys, participants are prompted 3 times a day: in the morning before school or work, in the afternoon after school or work, and in the evening with the Smartphone Ecological Momentary Assessment application (SEMA^3 app) [65].

At post- and follow-up assessment, all participants are contacted again for a telephone interview. Assessors are blinded to the diagnostic status diagnosed at baseline and study condition of the participant, and participants are asked not to mention either of those. CAU group members receive access to the online intervention after they completed all follow-up assessments and the interview.

Participants, Recruitment, and Eligibility

Participants are recruited in German-speaking countries using advertisements on social media platforms (ie, TikTok and Instagram), self-help forums, and websites (eg, Google ads). Additionally, we share information through partner organizations (eg, school social work, open youth work, and parent counseling), and during school visits. To be included in the study, participants must be between 11 and 17 years of age, understand German, and have access to both a device connected to the internet and a smartphone. In Switzerland, more than 99% of adolescents have their own smartphone and access to the internet [66]. Exclusion criteria are a known diagnosis of autism spectrum disorder, acute suicidality at baseline, and a past diagnosis of SAD for the subclinical group. In case of acute suicidality, we follow a predefined suicidality protocol described in the section “Project and Risk Management.”

Outcome Measures

Primary and Secondary Outcomes

The primary outcome is the severity of social anxiety assessed by the SPIN [67]. The National Institute of Health and Care Excellence guidelines recommend the SPIN as a screening and assessment instrument suited for adolescents [23]. Please see Table 1 for a detailed description and assessment points of the primary and secondary outcomes: social anxiety, social and role functioning, utilization of help, anxiety, depression, quality of life, self-esteem, therapy expectation, therapy motivation, negative effects of the intervention, satisfaction with the intervention, therapeutic alliance, and adherence to the intervention.

Table 1. Overview of assessments and assessment points during the SOPHIE study.

Construct	Description of assessment	Timeline of assessment					
		Baseline	Week 2	Midintervention or control at week 4	Week 6	Postintervention or control at week 8	Follow-up at week 20
Sociodemographic variables							
Demographic information	During the first telephone interview, participants are asked about their gender, age, nationality, native language, and living as well as family situation.	✓					
Socioeconomic status	During the first telephone interview, the *Family Affluence Scale* with 6 items is assessed as an indicator for socioeconomic status and demonstrates good psychometric properties to detect socioeconomic differences in Western European countries [68,69].	✓					
Primary outcome							
Social anxiety	The *Social Phobia Inventory* (SPIN) is a self-report questionnaire assessing 3 dimensions of social anxiety: fear, avoidance, and physiological symptoms. In 17 items, adolescents rate the frequency of each symptom on a 5-point Likert scale from *not at all* (0) to *extremely* (4) ([61], German version by [62]). The SPIN is a reliable self-report measure with good psychometric properties in adolescents [70,71]. Cut-off for subclinical social anxiety symptoms is set at 16 [63].	✓		✓		✓	✓
Secondary outcomes							
Mental disorders	The *structured clinical interview for mental disorders across the life span* is a structured clinical interview to assess the presence of SAD[a] and comorbid past and present mental disorders according to the Diagnostic and Statistical Manual of Mental Disorders-5 ([72], German Version of Kinder-DIPS; [73]). In this study, the full interview is conducted by phone at baseline. At post- and follow-up assessment, only the section for SAD and sections of previously met diagnoses are assessed.	✓				✓	✓
Global functioning	The *Global Functioning Social and Role Scale* is a structured interview that is also carried out via phone in this study [74]. Two subscales (social and role) allow for an assessment of the level of functioning (concurrently and in the past year) on a scale ranging from 1 to 10 with 10 representing the highest level.	✓				✓	✓

XSL•FO
RenderX

Construct	Description of assessment	Timeline of assessment					
		Baseline	Week 2	Midintervention or control at week 4	Week 6	Postintervention or control at week 8	Follow-up at week 20
Utilization of help	The *Client Socio-Demographic and Service Receipt Inventory* [75,76] is a standardized interview to assess the utilization of help and help seeking behavior. The applied version has already been tested in adolescents [76] and is administered during the postintervention and follow-up telephone interview.					✓	✓
Fear and avoidance	The *Social Anxiety Scale for Adolescents* measures fear of negative evaluation and social avoidance in adolescents with 18 items answered on a 5-point Likert scale from *not at all* (1) to *all the time* (5) [77]. Validity and reliability were tested in both clinical and nonclinical samples [77,78].	✓		✓		✓	✓
Anxiety	The *Generalized Anxiety Disorder 7* [79] questionnaire measures self-reported frequency of anxiety symptoms with 7 items answered on a 4-point Likert scale from *not at all* (0) to *nearly every day* (3). The German questionnaire produced good psychometric properties in adolescents [79,80].	✓		✓		✓	✓
Depression	The *Patient Health Questionnaire-9 for Adolescents* [81] assesses depressive symptomatology with 9 items asking about the frequency of symptoms over the last 2 weeks on a 4-point Likert scale from *not at all* (0) to *nearly every day* (3). The self-report questionnaire has good psychometric properties for depression detection in adolescents [82].	✓		✓		✓	✓
Quality of life	The KIDSCREEN-10 is used to measure health-related quality of life with 10 items answered on a 5-point Likert scale and has good psychometric properties [83].	✓		✓		✓	✓
Self-esteem	The *Rosenberg Self-Esteem Scale* [84] assesses self-esteem in 10 items on a Guttman scale. This questionnaire is applicable to different age groups; in this study, the adolescent version is applied.	✓		✓		✓	✓
Therapy expectancy	The *Credibility or Expectancy Questionnaire* [85] assesses treatment expectancy and credibility with 6 items. There are 2 rating scales, 1 from *not at all* (1) to *very* (9) and another from 0 to 100%. For this study, the wording of the items was adapted to the target group of adolescents.	✓					

XSL•FO
RenderX

Construct	Description of assessment	Timeline of assessment					
		Baseline	Week 2	Midintervention or control at week 4	Week 6	Postintervention or control at week 8	Follow-up at week 20
Therapy motivation	The *Motivation for Youth's Treatment Scale* (MYTS) [86] measures adolescent's motivation for therapy through a self-report questionnaire. Eight items are rated on a 5-point Likert scale from strongly disagree (1) to strongly agree (5). All adolescents complete this assessment at baseline, only adolescents randomized to the intervention group complete the MYTS at week 2, 4, 6, and 8.	✓	(✓)[b]	(✓)	(✓)	(✓)	
Negative effects of intervention	The *Inventory for assessment of negative effects in psychotherapy* (German: Inventar zur Erfassung Negativer Effekte in der Psychotherapy, Kinder-INEP; [87,88]) has been adjusted to the online format of the intervention, reducing the questionnaire by 6 items to 15 items. This questionnaire is only answered by adolescents in the intervention group.					(✓)	
Satisfaction with the intervention	The *ZUF-8* is an 8-item questionnaire for global, unidimensional assessment of patient satisfaction [89]. The questionnaire was adapted accordingly to measure satisfaction with the online intervention. Adolescents randomized to the intervention answer questions on a 4-point Likert scale from 1 to 4.					(✓)	
Therapeutic alliance	The *Working Alliance Inventory for guided Internet Interventions* (WAI-I; [90]) is a self-report questionnaire that measures therapeutic alliance in online interventions with therapeutic support. The 12 items rated on a 5-point Likert scale from *rarely* (1) to *always* (5) were adapted to adolescents. Only adolescents in the intervention group are assessed with the WAI-I.		✓	✓	✓	✓	
Adherence to the online intervention	Adherence is operationalized through the extent to which the online intervention is used. The number of finished modules, the number of completed exercises, and the time spent in the online intervention are recorded automatically. As in other studies of online interventions, adherence is calculated with respect to each of these variables and with respect to a composite measure [91].					(✓)	

[a]SAD: social anxiety disorder.

[b]Indicated time points in parentheses reflect assessments only administered in the intervention group.

Ecological Momentary Assessment

The same set of EMA questions is provided at all prompts: (1) 10 questions of the *Positive and Negative Affect Schedule for Children* [92] measure positive affect (happy, cheerful, proud, joyful, and lively) and negative affect (sad, scared, miserable, afraid, and mad). The Positive and Negative Affect Schedule for Children has been used in a diary study and showed good psychometric properties in intensive longitudinal designs [93]. (2) The *Social Phobia Weekly Summary Scale* [94] assesses maintaining factors of social anxiety. Six items rated on a 9-point Likert scale from 0 to 8 evaluate the extent of social anxiety, social avoidance, self-focused versus external attention, pre-event, and postevent processing. All items were adapted to

XSL•FO
RenderX

reflect the time frame of the EMA measurement (ie, "Since the last prompt") and the language of the target group. To assess all maintaining mechanisms of social anxiety suggested in the Cognitive Model by Clark and Wells [24] and based on similar existing items [95], we formulated 2 additional items to evaluate automatic thought processing and level of self-confidence in social situations: "In social situations, I have had many negative automatic thoughts running through my head" and "Since the last prompt, I have had little confidence in myself." Both items are rated on a 9-point Likert scale accordingly. (3) *Momentary social context* is assessed by 4 questions based on similar EMA items from a repository [95]; initially, participants indicate in which social situation they currently are: alone, family, close friends, boyfriend or girlfriend, colleagues, known persons, or strangers. Depending on their answer, they are asked if they would prefer to be alone or with someone (yes or no). Additionally, they indicate if they are currently in contact with others online (yes or no). Finally, they rate their experienced pleasantness in the current situation on a visual analog scale from not at all (0) to extremely (100).

Guardian Assessment

Guardians who provide their email addresses on the consent form voluntarily are assessed at baseline, midintervention, postintervention, and follow-up. In all assessments, they rate their child's social anxiety using the *Parents' Questionnaire on Social Anxieties in Childhood and Adolescence* (German: Elternfragebogen zu sozialen Ängsten im Kindes und Jugendalter) [96]. In 18 items, statements about the adolescent's behaviors and fears are rated on a 4-point Likert scale from not at all (0) to very much (3). Furthermore, guardians provide demographic data and answer questions about their child's treatment motivation and expectations during the baseline assessment. The *Motivation for Youth's Treatment Scale* [86] assesses guardians' motivation for treatment with 8 items rated on a 5-point Likert scale from do not agree at all (–2) to agree completely (2). The *Credibility or Expectancy Questionnaire—Parent Version* [97] measures guardians' expectations of the online intervention using 6 items. In total, 4 items are rated on a scale from not at all (1) to very (9), and 2 items on a scale from 0 to 100%.

Study Group Condition

SOPHIE Intervention

The internet-delivered self-help intervention SOPHIE (see Table 2) has a duration of 8 weeks and is based on the Cognitive Model by Clark and Wells [24] adapted to specific needs of adolescents [47] and existing evidence-based online interventions for adults with SAD [98-104]. The first version of the SOPHIE intervention was tested on 46 healthy adolescents. Based on their feedback, we improved the usability and understandability. An introductory module familiarizes adolescents with the intervention. Successively, 6 modules cover the maintaining mechanisms of the Cognitive Model and instruct adolescents to apply the learned strategies in exposure exercises in everyday life. The last module contains a short repetition and summary. The structure of each module includes a review of the previous module, an introduction to the current module's content, a summary at the end, and a quiz. Content is provided by animated video inputs, short text explanations, and exercises.

To enhance adherence and motivation throughout the intervention, adolescents receive guidance from e-coaches who provide weekly personalized support via a secured text-based messaging system. They summarize completed exercises, provide a preview of upcoming modules, send reminders to use the intervention, answer questions, and motivate participants by relating exercises to their personal goals. e-Coaches are psychology graduate students who were trained by the first or last author in offering guidance. Before sending, each guidance message is additionally peer-reviewed by another e-coach.

RenderX

Table 2. Description of all modules of the SOPHIE program[a].

Module	Image	Content
(1) Introduction		A user guide explains the structure and different elements of the online intervention. Participants are introduced to the 2 protagonists, Sophie and Leon, and can choose their avatar. They learn what social anxiety is, in which situations they may arise, and *set their personal goals* for the online intervention. Additionally, they are introduced to a progressive muscle relaxation exercise and are instructed to do this exercise daily.
(2) Emergence and maintenance of social anxiety		Participants learn about *etiological and maintaining factors of social anxiety*. In an exercise, they write down their personal anxiety cycle. For the following week, they are instructed to observe their social anxiety symptoms and enter their observations in their logbook.
(3) Automatic thoughts		Participants are introduced to *automatic thoughts* and their importance in maintaining social anxiety. In 2 exercises, they are instructed on how to recognize and modify their negative automatic thoughts. An additional relaxation exercise “safe place” is introduced to support their daily relaxation practice.
(4) Self-image		Participants learn about *self and other perspective* of a person, reasons for a positive self-image as well as possible consequences of a negative self-image. During an exercise, they are instructed to reflect on their assumptions of themselves, to recognize both negative and positive sides thereof, and to find a good balance. Participants learn 3 strategies to positively improve their self-image.
(5) Self-focused attention		Participants discover *self-focused attention* and the reinforcing impact it has on social anxiety. In an exercise, they train to shift their attention. In front of a virtual audience, they must tell a story and are instructed to focus their attention on the situation instead of themselves. They are introduced to a new relaxation exercise “relaxing world” to complement their relaxation practice.
(6) Reality tests I		Participants are introduced to reality tests (*exposure exercises*). To prepare for their own reality tests, participants establish their fear hierarchy. In the upcoming week, they conduct their reality tests and record the level of anxiety before and after.
(7) Reality tests II		Participants learn about strategies to deal with possible difficulties in reality tasks. Further, they are introduced to *socially competent behavior*. Thereby, examples of competent behavior are contrasted with examples of insecure behavior in social situations. Participants are instructed to continue with their reality tests.
(8) Repetition		The last module summarizes the content of the online intervention and participants reflect on their personal goals. They record a video of themselves in which they explain what social anxiety is, how they experience it, and how they learnt to cope with it. Later, they can replay this video to remind themselves of their progress.

[a]Displayed pictures were generated with the video program Vyond [105].

Care-as-Usual Group

Participants randomized to the CAU group are only contacted for assessments and receive access to the online intervention after follow-up. They are free to take advantage of any other health service. To account for additional help, the use of assistance is assessed post intervention and follow-up (details in Table 1).

Project and Risk Management

In weekly monitoring procedures, project implementation, clinical (eg, study withdrawals and adverse events), and research integrity (eg, blindness, data safety, important harms, or unintended effects) are ensured. Potential risks to participants are minimal. However, there is a potential inconvenience as filling out the questionnaires and the online intervention requires time.

In the case of suicidality (assessed at every assessment point by item 9 of the Patient Health Questionnaire [81]), a predefined suicidality protocol is applied; participants immediately receive an email with numbers for psychiatric services. Additionally, a member of the study team contacts the participant on the following working day to clarify acute suicidality. If acute suicidality is present, we offer additional help for instance by providing contact details on mental health services near to the adolescent’s home, if necessary, we support the referral to an appropriate service and decide on the continuation in the study. All participants must provide a safety contact in case that we cannot reach the adolescent who triggered the suicidality protocol.

Adverse events, all untoward events in a participant, including events not necessarily caused by or related to the online intervention, are monitored from randomization to follow-up 5 months after randomization. All adverse events are reported to the principal investigator, the ethics committee, and are documented in the participant’s case report form.

Data Management and Monitoring

All data are collected electronically except for informed consent and case report forms. Electronic data from all servers are extracted monthly and saved on a secure server of the University of Bern. All data are deidentified by removing names, email addresses, and location information, and are only accessible to the core study team as well as the head of research management for auditing purposes. Personal information is password-protected and stored in a secure electronic vault,

XSL•FO
RenderX

separately from outcome data. All data will be stored for 15 years after the termination of the study. The research management of the Faculty of Human Sciences of the University of Bern supervises data collection and storage in quarterly meetings.

All participants create password-protected accounts for the online intervention and are allocated a unique identification number. The online intervention is hosted on a secure platform of the University of Bern. All questionnaire and interview data are recorded via Qualtrics [64]. Qualtrics uses the same unique identification number. Thus, no personal data are entered in Qualtrics. EMA data are assessed with the SEMA^3 app and saved on a server of the University of Melbourne [65]. SEMA^3 requires personal data only to send out invitations and deletes them immediately afterward. For identification, participants are allocated a SEMA^3 numeric identification code.

Plan of Analysis

All analyses will follow the intention-to-treat approach. Patterns of missing data in the Growth Mixture Models will be analyzed, and in case of "missing at random" or "missing completely at random," multiple imputation will be applied.

Main Analyses

The primary outcome, that is, change in social anxiety, will be tested using Linear Mixed Effects Models. Time (baseline, midintervention, post intervention, and follow-up), intervention condition (SOPHIE and CAU), diagnostic status (SAD and subclinical social anxiety), and interactions (time*intervention condition; time*diagnostic status; intervention condition*diagnostic status; time*intervention condition*diagnostic status) will be specified as fixed effects, baseline SPIN value will be added as a fixed covariate and participant as a random effect to allow for between-person variation.

Further Analyses

Secondary outcomes (ie, global functioning, general anxiety symptoms, depressive symptoms, quality of life, self-esteem, and guardians' rating of their child's social anxiety) will be analyzed using Linear Mixed Effects Model as described earlier. In further analyses, therapy expectancy, therapy motivation (both adolescents' and guardians'), and satisfaction with the intervention will be added as moderators. Categorical outcomes (eg, diagnostic status) will be analyzed using General Linear Mixed Effect Models with intervention condition, diagnostic status, and time course as fixed effects and participants as random effect. Additionally, Growth Mixture Modeling will be used to identify subpopulations with comparable growth trajectories of social anxiety and secondary outcomes over time (latent classes) and to identify predictors of these classes.

Mediation Analyses

Mediation effects of therapeutic alliance and adherence to the intervention will be analyzed in a 1-1-1 multilevel mediation model with all variables measured at assessment time points (ie, baseline, midintervention, and post intervention), and all causal paths allowed to vary between participants.

Mediation effects of mechanisms of change in social anxiety will be explored in 2 different lower-level mediation analyses using multilevel modeling. In a 2-1-1 mediation analysis, time will be included as a fixed effect, baseline social anxiety as a level-2 fixed effect predictor, mechanisms of change (ie, automatic thoughts, avoidance, self-focused attention, pre-event, and postevent processing) as a level-1 random effect mediator, and momentary social anxiety as a level-1 random effect outcome. In a 1-1-1 mediation analysis, all constructs will be assessed at level-1. Thereby, social anxiety as a random effect predictor will be assessed concurrent with the random effect mediator, mechanisms of change in social anxiety, and the random effect outcome social anxiety will be assessed 1 prompt later (lead analysis).

Network Analyses

Baseline, mid-, post-, and follow-up data of current levels of symptoms and functioning will be modeled by network analysis to explore how networks differ by age, gender, diagnostic status, intervention condition, and assessment point in terms of centrality, closeness, betweenness, and clustering.

Sample Size

The sample size of 222 was determined in 2 a priori power analyses for the primary research question using G*Power [106] based on an intention-to-treat approach to account for possible dropouts and repeated measures ANOVA. In the SAD group, we expected a small to moderate effect size (Cohen d=0.35) [18,107], and for the group with subclinical anxiety, a small effect size (Cohen d=0.20) [38,108-110]. For both groups, we assumed an α level of 5%, power of 80%, and a correlation between measurements of r=0.4. Consequently, the SAD group should consist of 56 participants, and the subclinical social anxiety group of 166 participants.

Results

Data collection started in August 2021, and as of April 2023, a total of 106 participants are enrolled in the study. First results are expected in 2024.

Discussion

Due to the limited availability of mental health services for adolescents, online interventions offer the opportunity to provide early, low-threshold, and low-cost help. In this protocol, we describe an RCT that aims to test the efficacy of an online intervention for adolescents with subclinical social anxiety or a diagnosis of SAD compared to a CAU control group. A positive evaluation of this intervention holds several implications for the future: first, it may offer an efficacious intervention for both clinical as well as subclinical levels of social anxiety; second, the delivery format provides a high level of confidentiality as well as autonomy and may reach more adolescents in need than face-to-face psychotherapy interventions, in particular, those who need care but have not sought help yet; and third, it could also precede or complement more resource-intensive face-to-face interventions in terms of a stepped care approach [111-113].

XSL•FO
RenderX

Previous studies have provided initial evidence for the efficacy of online interventions for adolescents with social anxiety [28-30]. The study described in this protocol may extend them in several ways. So far, a comprehensive understanding on empirical evidence of age-adapted treatments to meet the needs of developing adolescents has yet to be fully established [47]. In this regard, findings based on moderator analyses of intervention effects and network analysis may provide more profound insights into which subgroups of adolescents an online intervention are especially beneficial and for which a different delivery format might be indicated [16]. Next, the empirical investigation of conceptually derived mechanisms of change may complement the efficacy and moderator analyses by highlighting which factors are particularly important for clinical change [114,115]. Lastly, to the best of our knowledge, this would be the first study to provide information on whether the same online intervention can be used as both indicated prevention and therapy for adolescents with social anxiety.

Despite these promises, this study will have some limitations. The self-selected sample will limit the generalizability of the study. Although the first version of the SOPHIE program was well accepted by adolescents, it is unlikely that 1 intervention is suitable for all participants spanning a large age range associated with heterogeneous needs and capacities. In this aspect, results on efficacy among subgroups that benefit most from the intervention, for example, based on their age, gender, or symptom severity, or based on idiographic analyses of the data, will be beneficial to better personalize interventions in the future [116]. Finally, there is some evidence that even answering EMA questions may lead to a change in behavior [117]. Since both the intervention and control group receive EMA prompts, this may have an impact on between-group comparisons.

Notwithstanding these limitations, the findings of this RCT may lead to a better understanding of SAD in adolescents, may provide important insights into the subgroups of adolescents for whom an online intervention may be an important complementary mental health service, and may help to optimize the effects of current interventions for SAD and subclinical social anxiety in adolescents by targeting the identified mechanism of change more directly. Overall, this online intervention may thereby offer a low-threshold prevention and treatment option to reduce the treatment gap and improve mental health care in adolescents.

Acknowledgments

We would like to thank Ingrid Odermatt and Noé Weigl for their contributions to programing the online intervention SOPHIE and Stefan Kodzhabashev for his technology support. Further, we like to thank all involved master students, Janin Ambühl, Lisa Dasen, Loris Di Ponzio, Alessja Frey, Laura Imboden, Chantal Messerli, Elina Mombelli, Elinor Sager, Elena Schoch, Claudia Tachezy, and Pascale Zürcher, for their help with data collection. Funding for the study is provided by the Division of Clinical Child and Adolescent Psychology and the Division of Clinical Psychology and Psychotherapy, University of Bern, Switzerland.

Data Availability

Data sharing is not applicable to this paper as no data sets were generated or analyzed for this protocol.

Authors' Contributions

NW wrote the initial version of the manuscript. All authors contributed to further drafts and approved the final manuscript. SJS is the principal investigator of the study.

Conflicts of Interest

None declared.

Abstract

Background: Numerous studies have revealed that adolescents with chronic physical or mental conditions (CPMCs) are at an increased risk for depression and anxiety, with serious direct and indirect negative effects on treatment adherence, family functioning, and health-related quality of life. As game-based approaches are effective interventions in treating anxiety and depression, we propose to explore the use of a multiplayer role-playing game (RPG) as a potential intervention for social isolation, anxiety, and depression.

Objective: The objectives of this study were to (1) determine the feasibility of using Masks, a multiplayer RPG, as an intervention for social isolation, anxiety, and depression in adolescents with CPMCs; (2) evaluate the viability of the research process; and (3) gauge participation in and engagement with RPG-based interventions.

Methods: This study is a remote synchronous game-based intervention for adolescents with CPMCs aged 14-19 years. Eligible participants completed a web-based baseline survey to assess anxiety, depression, and social isolation and to identify their gaming habits. After completing the baseline survey, they participated in 5 moderated Masks game sessions. In Masks, players assume the roles of young superheroes; select their character types, superpowers; and perform actions determined by the game's rule system and dice rolls. All game sessions were played using Discord, a communication platform commonly used by gaming communities. Games were led and moderated by game masters (GMs). After each game session, participants completed surveys to assess changes in anxiety, depression, and social isolation, and their attitude toward the game and the user experience. The participants also completed an exit survey after all 5 game sessions (modified version of the Patient Health Questionnaire and the Generalized Anxiety Disorder Questionnaire, and 17 open-ended questions). The GMs rated each game session and reported on gameplay, player behavior, comfort, and engagement levels of the players.

Results: As of March 2020, six participants were recruited for the pilot study to participate in moderated web-based game sessions of Masks; 3 completed all game sessions and all required assessments. Although the number of participants was too low to draw generalizable conclusions, self-reported clinical outcomes did seem to indicate a positive change in depression, anxiety, and social isolation symptoms. Qualitative analysis of postgame survey data from participants and GMs indicated high levels of engagement and enjoyment. Furthermore, the participants provided feedback about improved mood and engagement related to weekly participation in Masks. Lastly, responses to the exit survey showed interest in future RPG-related studies.

XSL•FO
RenderX

Conclusions: We established a workflow for gameplay and evaluated a research protocol for evaluating the impact of RPG participation on isolation, anxiety, and depression symptoms in adolescents with CPMCs. Preliminary data collected from the pilot study support the validity of the research protocol and the use of RPG-based interventions in larger clinical studies.

Introduction

Numerous studies have revealed that adolescents with chronic physical or mental conditions (CPMCs) are at an increased risk for depression and anxiety, with serious direct and indirect negative effects on treatment adherence, family functioning, and health-related quality of life [1-3]. Regular participation in social activities with peers is particularly crucial in adolescence where it can provide a critical key component for developing healthy psychological development and identity formation [4,5]. Moreover, support from peers can also play a significant role in helping young people with CPMCs cope with illness and with its "inherent psychosocial and lifestyle changes" [6].

A number of studies have shown advantages of web-based socialization and web-based peer support for patients with disorders such as autism [7,8], social anxiety disorder [9], and chronic conditions such as cystic fibrosis (CF), where the danger of cross-infection of respiratory tract bacteria [10-12] prevents patients with CF from socializing in person.

With the outbreak of the COVID-19 pandemic, social isolation has become an even more critical problem, preventing adolescents with CPMCs from socializing not only with their peers but also with family members and other members of their support networks [13-15]. A number of mobile apps and web-based interventions have emerged to help patients with CPMCs to deal with stress [16], social isolation [17,18], anxiety [19], depression [19,20], symptom burden [16], and disease management [21,22]. Although numerous studies have shown a positive impact of these apps [16-18,20-22], none of the app-based interventions that we reviewed had social elements that would allow patients to interact with their peers or members of their support networks. Moreover, we were unable to find the majority of the apps described in the reviewed studies on publicly available app stores such as Apple App Store, Google Play Store, or Steam, suggesting that the apps used as part of research studies either were not available to the general public or did not have long-term support from the developers. Another shortcoming of many app-based interventions is that they target a specific mental or physical health condition (eg, autism [23] and diabetes [21,22]) but do not generalize to broader populations of adolescents with CPMCs.

Several attempts have been made to develop or study game-based interventions for social isolation. The use of video games as mental health interventions has been well explored in recent years [24-26], but, surprisingly, little work has been done to research the use and impact of video games on social isolation. Pearce et al [27], Zhu [28], and Martinez et al [29] explored how individual players as well as entire families leveraged the *Animal Crossing: New Horizons* game to battle pandemic-related social isolation. Udapola [30,31] proposes the use of social virtual reality (VR) platforms as an intervention for socially isolated adolescents with significant illness. Although many studies have found VR interventions to be effective tools for cognitive behavioral therapy [32-34], the availability and cost of VR devices may prove to be a significant barrier to scaling VR-based interventions to large populations of socially isolated adolescents.

However, to the best of our knowledge, there are no studies that explore the use of role-playing games (RPGs) in facilitating adolescents with CPMCs to escape their real world by creating an in-game character that may allow for identity exploration without the limitations of their CPMCs. Furthermore, as of the time of this writing, we were unable to find studies that evaluate the impact of RPG participation on self-reported isolation, anxiety, and depression symptoms in adolescents with CPMCs.

According to the Adventure Game Industry Market Research Summary [35], an estimated 5.5 million people in the United States regularly play RPGs. There is more to RPGs than the sheer number of players—there is strong evidence to suggest that RPGs facilitate the creation and sustainability of game enthusiasts' communities [36,37].

We hypothesize that participation in RPG communities of their peers (other adolescents with CPMCs) may decrease social isolation, increase feelings of acceptance, and enhance peer support for adolescents with CPMCs. The gameplay itself and the community around the game may provide peer support around some of the struggles and difficulties that adolescents with CPMCs have, including physical and mental health maintenance, adherence to complex medication regimens, self-advocacy, reduction in depression and anxiety symptoms, and transition from pediatric to adult health care.

Before studying whether participation in RPG communities provides this benefit in adolescents with CPMCs, it is important to understand whether it is feasible to engage adolescents with CPMCs through RPG communities.

The goals of this pilot work are to (1) understand the feasibility of recruiting adolescents with CPMCs to participate in an RPG game; (2) assess the feasibility of using Masks, a multiplayer tabletop RPG game, to engage adolescents with CPMCs; and (3) develop a research protocol for using and evaluating RPG

XSL•FO
RenderX

games as potential clinical interventions for anxiety and depression associated with social isolation.

Methods

Initial Recruitment Challenges

We conducted a series of semistructured interviews with 12 patients with pediatric CF (aged 13-18 years) to understand their gaming habits and preferences and gauge their interest in a research study involving RPGs. For this first iteration, we considered setting up a private World of Warcraft (WoW) [38,39] server to allow us to create custom in-game quests for the participating patients with CF. However, 7 of the interviewed patients reported that they did not like WoW or did not want to spend multihour sessions going on quests with strangers. Three of the patients stated that they already spend between 1 and 3 hours per day playing video games and that their parents would object to their participation in a study that requires hours of computer-based gameplay. Lastly, 3 patients indicated that their parents perceived WoW as a violent RPG and would not allow them to participate in such a study.

In a second iteration, we conducted a round of semistructured interviews with a different group of 5 patients with pediatric CF (aged 14-17 years, no overlap with the first group). We asked the participants to describe elements of an RPG that they would be interested in playing. A word frequency analysis of the collected data showed the following words being present in every response: adventure, action, puzzle, superhero. After discussing interview results with several University of Pittsburgh game design instructors, a lead game designer from a Pittsburgh-based game design studio, and with members of 2 student-based RPG clubs, we selected the Masks RPG as a potential intervention for this study.

Our original Masks RPG-based study design called for weekly 3-hour game sessions. Once we began the recruitment phase, we focused on the population with pediatric CF. A total of 11 patients with CF expressed interest in participating in the study. However, during the informed consent process, once they understood the required time investment, 7 participants withdrew before being consented. Either the participants or their parents expressed concerns over the required time commitment. The remaining 4 participants were not able to find a common weekly 3-hour slot that would work for the entire group.

In our next recruitment iteration, we expanded the participant inclusion criteria to any pediatric onset chronic disease that requires rigid medication or treatment adherence, including CF, type 1 diabetes, sickle cell anemia, and pediatric cancers that require maintenance chemotherapy. From this population, we recruited and consented 8 participants and scheduled weekly Masks game sessions. A total of 6 of the 8 participants left the study after the first 2 game sessions, stating scheduling difficulties and interference with school activities as primary reasons for leaving the study.

On the basis of the recruitment and retention difficulties described above and the feedback received from participants who left the study, we redesigned the study workflow, shortened gameplay to approximately 1.5 hours per game session, and expanded participant inclusion criteria to all adolescents with CPMCs aged 14-19 years. It is important to note that shortening the gameplay sessions did not alter the game scenarios—we split scenarios between multiple game sessions, with each subsequent session's scenario, activities, and storylines picking up where the previous session left off.

Study Design

After the initial screening, participants completed an onboarding questionnaire to collect basic demographic information, as well as baseline data related to depression, social isolation, social support, and symptom burden. Questions included a modified version of the Patient Health Questionnaire omitting the last suicidality question due to anonymity and difficulty reaching participants who express risk (PHQ-8) [40], the Generalized Anxiety Disorder Questionnaire (GAD-7) [41], Social/Informational Support section of the RAND Social Support Survey Instrument (SSSI) [42], and the modified 4-question version of the revised UCLA Loneliness Scale (LS) [43-45]. PHQ-8, GAD-7, SSSI, and LS are extensively validated instruments that have shown good reliability, validity, and adaptability for patients across multiple research studies (Figure 1).

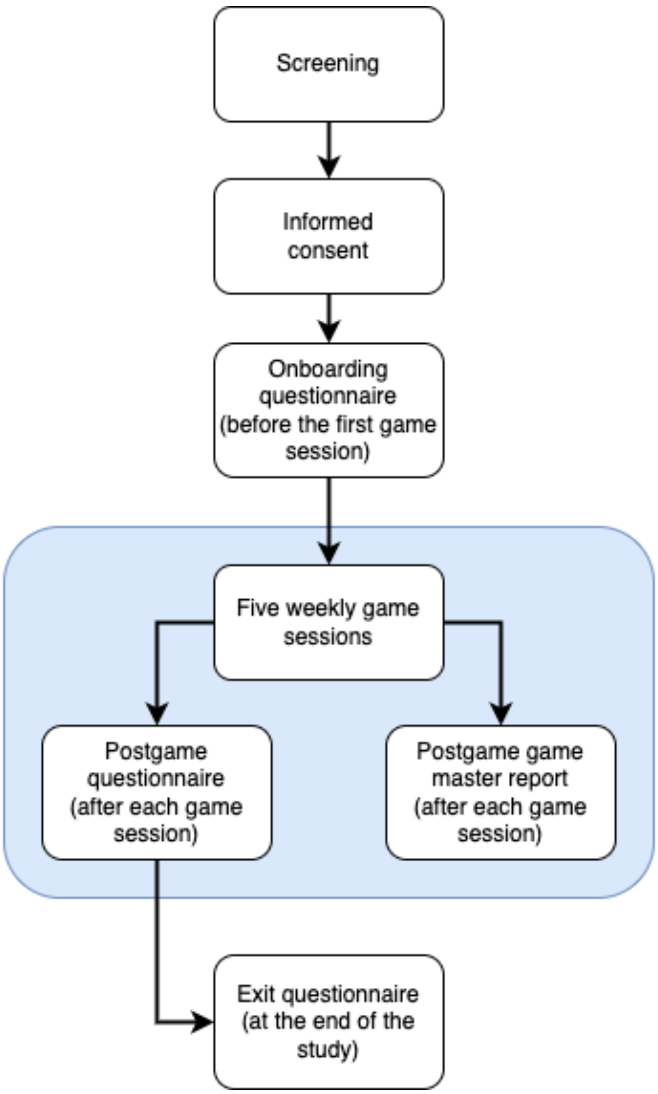
After completing the onboarding questionnaires, participants played a series of 5 weekly games, with the average game session duration of 1.5 to 2 hours.

Each game session was guided by 2 game masters (GMs). The role of a GM is to guide the narrative, environments, and the non-player aspects of the game, as well as provide guidance to players and address any player disputes. In the context of this study, the GMs also played an additional role of field researchers, recording their perceptions of how the players interacted with each other and with the game, whether players were engaged, and whether players discussed their CPMC symptoms or their personal lives with each other.

All GMs who helped facilitate this study were University of Pittsburgh students. At the time of the study, 2 of the GMs were second-year students at the School of Medicine, one was a second-year student at the School of Pharmacy and one a third-year student at the School of Engineering. All 4 GMs were selected based on 2 criteria: prior GM experience with tabletop RPGs such as Dungeons & Dragons (D&D) and prior academic research experience in a university setting. As part of the screening, all GMs had to learn how to plan and execute a Masks game session with this project's investigators as players. Once the GMs demonstrated their ability to plan, organize, and run game sessions, they were required to complete the Responsible Conduct of Research, Conflict of Interest, and Human Subjects Research (both biomedical and social/behavioral/educational) web-based training modules required by the University of Pittsburgh Human Research Protection Office.

Throughout the study, the GMs were responsible for planning, scheduling, and running game sessions, as well as for ensuring that participants complete postgame surveys.

The GMs rated each game session on the scale of 1 to 10 (1=worst and 10=best), provided their opinion on what could have made the session better, described any issues with



XSL•FO
RenderX

gameplay or with player behavior, and provided comments on comfort and engagement levels of the players.

At the end of each game, participants completed a 27-question Likert questionnaire (Textbox 1) to collect feedback on the game session. Questions focused on participants' interactions with other players and with the GM, as well as their opinions of the storyline, how the game was handled, and whether the game was engaging or entertaining.

Lastly, the participants completed an exit questionnaire after they concluded all 5 game sessions. The exit questionnaire contained a modified version of the PHQ-9 and GAD-7 questionnaires. Additionally, the exit questionnaire also contained 17 open-ended questions (Textbox 2), such as "What was the most frustrating moment or aspect of the game experience?" and "If you had a magic wand to wave, and you could change, add, or remove anything from the game experience, what would it be?"

Figure 1. Study design flow diagram.

XSL•FO
RenderX

Textbox 1. Postgame questionnaire (responses for the questions are on the scale of 1 to 5: 1=strongly disagree, 2=somewhat disagree, 3=neither agree nor disagree, 4=somewhat agree, 5=strongly agree).

1. I enjoyed playing the game tonight
2. I would like to play the game again
3. I felt emotionally safe playing the game
4. I felt the other players treated me with respect
5. I felt the other players treated each other with respect
6. I felt the other players were kind to me
7. I felt the other players were kind to each other
8. I felt comfortable talking to the other players
9. I was interested in what the other players had to say
10. I would like to get to know the other players more
11. Playing this game made me feel happy
12. Playing this game made me feel less anxious
13. Playing this game made me feel less depressed
14. Playing this game made me feel less alone
15. I felt comfortable talking about my experience with chronic physical or mental conditions (CPMCs)
16. I liked talking about my experience with CPMCs
17. I liked that I was able to play with other people with CPMCs
18. I liked that I was able to talk with other people with CPMCs
19. I am looking forward to the next gaming session
20. The game master was helpful
21. The game master made me feel safe
22. The game master talked too much
23. The game master talked just right
24. The game master talked too little
25. I liked having the game master present
26. I like the game Masks
27. I like role-playing games

XSL•FO
RenderX

Textbox 2. Masks research study exit questionnaire, open-ended questions.

1. What was the most frustrating moment or aspect of the game experience?
2. What was your favorite moment or aspect of the game experience?
3. Was there anything you wanted to do that you couldn't?
4. If you had a magic wand to wave, and you could change, add, or remove anything from the experience, what would it be?
5. What were you doing in the experience?
6. What was your role?
7. Why did you choose this particular role?
8. How would you describe this game to your friends and family?
9. Did you talk to your parents about playing this game?
10. Did your participation in this game interfere with other activities?
11. Did your parents mind that game sessions took 3 hours to complete?
12. Why did you agree to participate in this study?
13. Was it because of the pay, or were there any other reasons?
14. Did you ever feel uncomfortable during any of the game sessions? If so, why?
15. During the games, did you discuss your symptoms with any other players?
    - What were these discussions like?
    - What specifically did you discuss?
16. How did participating in these games make you feel?
17. Would you be interested in continuing playing this game or other games like it in the future, outside of this study?

Study Population

For the purposes of this study, we defined CPMC as any physical or mental condition where the symptoms have persisted for at least 1 year and where the participant has been receiving treatments from health care professionals for a period of at least 1 year. We required that each participant have consistent access to a computer and could demonstrate native-like fluency in the English language. Participants with impairments that prevent them from using a computer were excluded from the study because it would not have been possible for them to interface with the study materials.

Ethics Approval

Ethics Review

This study was reviewed and approved by the University of Pittsburgh Human Research Protection Office (protocol number STUDY19090313, “Multiplayer RPG as depression/isolation intervention”).

Informed Consent

After the initial screening phone call with the participant and parent dyad, the research team emailed the consent form to the parent and the participant for review and to have as a reference at the time of the consent form review. A research team member met with both the parent and the participant via a Zoom conference call to review the consent form and to answer any questions. The consent form included general explanations of what research is, specific information describing the study, explanation of inclusion criteria and how they relate to the specific participant being consented, detailed explanation of the game, participation requirements, potential benefits, and possible risks and discomforts. After the consent form review and after the parents and the participants confirmed that they understand the information and do not have additional questions, we asked the parents and the participants to digitally sign the consent form via the DocuSign electronic signature service. The final signed copy was automatically emailed to all parties and stored on the University of Pittsburgh DocuSign service cloud.

Privacy Protection

This study did not collect any identifiable data from the parents or the participants except for the data required for the consent forms. Signed consent forms were automatically stored on the University of Pittsburgh DocuSign service cloud, accessible only to the study’s principal investigator. After the consent process, participants were identified only by their chosen game character names, with no links to their names or their Health Insurance Portability and Accountability Act–protected information. Transcripts from game sessions (ie, Discord chat transcripts) and all raw survey data were reviewed after each game session by at least 3 investigators to ensure that no identifiable data were entered. Coded data from interviews, game transcripts, and survey responses were stored in a secure University of Pittsburgh–approved Microsoft OneDrive folder accessible only by the investigators.

XSL•FO
RenderX

Compensation

Participants were compensated US $20.00 per each completed game session and an additional US $20.00 for completing all the questionnaires associated with the study.

Intervention

Masks [46] is a tabletop role-playing system produced by Magpie Games. In Masks, players assume the roles of young superheroes in a team (such as the Teen Titans or the X-Men) as they come of age in the face of superheroic trials and tribulations.

A tabletop RPG is an RPG in which the players "describe their characters' actions through speech" and determine the actions of their characters based on their character sheets. The outcomes of the characters' actions are determined by a formal system of rules and guidelines. "Within the rules, players have the freedom to improvise; their choices shape the direction and outcome of the game" [47].

The players select playbooks [48], which are based around the type of superhero they want to be and create their own characters to play as. They are similar to other tabletop RPGs like D&D, because the key element of gameplay is acting as a character in scenarios designed and led by a GM. By acting as their characters in response to these scenarios, the group creates a narrative that they experience together. Dice and other tools to decide outcomes are used to add an element of unpredictability to the narrative and aid in the improvisation process.

Unlike most other RPGs, Masks' mechanics are more focused around a character's emotional state and personal development. For example, the Label system explains mechanically how the characters grow into their powers based on the realizations they make about themselves and the influence of others around them. Instead of taking damage in ways that could lead to their characters dying, the system focuses more on the feelings that challenges and enemies can impose on the characters. A character who fails to use his or her powers against a formidable opponent in a stressful situation could feel insecure or, potentially, angry. By focusing on emotional states rather than physical health, players are free to invest in their characters without fear of them dying, while being given opportunities to create dramatic and narrative tension.

To ensure that players are kept comfortable enough to take creative risks and better tell the story they want to tell, it is very important that practices such as the "Blackcard" be used to ensure that every player is having fun. The "Blackcard" is a sign that can be raised if anybody in the party is feeling uncomfortable out of character about something in the game. If it is raised, the game will stop, and the situation will be resolved out of character before play resumes.

Game Sessions

At the beginning of the study, we conducted game session 0 (zero), where the GMs explained the game mechanics to the players and the players selected their in-game characters. We used the *MASKS: A New Generation* core book (purchased directly from Magpie Games) for the world, scenario, rule descriptions, and character sheets [48]. Players selected their in-game characters from the list of predefined characters described in the core book (Table 1).

Table 1. Character types selected by the participants.[a]

Participant (in-game alias)	Character type	Abilities
Kichi Ito	The Delinquent	(1) Teleportation; (2) tricks illusions; (3) gadgetry and hacking; and (4) psychic weapons, emotion control, and power negation
Rio	The Bull	Someone or something changed you, made you into a perfect weapon: superhumanly tough, incredibly strong, and uniquely skilled at fighting. Decide how each of those abilities manifests
Ryder	The Janus	(1) Rodent or insect control; (2) one generation, venom, or webs; (3) energy absorption; (4) supernatural senses; (5) impossible mobility; and (6) substance mimicry

[a]PHQ-9: Patient Health Questionnaire.

Every subsequent game session began with a recap of the events from the previous session. According to participants' and GMs' feedback, this was helpful for the group as it kept everyone on the same page and ensured that no one had forgotten anything major from the previous sessions' storylines or activities.

After the recap, the GM described the setting for the current scene, and the players responded by describing their characters' actions and reactions, causing the scene to evolve and to change. If a character performed an action where the outcome was uncertain, the player had to roll the dice to find out what the character's action (or reaction) would be.

At the end of every session, the GMs debriefed the players by asking them to describe how the events of the session changed each character's opinion of themselves or of the team they are a part of. Afterward, the GMs asked for comments, questions, and concerns and asked the players if there was anything that they wanted to see more of or less of in the game.

Remote Play Tools

Despite "tabletop" being in the name, physical proximity is not required to play Masks. Games can easily be conducted using chat with tools such as Discord [49], allowing for play anywhere with reliable internet access.

Discord is a free voice, video, and text chat application with both mobile and desktop clients. Discord allows its users to create private, invite-only virtual servers, a feature that helps ensure participants' privacy and provides researchers with full control over the conversations and the interactions. We chose Discord over comparable communication tools such as Slack or Microsoft Teams because of its popularity in web-based gaming communities [50], availability of clients for all major

XSL•FO
RenderX

operating systems (ie, MacOS, Microsoft Windows, iOS, and Android), and its documented use in multiple research studies [51-54].

For this study, we created a private server accessible only to the research team members and the participants (players). We used the text chat function in this server to coordinate scheduling and the voice chat functionality to conduct game. Although Discord can also display video during voice calls, we disabled that functionality to protect participants' privacy.

Because Masks requires each player to roll a pair of 6-sided dice, we used M.A.D.D.I.E. ("Masks Automated Discord Dice Interpreter & Explainer!"), a user-created Discord chatbot to simulate dice rolls and facilitate game mechanics. In a dedicated text channel accessible within Discord, M.A.D.D.I.E responds to a concise syntax with both the requested dice rolls and relevant portions of the playbook describing its consequence, reducing the need for manual referencing, and allowing for smoother gameplay.

Lastly, in lieu of having each participant maintain a physical character playbook, we used a Google Drive–hosted common player sheet for character creation and tracking [55].

Data Analysis Methods

It is important to note that this pilot feasibility study had only 3 participants and that the statistical methods described in this section were initially chosen with a larger study in mind.

To determine how the participants' perceptions of the game and self-reported anxiety and depression scores changed over time, we calculated the change in per-question response score from session to session, as well as the overall mean response change per participant. When more data are collected from future studies, we will use the Wilcoxon signed rank test to compare both before and after changes in assessment measures.

Because of the small number of participants who participated in this study, we decided to report the participants' and the GMs' paraphrased or directly quoted responses. In future iterations of this study, we plan for analyzing participants' open-ended text responses using inductive theme analysis.

Results

Overview

As of March 2020, we recruited 6 adolescents with CPMCs aged 14-19 years through the UPMC Children's Hospital of Pittsburgh and the ETUDES Center (the Center for Enhancing Triage and Utilization for Depression and Emergent Suicidality in Pediatric Primary Care) [56].

Of the 6 consented participants, 4 participated in the initial game sessions and 3 completed all game sessions and all required surveys.

The 3 participants who participated in all game sessions had the mean and median age of 17 years. Participants identified their gender as cisgender male, transgender female, and nonbinary assigned female at birth. Two of the participants were White, and one was African American. Two of the participants completed 11 grades of high school, and one participant recently graduated from high school (completed 12 grades).

The participants' self-reported CPMCs included sensory processing disorder and diabetes, and all 3 participants indicated that they need or use more medical care, mental health, or educational services than is usual for most children their age. All participants reported that they have at least 5 people in their immediate support network who provide emotional support "most of the time" to "all of the time." PHQ-8, GAD-7, SSSI, and LS scores at the time of onboarding are reported in Table 2.

All participants indicated that they prefer to play with other people rather than alone, on average playing between 10 and 20 hours per week, with game genre preferences leaning toward action, adventure, and strategy or puzzles. All participants had prior experience with video game or tabletop RPGs, including games such as D&D, Minecraft [57], Stardew Valley [58], and Undertale [59].

Even though we did not have enough participants in this pilot study to measure the impact of participation in Masks on the participants' quality of life and mental health with any statistical significance, it is worth mentioning that PHQ-9 and GAD-7 scores we did collect indicated a reduction of depression and anxiety symptoms. Moreover, the postgame questionnaire results showed a consistent positive change in the participants' opinion of the game from one game session to the next.

Responses to the postgame questionnaire (Textbox 1) indicated a positive trend in participants' opinions of and engagement with Masks, individual game sessions, and their comfort levels with other players and with the GMs. Figure 2 shows the trend in the mean response change to the postgame questionnaire over the course of 5 sessions.

In the exit questionnaire, all 3 participants reported that they talked to their parents and friends about the game and the study, that their participation in game sessions did not interfere with other activities, and that their parents did not mind that each game session took several hours to complete.

One participant reported that initially they had difficulties following the story. Another participant reported that at first, they "had a really hard time talking [...] and wanted to stay quiet."

Favorite aspects of the game included creative environments, unpredictable situations, and doing "something stupid as a team and [working it out together]."

All 3 participants indicated that there was never a situation in the game where they wanted to do something but could not either because of the game environment constraints or due to any issues with other players or the GMs.

To the question of "Why did you choose your particular role?" one participant responded, "I've always enjoyed playing the 'bad boy' type characters," while another indicated that "[the role] is similar to how I see myself."

All 3 participants indicated that the game was fun to play and that the characters and other players were "comfortable" and

XSL•FO
RenderX

"relatable," and only 1 participant reported being initially too nervous to talk. None of the participants discussed their physical or mental health during game sessions.

All 3 participants reported that they initially agreed to join the study because of the compensation but "ended up having a really good time."

It is also worth noting that to the question "Would you be interested in continuing playing this game or other games like it in the future, outside of this study?" all 3 participants answered "Yes."

Lastly, all participants indicated that playing the game made them "happy" and "excited." To quote one of the participants, "It made me very happy. I felt safe and it was a lot of fun. It was one of my favorite parts of the week. I looked forward to it every week."

Table 2. Participants' PHQ-9[a], GAD-7[b], LS[c], and SSSI[d] scores from the onboarding questionnaire.

Participant (in-game alias)	PHQ-8 score	GAD-7 score	LS score	SSSI score
Kichi Ito	10	2	40	9
Rio	18	5	30	10
Ryder	11	3	23	8

[a]PHQ-9: Patient Health Questionnaire.

[b]GAD-7: Generalized Anxiety Disorder Questionnaire.

[c]LS: UCLA Loneliness Scale.

[d]SSSI: RAND Social Support Survey Instrument.

Figure 2. Overall mean change in participants' engagement and comfort with the game over the course of 5 sessions.

GM Postgame Reports

The GMs reported minor technical problems, the most common being connection issues to Discord servers. The GMs did not report any behavior issues (such as toxic behavior or negative language) among the players. The only reported minor issues included lateness to a game session from one player. After the first session, the GMs reported that one player did not feel comfortable and was shy throughout the gameplay. The players did not discuss their personal lives or any topics related to their physical or mental health in any of the game sessions.

Discussion

In this paper, we presented our pilot work on (1) determining the feasibility of using Masks, a multiplayer RPG, as an intervention for social isolation, anxiety, and depression in adolescents with chronic physical or mental health conditions; (2) evaluating the viability of the research process; and (3) gauging participation in and engagement with RPG-based interventions.

XSL•FO
RenderX

We found that recruiting adolescents to participate from clinical settings was difficult despite study design changes. These recruitment difficulties were mainly due to scheduling difficulties and dedicated time requirements.

For those participants who did participate, we were able to establish a workflow for gameplay and successfully conducted 5 sessions. Participants overall reported satisfaction and enjoyment with gameplay but did not engage in discussing their CPMCs during play as hypothesized. Of particular interest were participants' preferences to play with other people rather than alone and participants' prior experience with multiplayer games. These findings correspond to findings in other studies related to game-based interventions [60-63], suggesting that participants with prior multiplayer game experience are more likely to participate in game-related studies. These findings also suggest that in future iterations of this study we will attempt to recruit adolescents with CPMCs from multiplayer game communities rather than from clinical settings.

Although the number of participants was too low to draw generalizable conclusions, self-reported clinical outcomes did seem to indicate a positive change in depression, anxiety, and social isolation symptoms. Furthermore, the participants provided feedback about improved mood and engagement related to weekly participation in Masks.

It is also important to note that all participants reported that they talked to their parents and friends about the game and the study. Several studies suggest that parents or caregivers of children with CPMCs perceive children's distress symptoms (anxiety, depression, and physical symptom burden) differently, with parents or caregivers consistently rating the children's symptoms lower than the children [64-68]. In future iterations of this study, we will explore gameplay design features that could facilitate and promote communications between children and parents or caregivers.

In discussing this work, it is important to acknowledge its limitations. One of the main limitations of this study was recruitment and retention. In the initial phases, we attempted to recruit from clinical practices and hospital settings, but because of scheduling difficulties, dedicated time requirements, and school and family obligations, most participants dropped out of the study. Because of time requirements and scheduling constraints, participants participated in only 5 consecutive game sessions of the planned 10. Another limitation was that one participant did not complete all the questionnaires despite multiple reminders from the GMs and the research team. It is also worth noting that we do not know how the fact that the GMs and the players are all strangers to one another affects interaction and gameplay dynamics compared with a typical game of Masks where the players have had prior social interaction. Although our limited data show that the participants reported being comfortable with the GMs and each other, it would be important to empirically compare a game dynamics and comfort levels of players who are strangers to each other versus players who know each other outside of the gameplay world. Lastly, we planned to compare pre- and post-LS and SSSI scores to determine if the scores have improved over time with each game session. However, we were unable to compare these scales with poststudy values because of accidental omission of including them in the exit questionnaire.

Although the small number of participants (n=3) does not allow us to make generalizable conclusions about the efficacy of RPG-based interventions, we did establish a workflow for gameplay and evaluated a research protocol for evaluating the impact of RPG participation on isolation, anxiety, and depression symptoms in adolescents with CPMCs. It is also worth noting that many recent and past research studies focused on developing custom interventions for a specific health or mental condition. From our own experience [69-72], we know how expensive and time-consuming it is to develop game-based interventions and how difficult and costly they are to maintain and support. This work strongly suggests that it is possible to take a widely available and relatively inexpensive multiplayer tabletop RPG, one that already has an established support network and gamer community, and use it as a possible intervention for social isolation.

Many support groups, community centers, and even entire neighborhoods already have established community game events (eg, game nights and game jams), with a positive impact on player engagement, mental health, and community building [73-76]. If future studies with larger patient samples show significant short- and long-term improvement in social isolation, depression, and anxiety symptoms, clinical practices that provide health care services to adolescents with CPMCs should consider either partnering with existing gamer communities or establishing their own consistently recurring multiplayer RPG events for their patients. Such "game nights" could potentially be used as a supplement to existing group therapies.

Lastly, we believe that the preliminary data collected from the pilot study support the validity of the research protocol and the use of RPG-based interventions in larger clinical studies.

Acknowledgments

This study was supported in part by two grants: (1) a grant from the National Institute of Mental Health, "The Center for Enhancing Triage and Utilization for Depression and Emergent Suicidality in Pediatric Primary Care" (ETUDES Center, P50MH115838), and (2) a grant from the University of Pittsburgh Office of the Chancellor Pitt Seed Project. We would also like to thank Brandie George-Milford (program director) and Shruti Idnani (research assistant) at the University of Pittsburgh ETUDES Center for helping with recruitment and study coordination. A special thanks to Drs Traci Kazmerski, Scott Maurer, and Daniel Weiner for their help with the study design and participant recruitment.

Abstract

Background: Among chronic diseases, cognitive, neurological, and cardiovascular impairments are becoming increasingly prevalent, generating a shift in health and social needs. Technology can create an ecosystem of care integrated with microtools based on biosensors for motion, location, voice, and expression detection that can help people with chronic diseases. A technological system capable of identifying symptoms, signs, or behavioral patterns could provide notification of the development of complications of disease. This would help the self-care of patients with chronic disease and save health care costs, promoting the autonomy and empowerment of patients and their caregivers, improving their quality of life (QoL), and providing health professionals with monitoring tools.

Objective: The main objective of this study is to evaluate the effectiveness of a technological system (the TeNDER system) to improve quality of life in patients with chronic diseases: Alzheimer disease, Parkinson disease, and cardiovascular disease.

Methods: A multicenter, randomized, parallel-group clinical trial will be conducted with a follow-up of 2 months. The scope of the study will be the primary care health centers of the Community of Madrid belonging to the Spanish public health system. The study population will be patients diagnosed with Parkinson disease, Alzheimer disease, and cardiovascular disease; their caregivers; and health professionals. The sample size will be 534 patients (380 in the intervention group). The intervention will consist of the use of the TeNDER system. The system will monitor the patients by means of biosensors, and their data will be

XSL•FO
RenderX

integrated into the TeNDER app. With the information provided, the TeNDER system will generate health reports that can be consulted by patients, caregivers, and health professionals. Sociodemographic variables and technological affinity will be measured, as will views on the usability of and satisfaction with the TeNDER system. The dependent variable will be the mean difference in QoL score between the intervention and control groups at 2 months. To study the effectiveness of the TeNDER system in improving QoL in patients, an explanatory linear regression model will be constructed. All analyses will be performed with the 95% CI and robust estimators.

Results: Ethics approval for this project was received on September 11, 2019. The trial was registered on August 14, 2020. Recruitment commenced in April 2021, and the expected results will be available during 2023 or 2024.

Conclusions: This clinical trial among patients with highly prevalent chronic illnesses and the people most involved in their care will provide a more realistic view of the situation experienced by people with long-term illness and their support networks. The TeNDER system is in continuous development based on a study of the needs of the target population and on feedback during its use from the users: patients, caregivers, and primary care health professionals.

Introduction

Background

With the increase in population aging in Europe, chronic diseases are becoming more prevalent [1]. This reality represents a major challenge to health care systems due to comorbidities and outcomes such as increased dependency [2-4]. It is a priority to promote the autonomy and empowerment of patients and their caregivers, improve their quality of life (QoL), and provide tools enabling better monitoring by health professionals [5-7].

Among chronic diseases, cognitive, neurological, and cardiovascular impairments are becoming increasingly prevalent, generating a shift in health and social needs [8]. According to the World Health Organization (WHO) in a 2018 report, cognitive impairment and dementias, including Alzheimer disease (AD), remain one of the greatest global public health challenges facing our society [9]. The number of people worldwide living with a cognitive impairment such as dementia, is estimated at 44 million; this is expected to double by 2030 and is likely to increase to around 152 million by 2050. Among neurological disorders, Parkinson disease (PD) affects 1.2 million people in Europe [10]. Patients with PD, in addition to symptoms related to movement disorders, also develop cognitive impairment and emotional and behavioral disturbances that are important to follow closely [10]. Cardiovascular disease (CVD) accounted for 31% of all global deaths in 2016, and it is considered the leading cause of premature death (37% of all deaths under the age of 70) and disability in Europe and worldwide [11]. Early detection of disease progression and early treatment is essential [12].

Technology can create an ecosystem of care integrated with microtools based on biosensors for motion, location, voice, and expression detection that can help people with chronic diseases [13]. Today, these data streams, including sensor measurements, activity logs, and user-generated content, are used to measure or provide robust proxies for human behavior and function in both health and disease. This is called digital phenotyping [14].

Digital phenotyping is the in situ, moment-to-moment quantification of the human phenotype at the individual level using data from personal digital devices [15]. These microtools are able to recognize changes in a person's habitual behaviors, movements, and mood through a multisensory system composed of smartphones, wearables, and other connected devices [16]. In addition, digital phenotyping allows the integration of an interactive communication service between health and social services, which can bring advantages in patient care and help detect risk situations, improving the autonomy of patients and the care they receive from caregivers and health professionals [17].

The development of a technological system capable of identifying symptoms, signs, or behavioral patterns that could provide alerts for the development of complications of these diseases would help the self-care of people with chronic diseases, their caregivers, and health professionals, as well as save costs for the health care system [18,19]. Some studies on digital phenotyping in patients with chronic disease have demonstrated its usefulness in treatment for mental health problems, diabetes, asthma, and CVD, showing positive effects on self-care and adherence to treatment [20,21]. This has been achieved by detecting clinical phenomena through digital tools that have enabled health professionals to adapt their assistance to the environment and characteristics of patients [21].

Until now, research on digital phenotyping has been led and developed by teams specialized in the technological field. As suggested by Huckvale et al [20], these challenges must be addressed under a multifaceted and multidisciplinary perspective involving health professionals and users in the development of such technological systems.

Needs such as the detection of behavioral changes in patients with dementia, gait changes and fall prevention in patients with

XSL•FO
RenderX

PD, and the close monitoring of risk factors for CVD could be covered by intelligent monitoring system [19]. This would help the self-care of patients with chronic diseases, promoting the autonomy and empowerment of patients and their caregivers and improving their QoL.

Objectives

The main objective of this study is to evaluate the effectiveness of a technological system (the TeNDER system) to improve QoL in patients with chronic diseases, including AD, PD, and CVD.

The secondary objectives are (1) to describe the satisfaction of patients, caregivers, and health professionals with the TeNDER system; (2) to describe the characteristics of the usability of the TeNDER system from the perspective of its potential users; and (3) to explore whether the use of the TeNDER system increases caregivers' perceived satisfaction with the care provided and, in relation to this, improves their QoL.

Methods

Design

A multicenter, randomized, parallel-group clinical trial will be conducted with a follow-up of 2 months. The unit of randomization will be the patient.

This study protocol is part of a proposal with European funding under the European Union's Horizon 2020 Research and Innovation Programme (grant 875325). The European consortium that developed the proposal is composed of different countries: Spain, Portugal, Italy, Slovenia, Greece, Germany, and Belgium [22].

The TeNDER project is developed in 4 European countries (Spain, Germany, Italy, and Slovenia). To account for the differences in the health systems of the participating countries and organizations, this research protocol refers to the primary care health centers (PCHCs) of the Madrid Health Service, which belongs to the Spanish public health system.

The TeNDER project brings together experts in technological development and users, including chronic patients, their caregivers, and primary care health professionals (PCHPs). Therefore, it will have an initial phase of cocreation in which the needs of the users will be explored. Based on the results, the technical team will work on improving and adapting the TeNDER system.

Study Population

The TeNDER project will include patients diagnosed with at least one of the following chronic conditions: PD, AD, other dementias, and CVD. Along with the patients, their caregivers, and their health professionals from the PCHCs will also be included as participants.

All participants must accept and sign the informed consent form. If a patient does not have the capacity to do so, a family member will sign the form on their behalf.

General Inclusion Criteria for Patients

Patients will be included if they are older than 60 years at follow-up, are referred by a PCHP at the PCHC, and are able to understand the local language. If a patient is dependent on others, they must have a caregiver or other responsible party.

General Exclusion Criteria for Patients

Patient who according to the judgment of their caregiver or PCHP are unable to follow the requirements of the study (eg, patients with inability to move or move around at home) or who have a life expectancy of less than 6 months will be excluded.

Specific Criteria for Patients With Each Chronic Illness

Patients with PD must have a confirmed diagnosis. Patients with AD must have a Mini Mental State Examination score between 19 and 28 points. Patients with a Global Deterioration Scale over 6 or 7 will be excluded. Patients with CVD will include those with the following conditions: heart failure with NYHA (New York Heart Association) Scale grade II to III heart function, and stable coronary artery disease or artery coronary disease with or without ST-elevation, atrial fibrillation, pacemaker, and stroke. Patients with arterial coronary disease that occurred less than 4 weeks ago or with severe aortic stenosis will be excluded.

Inclusion Criteria for Caregivers

Caregivers of the selected patients who are aware of the patient's health and social situation and who provide direct care or support for daily activities will be included. In addition, caregivers must be able to use a smartphone.

Exclusion Criteria for Caregivers

Caregivers will be excluded if they do not understand the local language.

Inclusion Criteria for PCHPs

Medical doctors and nurses attending the adult population of the participating PCHC will be included. They must carry out their professional activity in a PCHC that participates in the study and have at least one year of professional experience. They should be able to provide continuity of care for the patient during the intervention.

No exclusion criteria were applied for the PCHPs.

Sample Size

The European consortium that developed the proposal called for a sample size of 1766 patients (1031 in the control group and 735 in the intervention group) with the aim of using the TeNDER system to achieve an improvement in QoL, as measured by the Short Form–36 Health Survey (SF36) [23], of 6 points in the intervention group as compared to the control group.

According to previous studies, the SD for QoL score in the population with the chronic diseases under study (PD, AD, and CVD) ranges between 16 and 27 [23-25]. For the power calculation, we used the highest value of this SD. Therefore, the sample size will allow a power of 98.8% to detect ≥6

XSL•FO
RenderX

differences in the overall score of the SF36 questionnaire, if they exist. Calculations were performed with Epidat (version 4.2; Xunta de Galicia).

In the PCHC of the Madrid Health Service, as part of the European consortium, 534 patients will be included (380 in the intervention group and 254 in the control group). No differentiation by pathology will be established.

Recruitment

Five PCHCs in Madrid will be recruited. A total of 187 PCHPs will be invited to participate in the study. Based on experiences in previous studies, we expect a participation rate of 45%, which means 84 participating professionals. If necessary, the number of participating PCHCs will be expanded to reach the required sample size. PCHPs will participate in the study on a voluntary basis after signing the informed consent form.

Each participating PCHP will recruit 8 patients with a quota for each disease (5 with CVD, 1 with PD, and 2 with AD) consecutively as they attend the office. After the recruitment of patients, their caregivers will be invited to participate. For independent patients, it will not be necessary to recruit a caregiver.

During the recruitment interview, the PCHP will provide all information about the study as a detailed verbal explanation accompanied by a patient information sheet, making sure that the patient understands it.

Randomization

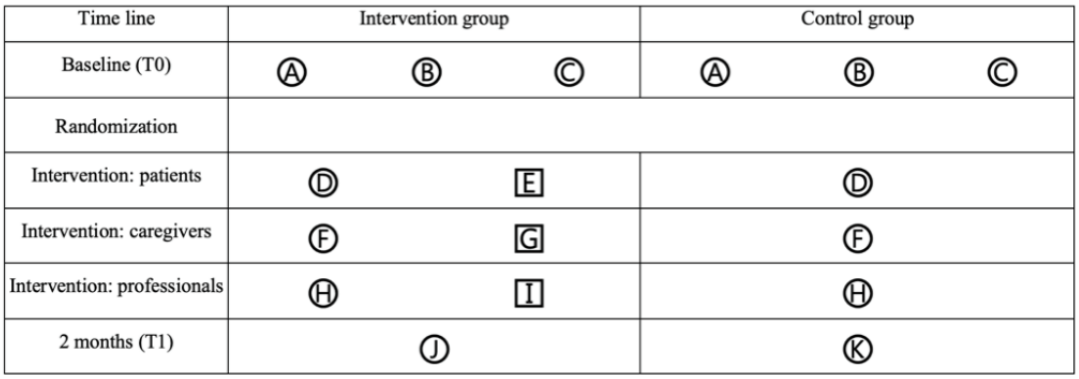
Once the participants have been selected, after the initial visit, the patients will be randomized by pathology. Patients included in the intervention group will be included together with their caregiver and PCHP, creating a participant unit (patient-caregiver-PCHP or patient-PCHP). There will be no masking in any phase of the study. Assignment will be performed centrally by the Research Support Unit of the Primary Care Management of Madrid.

Patients in the intervention group will be fitted with the TeNDER system device best suited to their needs and will be treated according to standard clinical practice. Patients in the control group will be treated according to standard clinical practice.

Subsequently, each PCHP will be informed of which patients have been assigned to each group; based on this, they will have a different role in each case (ie, using the TeNDER system with the intervention group and usual practice with the control group).

Intervention

The intervention is described in Figure 1 as recommended by Perera et al [26]. The intervention includes the use of the TeNDER system, a tool created by the consortium of the TeNDER group under the coordination of the Visual Telecommunications Applications Group (Grupo de Aplicación de Telecomunicaciones Visuales; GATV) of the Polytechnic University of Madrid.



The TeNDER system integrates multiple monitoring sensors that provide data to build an integrated technological ecosystem. The patient is monitored on a daily basis through one or more devices that offer different monitoring records (Table 1). The type of device will be chosen by the participant unit according to the patient's health status and their needs as expressed by the patient and their caregiver.

With the registered information, the TeNDER system will generate different functionalities (Textbox 1) that can be used through a mobile app and a web app. The functionalities for each participant will be activated according to their profile. Patients will have access to all functionalities, while caregivers and professionals will only be able to access functionalities that the patient authorizes.

Each participant unit will receive assistance in downloading and installing the app, creating an account, and creating a user profile. The use of the TeNDER system does not require advanced knowledge, only a basic user level. However, technical support will be provided by the GATV of the Polytechnic University of Madrid.

Textbox 1. Functionalities of the TeNDER system.

Functionalities

- Monitoring of variables collected by devices and biosensors
- Consultation of records and reports generated from the data collected by the biosensors
- Use of a smart calendar in which to schedule important events, medical appointment reminders, and medication reminders
- Possibility to generate notifications, including reminders and alerts
- Instant messaging channel for the exchange of messages between patient, caregiver, and primary care health professional
- Recommender function to explore a certain topic with the patient and, based on their answers, provide useful recommendations

Data Collection

Two types of data will be collected based on the nature of the data: direct data (through questionnaires) and indirect data (through devices and biosensors).

Direct Data Collection

Once participants have agreed to participate in the study, they will be scheduled for the baseline visit (T0). At this visit, baseline and tool cocreation data will be collected. The final visit (T1) will take place 2 months after the intervention. Data collection during both visits will take place at the PCHC or at the patient's home and will be carried out as face-to-face hetero-administered interviews by 2 project nurses. Data will be collected through questionnaires, and interviews will be indexed in an electronic data collection record (eDCR).

The primary outcome variable will be the QoL of patients measured using the SF36 questionnaire [23]. This is a 36-item questionnaire that includes 8 domains: physical functioning, role limitations due to physical problems, bodily pain, general health perceptions, mental health, role limitations due to emotional problems, social functioning, and vitality. Eight domain scores and a summary score (range 0-100) can be obtained; higher scores indicate better health-related QoL (HRQoL). In addition, six Likert-type questions are used to collect proxy indicators of QoL related to the TeNDER system. These questions are related to the perception of improved autonomy, support, improved self-care, and safety. In addition, we will collect sociodemographic variables such as sex, age, and nationality from patients, caregivers, and PCHPs. Also, technology affinity among the 3 types of users will be collected through a single ad hoc question. Clinical information collected from patients will include their main disease and other chronic diseases. The degree of autonomy and the need for help will be studied through ad hoc questionnaires at T0 and T1.

For a description of the usability of and satisfaction with TeNDER system after the intervention, the validated System Usability Scale questionnaire [24,25] will be administered to patients, caregivers, and PCHPs.

XSL•FO
RenderX

Caregivers' QoL related to the care provided and the perceived satisfaction with the care provided will be studied through an ad hoc questionnaire.

The questionnaires (at T0 and T1) are included in Multimedia Appendix 1.

Indirect Data Collection

Indirect data collection will be performed through devices and biosensors. These data are transmitted to the TeNDER cloud platform using an intermediary broker messaging service (RabbitMQ). A mini PC, on which the local health tracking tool server is installed, serves as a gateway for the biosensors to communicate with the cloud.

To ensure seamless data collection, most sensors are connected to the local area network wirelessly. The biosensors collect a wide range of data, including the following:

- The Withings sleep analyzer captures sleep data, monitors heart rate and breathing rate, and is able to detect apnea states.
- The Smartwatch Fitbit Versa 2 detects heart rate and number of steps taken. In addition, raw accelerometer measurements extracted by the device help track fall incidents and patient location.
- A location sensor measures the signal strength of the smartwatch (via the Bluetooth connection) to determine position and presence at room level.
- A microphone and speaker provides real-time audio recording and is able to identify screams or cries through the collection of recordings and tone of voice.
- The Aqara Hub integrates several secondary devices, such as a room temperature and humidity sensor and binary door, window opening, and window closing sensors.
- The RealSense device captures the patient's skeleton motion data in the form of coordinates in space. When combined with the Fitbit Versa 2 smartwatch, the system is able to identify the skeleton, and with the additional use of a microphone, can detect falls.

Storage and Security of Collected Data

All the direct data will be stored in an eDCR on the EUSurvey platform. This platform is developed by the Commission of the European Union and complies with the European Union Regulation No 2018/1725 of the European Parliament and of the Council of 23 October 2018, by which it guarantees data privacy through its policy on the protection of natural persons with regard to the processing of personal data. Only project researchers will have access to the data stored in EUSurvey by means of a username and password. The data collected will be pseudoanonymized using an alphanumeric code, and only the researcher administering the questionnaire to the participant will be able to link these data to the participant. The data stored will remain in the database for up to 25 years after the end of data collection in accordance with current regulations.

As for indirect data, the TeNDER System platform is hosted on domains recommended and endorsed by the European Union, which guarantees the highest standards of security and privacy protection. Once collected, the data are temporarily stored on the device itself for a few days if there is no connection to the TeNDER system. After connection, the data are stored in an anonymized form in the secure infrastructure of the TeNDER system and can be accessed by project researchers using credentials and tokens.

Data Analysis and Statistical Plan

A descriptive analysis of the characteristics of the participants will be performed with frequencies and percentages for qualitative variables and the mean (SD) or median (IQR) for the quantitative variables, according to their distribution. The mean difference in QoL score between the intervention and control groups will be studied with the corresponding 95% CIs at T1 (2 months). Differences in qualitative variables will be analyzed with the Pearson chi-squared test, and differences in normally distributed quantitative variables will be analyzed with the Student *t* test (2-tailed).

To study the effectiveness of the TeNDER System in improving QoL in patients, an explanatory linear regression model will be constructed. The dependent variable will be the mean difference in QoL score between the intervention and control groups at T1 (2 months). As patients will be recruited grouped by cluster (ie, PCHC), all the estimations will be performed with robust estimators. The analyses will be performed with Stata (version 14; StataCorp).

Ethical Considerations

This study protocol was approved by the Ethics Committee for Research Involving Medicinal Products of the Hospital 12 de Octubre (20/450) and obtained permission from the Central Research Commission of the Primary Care Healthcare Management of Madrid (PC:39/20) to carry it out in the primary care setting of the Community of Madrid. The processing, communication, and transfer of data will be carried out in accordance with the provisions of the General Data Protection Regulation of the European Union (RGPD 2016/679) of the European Parliament and of the Council of 27 April 2016 and the Organic Law on Data Protection and Guarantee of Digital Rights in the Spanish territory (LOPDGDD 3/2018 of 5 December).

Results

Ethics approval for this project was received on September 11, 2019. The trial was registered on August 14, 2020 (ClinicalTrials.gov NCT05681065). Recruitment commenced in April 2021 and the expected results will be available during 2023 or 2024.

Discussion

Previous studies on the use of technological tools by people with chronic disease have shown an improvement in their self-management, self-care, and adherence to therapy. However, few studies have examined all users involved in the care of chronic patients in their use of these tools.

The strength of this work is to investigate the use of a technological tool focused on health and self-care by, on one hand, patients with chronic disease older than 65 years, and on

XSL•FO
RenderX

the other hand, their caregivers or family supporters, as well as, finally, the health professionals who are responsible for monitoring their health status, in particular the PCHPs. This clinical trial among patients with highly prevalent chronic diseases and the people most involved in their care will provide a more realistic view of how technology can be integrated into their lives as an aid to care.

Another strong point is the involvement of users in the development and improvement of the TeNDER system. To this end, this work includes a cocreation phase in which the needs of the users are explored in order to develop a system that is adapted to them.

The main objective of this study is to improve the QoL of chronically ill patients older than 60 years. Despite the difficulties of achieving this with a 2-month intervention, there are certain proxy indicators of QoL that are sensitive to improvement, and this can be reflected in the HRQoL. Therefore, ad hoc questions have been included as variables that aim to detect elements that have an impact on QoL, such as safety and autonomy.

Among the main limitations are that due to the nature of the intervention, the trial cannot be masked. This may result in participants who are in the intervention group perceiving an improvement in their health follow-up; therefore, the difference in score with respect to the control group will increase. Thus, we propose to look for an increase of at least 6 points in the main improvement variable (QoL). In the same sense, the use of the TeNDER system can also lead to an improvement in patients' adherence to treatment, as they feel observed and monitored by the system (ie, the Hawthorne effect).

Another limitation is selection bias in the sample of participants. In many cases, older people and people with low digital literacy have the greatest need for health support. However, since the intervention requires the use of technology, it may be those with the greatest interest in its use who agree to participate in the study. This may result in a missed opportunity to address the digital divide. Studying the effectiveness of a technological system in an older population (ie, patients aged >60 years) may imply an initial reluctance toward technology. The digital age gap can be a barrier to use, and as a consequence, this can affect satisfaction and usability.

In order to reduce this effect and to be able to achieve good satisfaction and adapt the system to the participating population, the TeNDER system is developed based on a study of the needs of the target population (patients, caregivers, and PCHPs) and is constantly improved based on feedback from them.

In addition, in order to reduce the frustration that may arise with the use of technology, continuous telephone support will be provided to address any doubts or problems that may arise for participants.

Abstract

Background: Childhood asthma is imposing a great financial burden on the pediatric health care system. Asthma costs are directly related to the level of asthma control. A substantial part of these costs may be preventable by the timely and adequate assessment of asthma deterioration in daily life and proper asthma management. The use of eHealth technology may assist such timely and targeted medical anticipation.

Objective: This paper describes the Ambulatory Pediatric Asthma Care (ALPACA) study protocol to investigate the effectiveness of an eHealth intervention consisting of remote patient monitoring and teleconsultation integrated into the daily clinical care of pediatric patients with asthma. This intervention aims to reduce health care utilization and costs and improve health outcomes compared to a control group that receives standard care. In addition, this study aims to improve future eHealth pediatric asthma care by gaining insights from home-monitoring data.

Methods: This study is a prospective randomized controlled effectiveness trial. A total of 40 participants will be randomized to either 3 months of eHealth care (intervention group) or standard care (control group). The eHealth intervention consists of remote patient monitoring (spirometry, pulse oximetry, electronic medication adherence tracking, and asthma control questionnaire) and web-based teleconsultation (video sharing, messages). All participants will have a 3-month follow-up with standard care to evaluate whether the possible effects of eHealth care are longer lasting. During the entire study and follow-up period, all participants will use blinded observational home monitoring (sleep, cough/wheeze sounds, air quality in bedroom) as well.

Results: This study was approved by the Medical Research Ethics Committees United. Enrollment began in February 2023, and the results of this study are expected to be submitted for publication in July 2024.

Conclusions: This study will contribute to the existing knowledge on the effectiveness of eHealth interventions that combine remote patient monitoring and teleconsultation for health care utilization, costs, and health outcomes. Furthermore, the observational home-monitoring data can contribute to improved identification of early signs of asthma deterioration in pediatric patients. Researchers and technology developers could use this study to guide and improve eHealth development, while health care professionals, health care institutions, and policy makers may employ our results to make informed decisions to steer toward high-quality, efficient pediatric asthma care.

Introduction

Background

Asthma is one of the most common pediatric chronic diseases with a prevalence between 7% and 10% [1,2]. Childhood asthma imposes a significant physical and social burden on the affected child and their family. It may prevent children from participating in play and recreational activities, hamper social contacts, and lead to school absence and reduced school performance [2-4]. As a result, children with asthma have a reduced quality of life (QoL) in comparison to their healthy peers [5-7].

Asthma is also imposing a great financial burden on the pediatric health care system [8]. High-income countries spend between 1% and 2% of their health care budget on asthma [1,9]. For example, in the Netherlands, direct pediatric asthma health care costs have doubled over the last 2 decades and amounted to €90.8 million (US $92 million) in 2017 [10], compared to US $5.92 billion in the United States in 2013 [11]. Hospital and pharmacy costs occupy an increasing share and are the primary contributors to the total health care costs [10,11]. Additionally, pediatric asthma also exerts a large indirect economic burden due to missed school and workdays [12]. The economic burden of asthma is disproportional along with the severity of the disease [13]. Moreover, asthma costs are directly related to the level of asthma control, as poor control is associated with more hospitalizations, emergency visits, and other health care contacts [14].

A substantial part of these costs may be preventable and asthma outcomes can be improved if we are able to overcome existing challenges in pediatric asthma care. These challenges include (1) a limited opportunity for health care professionals (HCPs) to retrieve objective insight into the severity and dynamics of asthma symptoms in daily life [15], (2) the difficulty of attuning an optimal treatment that not only treats the intermittent symptoms but also the underlying inflammation sufficiently [16], (3) low adherence and poor inhaler technique of asthma therapy in children with asthma [17,18], and (4) inadequate assessment of severity or failure of the family to call for help when required [19].

The use of eHealth technology, like remote patient monitoring and teleconsultation, may help overcome these challenges [20]. In recent years, the development and validation of these types of eHealth technologies for pediatric asthma have skyrocketed [21-23]. Studies cautiously show evidence that eHealth can improve health outcomes and QoL and that it can be cost-effective [22,24,25]. However, the generalizability of these results is hindered by high heterogeneity in study end points and designs and poor quality of evidence [26-28]. Moreover, these results are often limited to a single disease management or monitoring domain (eg, medication adherence [29]), but asthma is a multifaceted disease with variable manifestations influenced by asthma severity, the level of adequate disease management, and the influence of (environmental) triggers [2,30]. There is limited scientific evidence that provides insights into the combination of monitoring parameters and interventional tools to predict early signs of asthma deterioration in a timely manner [31,32]. A recent study showed that remote patient monitoring may identify cues and causes of asthma control deterioration at home and help provide insights into patterns of asthma [33]. Furthermore, another study showed that teleconsultation and remote patient monitoring allows patients and caregivers to rapidly regain asthma control through timely and targeted medical anticipation, thereby progressing from reactive to proactive therapy and preventing asthma exacerbation [34].

The research gap, therefore, lies in the evaluation of pediatric asthma eHealth strategies consisting of a multidomain remote patient monitoring and teleconsultation approach while using a high-quality research design with relevant clinical end points on health care utilization, asthma outcomes, and QoL [26].

Objectives

In this study, called Ambulatory Pediatric Asthma Care (ALPACA), we will investigate an eHealth intervention for pediatric asthma care, in which multidomain, objective remote patient monitoring (ie, lung function, therapy adherence, and oxygen saturation) and teleconsultation (ie, web-based app to chat with HCPs, symptom questionnaires, and share videos) are integrated into clinical care and the patients' daily lives for 3 months.

The main study objective is to investigate whether children with asthma who use this eHealth intervention have reduced asthma health care utilization and costs compared to a control group that receives standard care for 3 months.

We will investigate the effects of this eHealth intervention on asthma outcomes (ie, asthma control, lung function, and the number of exacerbations), therapy adherence, self-management, and QoL after the intervention period of 3 months and at the 3-month follow-up. Overall use, acceptance, and satisfaction will be evaluated as well.

To enable further improvement of pediatric eHealth asthma care, we will exploratively investigate possible relations between objective home-monitoring parameters and asthma outcomes, the relation between self-reported dyspnea and home-measured lung function, and possible early signals in the preluding period before an asthma exacerbation. Moreover, we will explore the contribution of different eHealth intervention elements to asthma outcomes, patient-reported outcomes, and decision-making and identify patient characteristics of participants with successful eHealth care outcomes, such as health care utilization and adherence.

XSL•FO
RenderX

Hypothesis

Based on the recent literature [22] and results from previous studies [33-35], we hypothesize that over 3 months, compared to standard care, the ALPACA eHealth intervention will lead to a significant reduction in health care utilization and costs with at least equal asthma outcomes and QoL.

Methods

Study Design

The ALPACA study is a prospective 2-arm randomized controlled effectiveness trial of an eHealth intervention in pediatric patients with asthma, which builds on a previous eHealth feasibility trial [34]. Participants will be randomized to either eHealth care (ie, intervention group) or standard care (ie, control group). During the 3-month follow-up, all patients will receive standard care and blinded observational home monitoring to evaluate the sustained effects of eHealth compared to the control group. The study protocol was designed in accordance with the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) guidelines (Table 1) [36].

Ethics Approval

This study protocol was approved by the Medical Research Ethics Committees United (NL74559.100.21) and registered in ClinicalTrials.gov (NCT05517096). The data handling and storage will comply with the European Union (EU) General Data Protection Regulation (GDPR).

Study Setting and Eligibility Criteria

A total of 40 children with moderate-to-severe pediatrician-diagnosed asthma between 4 and 11 years of age will be recruited from the Medisch Spectrum Twente (MST) hospital in Enschede, the Netherlands. Pediatrician-diagnosed asthma includes confirmation of asthma diagnosis with a positive reversibility or challenge test [2]. Children are classified as having moderate or severe asthma if they meet one of the criteria shown in Table 2. Children with comorbid chronic diseases, previous asthma eHealth care intervention trial experiences [34], or children/parents with an inability to understand or speak Dutch are not eligible to participate. Additionally, children that do not live for more than 80% at the same address or those who do not have a stable Wi-Fi connection at home are excluded from participation.

Participants will be recruited from the pediatric department of MST using consecutive sampling, which is expected to take 40 weeks. A study flyer will be displayed in the pediatric ward and distributed among pediatric patients with asthma after an outpatient visit. Patients who indicate that they may be contacted will be contacted after 1 week, but patients may also contact the researchers themselves for further verbal and written study information. Offline written informed consent from parents will be obtained prior to participation in this study.

Table 2. Criteria for classification as moderate or severe asthma.

Condition	Moderate asthma	Severe asthma
Medication	GINA[a] step 3/4 or uncontrolled (C-ACT[b]<20) in GINA step 2 [2]	Step 5 or uncontrolled (C-ACT<20) despite medium to high-dose ICS[c]-LABA[d] in step 4
Recent exacerbation (<3 months) despite controller medication	Needing a salbutamol regimen of oral cortical steroid therapy	Leading to a hospital admission
Bronchial hyperreactivity assessed with an exercise challenge test in cold air [37,38]	Between 25% and 50% decrease in FEV1[e] [39]	>50% decrease in FEV1 [39]

Randomization and Blinding

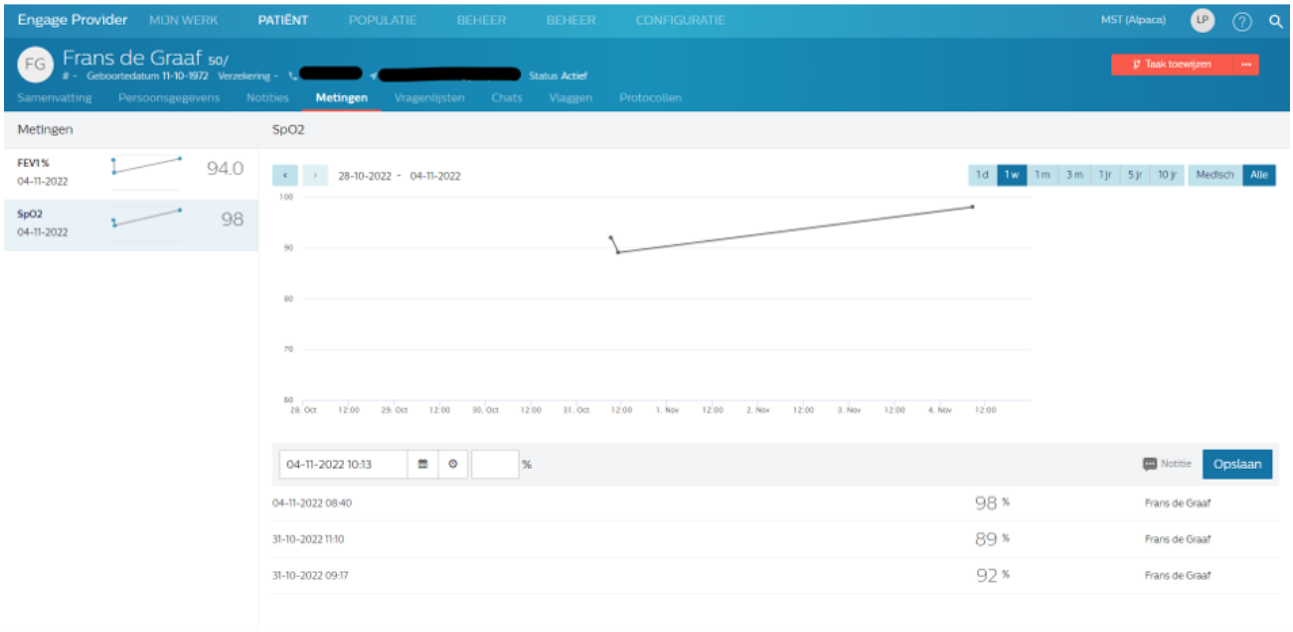
Patients will be randomized to either eHealth care (intervention group) or standard care (control group) during the intervention period (t_1) by independent block randomization at the first home visit. The electronic data capture (EDC) software Castor (Castor) will allocate the participants using stratified block randomization with multiple block sizes (2, 4, and 6) into either group A or group B with an allocation ratio of 1:1 [40]. Castor randomly mixes these block sizes and hides the block size from the executor, which guarantees concealed allocation [40]. Randomization will be stratified on the number of hospital visits concerning asthma in the past 6 months (using 4 strata: 0-1 visit, 2-3 visits, 4-5 visits, or 6 or more visits), as it is known that previous exacerbations and health care utilization are risk factors for future exacerbations [2,41]. From this point, the blinding will be broken as the researchers, HCPs, and patients will need to know whether they should prepare for, provide, or receive eHealth care, respectively.

Intervention

The eHealth care intervention, consisting of remote patient monitoring and teleconsultation, was designed to detect loss of asthma control timely and accurately in daily life, increase awareness about the severity of asthma symptoms, and improve the safety of care for both physicians and patients by using objective measurements as the basis for shared decision-making. The technologies that are used for this eHealth care are a web-based patient portal, remote monitoring devices, and home-nebulizer therapy. This intervention was designed based on previous work on multidomain monitoring [33] and clinically implemented eHealth care [34].

XSL•FO
RenderX

eHealth Technologies



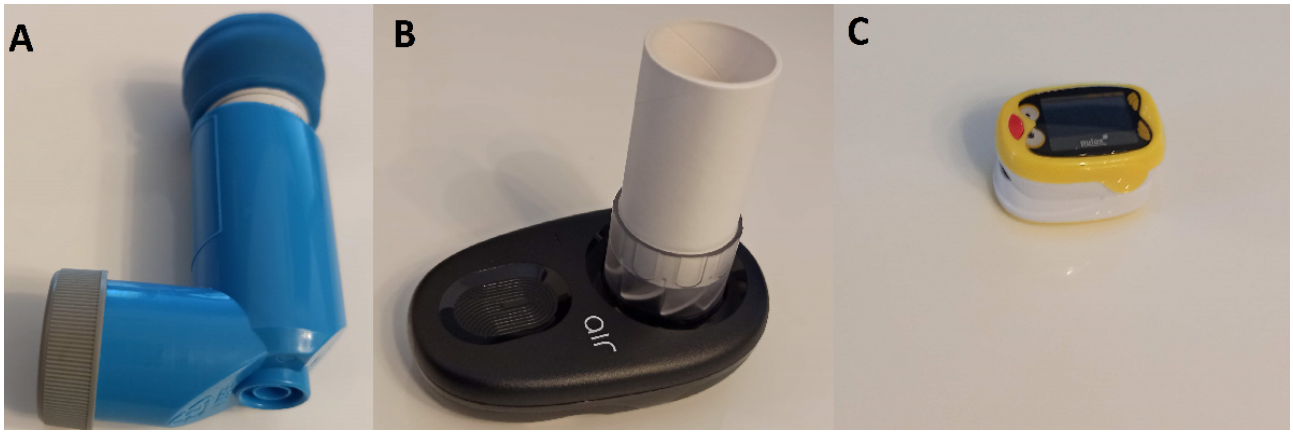
Web-Based Patient Platform

For the eHealth care, component a digital platform called Engage will be used that allows HCPs and patients to collaborate by facilitating web-based communication, displaying home measurements and questionnaire data, and allowing HCPs to share educational content. The configuration of the patient platform was specifically developed for this study in collaboration with the HCPs using the elements of the customizable Philips VitalHealth Engage platform (Royal Philips). This is a certified platform according to the European Medical Device Regulation; it is Conformité Européenne (CE) certified, classified as a class IIa medical device, and has been used in several clinical trials.

For patients, the Engage platform involves a personal page designed to provide children/parents the opportunity to unobtrusively share a request for help and integrate time- and event-based repeated measures or diary entries [42]. The page includes a chat function to allow the children/parents and HCPs to communicate in real time or according to their availability and wishes. The participants also have the option to share photos, sound recordings, or video files with the HCP (eg, to aid in the clarification of symptoms). Participants can enter their spirometry and oxygen saturation (SpO_2) measurements into the platform. Additionally, participants will be requested to fill in the Childhood Asthma Control (C-ACT) questionnaire on their page weekly.

For HCPs, the platform provides access to a dashboard for each patient, which displays trends of the measurements and allows access to details of measurements and questionnaires (Figure 1).

Figure 1. Example of health care professional (HCP) dashboard for lung function and oxygen saturation measurement of a specific patient.

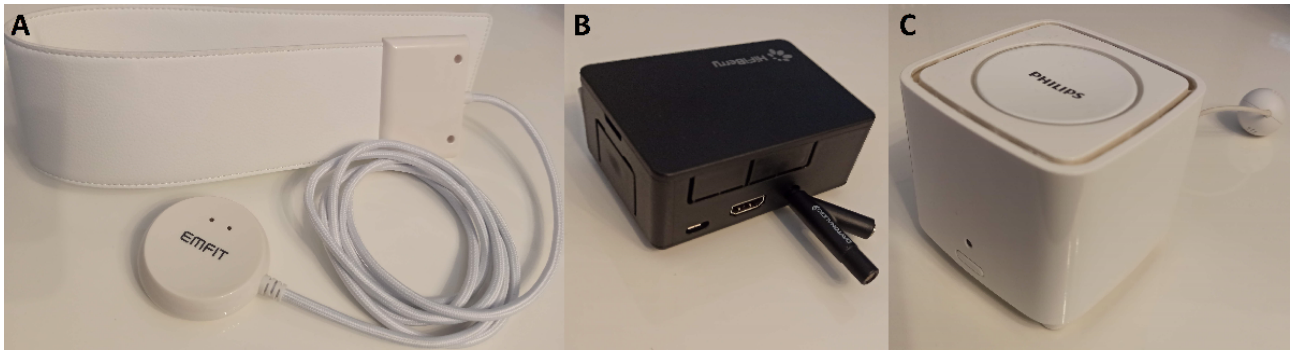


Remote Monitoring Devices

Our study combines several remote monitoring devices to actively monitor the participants in the intervention group during the eHealth care component. A total of 3 interventional monitoring devices, FindAir ONE smart inhaler (FindAir Sp), NuvoAir Air Next spirometer (NuvoAir AB), and Pulox PO-210B pulse oximeter (Novidion Gmbh; Figure 2), as well as a smartphone, will be provided to the children and their parents. Data reports will be shared by the participant through the Engage platform and automatically stored and accessible for HCPs through web-based cloud storage.

XSL•FO
RenderX

Figure 2. Interventional monitoring devices: from left to right: A) FindAir ONE smart inhaler to track rescue use and controller adherence. B) NuvoAir Air Next spirometer to track lung function. C) Pulox PO-210B pulse oximeter to monitor oxygen saturation during exacerbation.



The FindAir ONE is a smart inhaler cap that will be placed on top of metered dose inhalers of the participants. It will always be used in combination with valved holding chambers. The sensor continuously collects data on the date and timestamps of inhalation, which is automatically synced and can be assessed in real time by both the patient and HCP on the FindAir platform.

NuvoAir Air Next is a handheld spirometer designed for home monitoring of lung function, with a built-in temperature sensor to compensate for the flow and volume for the body temperature pressure saturated correction [43]. This measurement will be performed twice per week or upon indication of the HCPs or the participants themselves during symptoms.

The Pulox PO-210B is a children's edition of SpO_2 pulse oximeter. It will be used offline as needed within the intended use for clinical reasons, in case of asthma exacerbations to monitor SpO_2, and if the lung function measurement quality is poor.

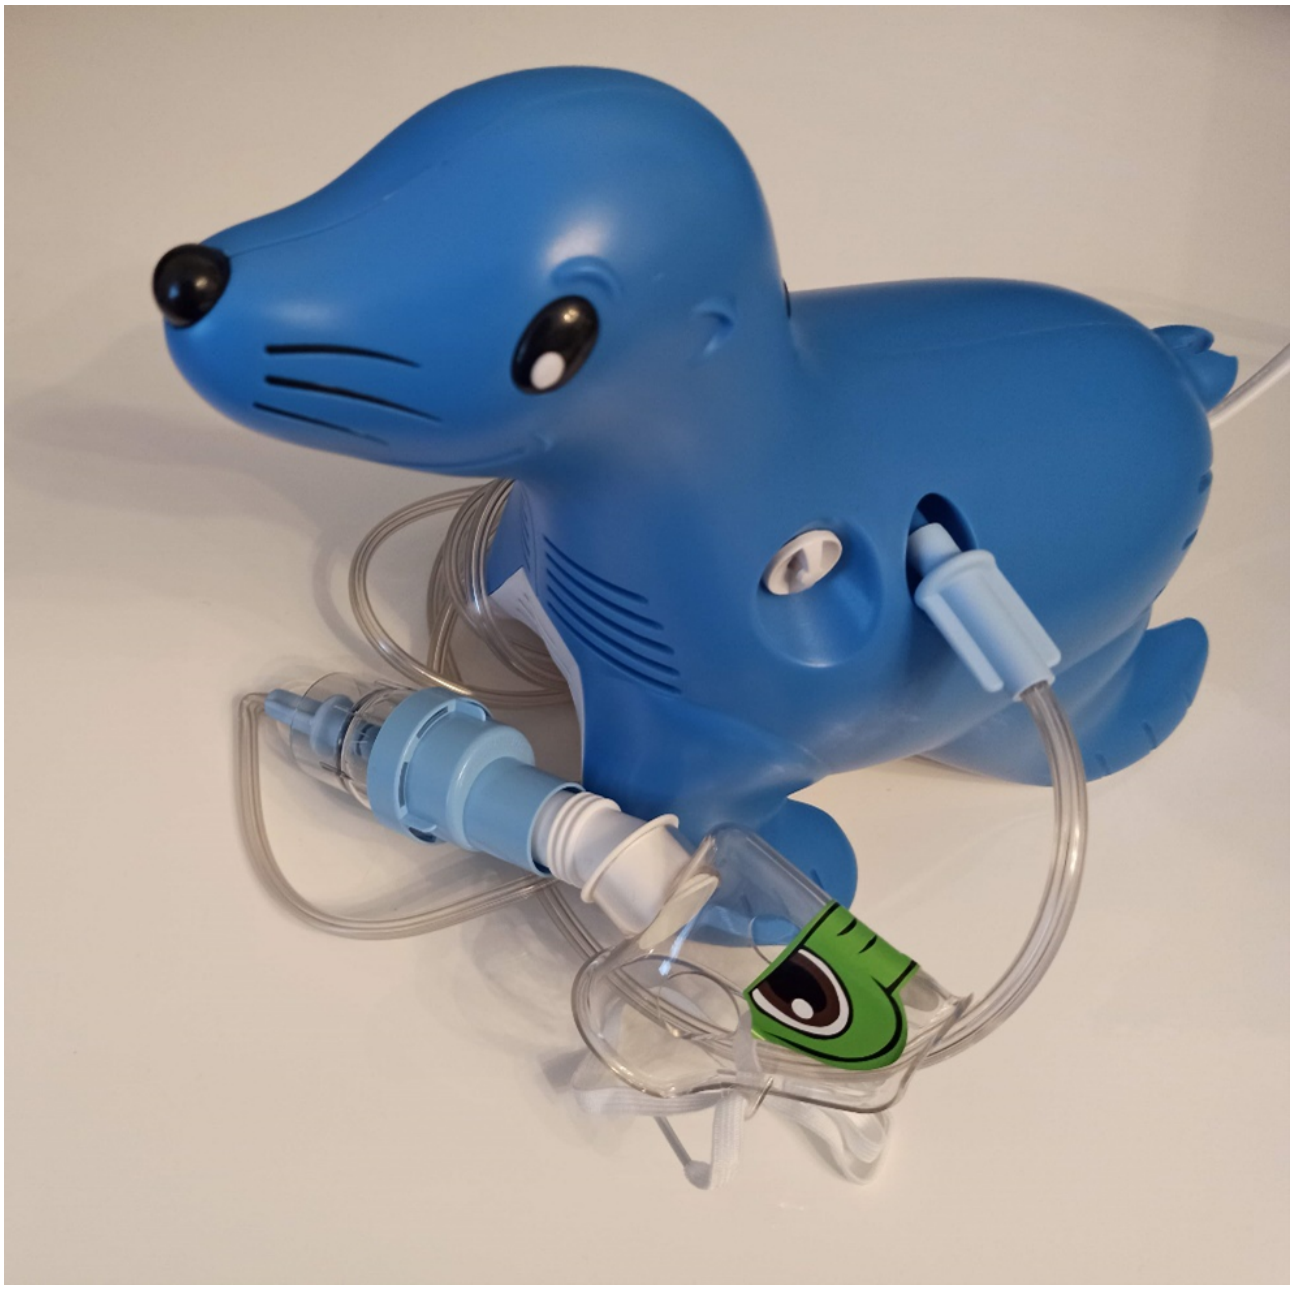
In addition, and not part of the intervention, 3 investigational devices, namely, an Emfit QS+ACTIVE sleep monitor (Emfit Ltd), a Philips cough monitor, and a Philips Snifferbee air sensor (Figure 3), will exclusively be used for observational research purposes in both the intervention and standard care group and follow-up of this study. The observational data of the investigational devices will therefore be stored in the cloud (Emfit QS platform and Philips platform). The data will not be shown to the HCPs and patients and only be used to investigate possible relations between objective home monitoring parameters and asthma outcomes.

Figure 3. Investigational observational monitoring devices: from left to right: A) Emfit QS+ACTIVE ballistography sleep sensor to track sleep. B) Philips cough and wheeze monitor to track respiratory sounds during sleep. C) Philips Snifferbee air sensor to track air quality in participants' bedrooms.

The Emfit QS+ACTIVE is a commercially available contactless sleep monitor that can provide a detailed description of sleep quality using ballistography [9]. The sensor is installed under the mattress to monitor activity, heart rate, and respiration rate at night and has been validated and previously used for sleep studies in both adults and children [44-46]. The device is CE marked and will be used for its intended use.

The Philips cough monitor is a device intended to store and transmit respiratory sound features and snippets (1 second), which are measured by the microphone in the device. The device will be placed next to the bedside to monitor nocturnal coughing and wheezing.

Snifferbee is Philips' air quality monitor prototype. It consists of multiple sensors to detect air quality and identify triggers for asthmatic reactions. Snifferbee can measure particles in the room air of 2.5 µm (optical scattering sensor), along with temperature, humidity, and carbon dioxide levels (with a nondispersive infrared sensor). The SnifferBee will be used within its intended use to measure air quality in the participants' bedrooms.



Home Nebulizer Therapy

All participants will receive a Philips Sami the Seal nebulizer for the intervention phase and will be trained and supervised for correct use and nebulizer hygiene (Figure 4) [47]. Nebulizing

XSL•FO
RenderX

therapy is often started when bronchodilator inhalers do not have the expected effect anymore or in the hospital during an acute exacerbation. During the intervention phase of this study, nebulizing therapy may be started at home under the supervision of an experienced HCP (via video call). Criteria for starting nebulizing therapy under supervision at home during the intervention period are (1) SpO_2 ≤94% without significant effect of the reliever inhaler medication (as recommended by the Dutch Pediatricians Association) [48]; (2) reproducible lung functions <50% predicted, without significant effect of the reliever inhaler medication (defined as an increase of at least 10% and increase to lung function above 50% predicted); or (3) on the advice of the pulmonary pediatrician.

Figure 4. Philips Sami the Seal home nebulizer.

eHealth Care Intervention

Intervention Group

Participants will be in contact with the HCPs via the web-based Philips Engage platform (Figure 1). HCPs will provide care according to current care standards [2,48] while applying a state-of-the-art web-based care pathway [34]. Within this care pathway, HCPs aim to build up the confidence of the participants and their parents by enhancing their understanding and self-management of the disease via feedback on the web-based communication platform substantiated with monitoring data during real-life events. The key focus will be on important asthma management issues, such as symptom perception, therapy adherence, inhalation techniques, trigger control, and acute asthma management [2]. Participants will be repeatedly and pragmatically supported and coached using elements from behavioral theories (eg, self-monitoring, goal setting, immediate feedback, contingency management) and be involved in shared

XSL•FO
RenderX

management to progress on an individual pace toward self-assessment and self-management [49].

During the eHealth intervention, HCPs (ie, nurse practitioners, a technical physician, and a pediatric pulmonologist) will be notified in real time of new communications on the Engage platform by push notifications and will respond at least within 1 workday to allow for timely anticipation. Participants will be instructed to not wait for communications in the case of an emergency and to proceed to emergency care. Moreover, once a week, the HCPs will have a multidisciplinary meeting to discuss data trends and patient communications to adjust the individual treatment strategies as necessary. HCPs will always have the option to invite patients for a hospital visit if this is needed to fulfill the current care standards [2,48].

Standard Care Control Group

Participants in the control group will receive standard care and therefore will not receive the home nebulizer. The spirometer, pulse oximeter, and smart inhalers will be provided but only used for observational monitoring in the control group, similar to the investigational devices (cough monitor, air quality sensor, and sleep monitor). The control group will be able to use the Engage portal to share measurements and questionnaire data, but they will not receive any feedback or data interpretation. This same protocol holds for the 3-month follow-up period to be able to assess differences in the primary and secondary outcome parameters after cessation of the intervention.

Outcome Measures

Demographic characteristics (age, gender, medication use, other medication use, allergy due to aeroallergens, eczema, doing sports, and smoking behavior at home) will be retrieved from electronic patient records.

The primary outcome variables are health care utilization and costs. All health care activities (ie, hospital admissions, outpatient visits, emergency visits, diagnostic activities, etc) will be labeled using the Dutch health care registration system of the Dutch Healthcare Authority. The accompanying health care costs will be calculated using activity-based costing [50]. Furthermore, the specific eHealth care costs will be calculated using bottom-up gross costing, consisting, for example, of the working hours of the HCPs and the depreciation costs of the monitoring devices [50].

Multimedia Appendix 1 contains the description and analysis of other outcome variables to investigate the effects of the eHealth intervention, which will enable research that can further improve pediatric eHealth asthma care.

All data will be handled according to the EU GDPR and the Dutch Act on the Implementation of the GDPR and securely stored in the Castor EDC system.

Sample Size

Previous data from an eHealth clinical feasibility study (N=30) using a comparable intervention within the same patient population revealed a reduction in health care utilization of 80% [34]. This data showed an average reduction in the number of outpatient consultations from 3.9 to 0.7 (SD 1.8) per patient per half year.

A power simulation was performed for a Mann-Whitney-Wilcoxon 2-sided test. The health care utilization was assumed to be Poisson distributed with means according to the clinical feasibility study. For the control group, the Poisson rate was equated to the historical data of the pilot divided by 2 to account for the study durations. The intervention group's rate was taken to be the postdata of the feasibility study divided by 2. As the ALPACA study makes use of the intention-to-treat principle, noncompliance to the intervention was included in the simulation. The number of nonadherent participants was random in the simulation according to a binomial distribution (similar to the clinical feasibility study data, with 3 out of 33 participants). This was used to calculate the control group rate, which is a conservative estimate of no benefit from the intervention. Together with the assumption of an Alpha Type 1 error of 0.05, the sample size calculation results in 36 (18 intervention and 18 controls), with a power of 97.1% for the primary outcome and 80% for secondary follow-up effects (assuming a lasting effect of 80%). Accounting for dropouts (n=4), we would need to include 40 children.

Study Procedures

After enrollment ($-t_1$), an HCP will perform a home visit (t_0) to allocate the participant to the intervention or control group, install the monitoring devices, and carefully instruct participants about the use of the eHealth platform and monitoring devices. All oral instructions will be complemented with written and digital instruction flyers to ensure that all the instructed information can be retrieved afterward. A second home visit (t_2) is planned after the intervention period to check all devices. Moreover, an in-person semistructured interview will be held to evaluate the user experience of the interventional and investigational technology together with filling in the feasibility and acceptance questionnaires (Multimedia Appendix 1). A third, final home visit (t_e) will be held at the end of the study after follow-up (t_3) to retrieve all monitoring devices and evaluate this period via the evaluation questionnaires (Multimedia Appendix 1).

Data and Statistical Analyses

Descriptive statistics will be used to examine all continuous outcome measures expressed in mean and SD for normally distributed variables and with median and IQR for nonnormal distributed variables. Univariate analyses will be performed with SPSS software (version 22.0; IBM Corp). The homogeneity of variances will be verified with the Levene test. Histogram plots and the Shapiro-Wilk test will be used to determine whether the variables are normally distributed among the groups. A *t* test (or nonparametric Mann-Whitney U test) will be used to compare the primary outcomes between eHealth care and standard care, and $P \leq .05$ will be considered significant. The analysis will be performed according to the intention-to-treat principle [51], and missing data will be handled with pairwise deletion. An interim analysis will be conducted after half the participants are done with the intervention. In case the interim

XSL•FO
RenderX

analysis reveals a significant increase in health care utilization in the intervention group, this study will be prematurely ended.

Results

This study was approved by the Medical Research Ethics Committees United on August 11, 2022, and by the institutional review boards of Philips on August 8, 2022, and MST on January 11, 2023.

The expected timeline of the ALPACA study is 15 months, including an enrollment period of 9 months and a study duration of 6 months. As of August 2023, we expect to start enrollment, which will make data collection compete in May 2024. The results are expected shortly afterward in July 2024.

Discussion

Expected Knowledge Contribution

Childhood asthma is imposing a great financial burden on the pediatric health care system, but a substantial part of the costs may be preventable by timely and adequate medical anticipation using eHealth. Therefore, In the ALPACA study, we will investigate whether children with asthma who use an eHealth intervention have reduced asthma health care utilization and costs compared to the control group. This study protocol applies a combination of relevant monitoring domains of pediatric asthma based on the recent literature [22,33,34] and guidelines [2]. Primary validated monitoring devices will be combined with web-based communication between HCPs and patients to enable pediatricians to make well-informed and substantiated treatment decisions and allow targeted support for optimal disease management. This randomized controlled effectiveness trial design captures an extensive prospective longitudinal home monitoring data set, which allows the evaluation of the effect of eHealth pediatric asthma care on health care utilization, asthma outcomes, and QoL, including additional information about longer-lasting effects after cessation of eHealth care. Moreover, the holistic eHealth monitoring of physiological, environmental, and disease management data allows a comprehensive set of secondary analyses for insight into pediatric asthma. This study may therefore contribute to the existing knowledge of eHealth applications in secondary health care and to a better understanding of the value of home-monitoring diagnostics for pediatric asthma.

Strengths and Limitations

This study is a follow-up of a quasi-experimental eHealth evaluation study [34]. Therefore, the involved HCPs of the hospital are experienced with using eHealth technology, and the care pathway is already aligned to deliver remote care in a safe and efficient way, which are commonly the most important barriers to successful eHealth evaluation trials [52]. Moreover, improvements based on prior eHealth trials within our hospital are integrated into this protocol to maximize its feasibility.

Another strength of the ALPACA study is the fact that it uses a set of home-monitoring devices chosen to be as unobtrusive as possible to minimize the daily living burden of the participating children and their parents. The current literature shows an increase in the development and evaluation of these unobtrusive sensing systems, enabling adherent long-term use for monitoring chronic disease course and management [53]. Additionally, this study uses a communication platform to provide children and their parents the opportunity to unobtrusively share a request for help or advice and integrate time- and event-based repeated home monitoring measurements or diary entries to obtain valid, real-life self-reports [42].

Objectified feedback to participants in eHealth care about inhalation technique (via videos) and therapy adherence (via smart inhaler data) could be a great addition to the current asthma care for children [54], as inhalation technique and therapy adherence appear to be poor but often remain “the elephant in the room” and stay unaddressed [55-58]. Automated synchronization of the mobile device and the inhaler add-ons provides a burden-free way to increase awareness of therapy adherence among children with asthma and their parents and provides HCPs with the necessary information to make informed medication adjustments [34,59].

Since a critical evaluation of financial cost-effectiveness is lacking in the literature for electronic health tools in pediatric asthma [60], the design of the ALPACA study is favored, as all direct hospital health care utilization is registered in combination with asthma outcomes. This gives us the opportunity to perform a thorough cost analysis of the care transformation to eHealth care. Moreover, the follow-up period of this study allows us to investigate whether the effect may endure when eHealth is ceased, providing interesting information on the possible long-term benefits of eHealth care.

A limiting factor in eHealth studies may be the timing of inclusion, as the asthma outcomes are subject to the episodic variation of asthma (viral infection, weather conditions, and pollen seasons) and COVID-19 regulations (lockdowns versus free contact) [2,61]. This effect is canceled to a great extent by the randomized design of this study. However, this study may be limited in the secondary pre-post evaluation of the different eHealth intervention elements. In addition, the worldwide generalizability of this study may be limited based on the eligibility criteria (children who live >80% of the time at the same home and have a stable WiFi connection).

Previous research has shown that the circadian rhythm influences the severity of asthma symptoms [62,63]. Symptoms tend to be worse during the night and gradually improve during the day. To avoid any bias of this circadian rhythm on the spirometry measurements, we will instruct all participants to perform the standard monitoring measurements at approximately equal times prior to dinner.

Implications for Pediatric Asthma Health Care

The results of the ALPACA study may benefit future pediatric asthma health care in several ways. Researchers and the technology industry will be able to tease out relevant intervention elements that can act as digital markers for composing effective interventions, which can guide them in appropriate eHealth development [35]. Moreover, hypothesized health care utilization reductions provide positive incentives and increase the sense of urgency among stakeholders to take

XSL•FO
RenderX

joint action toward scalable eHealth solutions [64]. Additionally, HCPs, health care institutions, and policy makers may use the ALPACA results to make informed decisions to steer toward a new, high-quality efficient pediatric asthma care pathway that goes beyond current traditional planned follow-up care and evolves toward proactive and targeted care, wherein the patient is actively involved via shared decision-making and self-management while being safeguarded by home-monitoring technology.

Abstract

Background: The number of people with cognitive deficits and diseases, such as stroke, dementia, or attention-deficit/hyperactivity disorder, is rising due to an aging, or in the case of attention-deficit/hyperactivity disorder, a growing population. Neurofeedback training using brain-computer interfaces is emerging as a means of easy-to-use and noninvasive cognitive training and rehabilitation. A novel application of neurofeedback training using a P300-based brain-computer interface has previously shown potential to improve attention in healthy adults.

Objective: This study aims to accelerate attention training using iterative learning control to optimize the task difficulty in an adaptive P300 speller task. Furthermore, we hope to replicate the results of a previous study using a P300 speller for attention training, as a benchmark comparison. In addition, the effectiveness of personalizing the task difficulty during training will be compared to a nonpersonalized task difficulty adaptation.

Methods: In this single-blind, parallel, 3-arm randomized controlled trial, 45 healthy adults will be recruited and randomly assigned to the experimental group or 1 of 2 control groups. This study involves a single training session, where participants receive neurofeedback training through a P300 speller task. During this training, the task's difficulty is progressively increased, which makes it more difficult for the participants to maintain their performance. This encourages the participants to improve their focus. Task difficulty is either adapted based on the participants' performance (in the experimental group and control group 1) or chosen randomly (in control group 2). Changes in brain patterns before and after training will be analyzed to study the effectiveness of the different approaches. Participants will complete a random dot motion task before and after the training so that any transfer effects of the training to other cognitive tasks can be evaluated. Questionnaires will be used to estimate the participants' fatigue and compare the perceived workload of the training between groups.

Results: This study has been approved by the Maynooth University Ethics Committee (BSRESC-2022-2474456) and is registered on ClinicalTrials.gov (NCT05576649). Participant recruitment and data collection began in October 2022, and we expect to publish the results in 2023.

Conclusions: This study aims to accelerate attention training using iterative learning control in an adaptive P300 speller task, making it a more attractive training option for individuals with cognitive deficits due to its ease of use and speed. The successful replication of the results from the previous study, which used a P300 speller for attention training, would provide further evidence to support the effectiveness of this training tool.

Introduction

Background

Cognition includes many facets of complex processing functions, such as, and not limited to, attention, the acquirement of knowledge, memory, decision-making, and comprehension [1]. Cognitive deficits often present as symptoms in many underlying neurological disorders.

In the aging population, cognitive decline is common, however, can be accelerated by neurodegenerative diseases, such as dementia, or through brain trauma and stroke. Furthermore, the increased prevalence of cognitive deficits is apparent in every age demographic. As a result of the COVID-19 pandemic, many long-term neurological effects have been identified in patients who have experienced COVID-19 infection. In a study published by Hartung et al [2], it was identified that of a sample group of 969 patients, approximately 26% of patients experience mild cognitive impairment in the aftermath of the infection. Other cognitive diseases, such as attention-deficit/hyperactivity disorder (ADHD) and autism spectrum disorder, are common neurocognitive disorders that are identified in children. All these diseases feature a profound effect on the quality of life of the individual because of impairments in cognition [3-5].

The common treatments for these conditions are pharmacological interventions or therapeutic interventions. However, these disorders have no known cure, and rather, treatments are created to alleviate the symptoms of the disorder.

Pharmacological interventions, such as the use of psychostimulant medicines, have been rendered highly effective in treating symptoms of cognitive deficits. However, they have been criticized for the adverse effects which can occur due to their use [6]. Methylphenidate and lisdexamfetamine are 2 common psychostimulants used in the treatment of a variety of cognitive disorders, including ADHD. Both stimulants have shown to be efficacious in the treatment of the symptoms associated with the disorder but can result in insomnia, decreased appetite, headaches, and abdominal pain [7].

Cognitive disorders and their interventions, both pharmacological and nonpharmacological, can be highly costly, not only for the individual but also for health care systems globally [8,9]. This can cause great distress for individuals, as diagnosis and treatment for cognitive disorders can become inaccessible, as well as immense pressure on health care systems due to the increasing burden of these diseases. For these reasons, there is a clear need for low-cost and effective treatments for neurocognitive disorders.

Neurofeedback Training

Electroencephalographic neurofeedback (EEG-NFB) is a type of brain-computer interface (BCI), which provides real-time feedback to the individual based on neural signals of interest as measured by electroencephalography (EEG), thus training the individual to self-regulate their brain activity [10]. EEG-NFB was introduced in the 1960s independently by Nowlis and Kamiya [11], and Sterman et al [12], and was commonly referred to as EEG biofeedback. Nowlis and Kamiya [11] presented data to confirm that patients could control their brain activity as a result of engaging with rewards using an EEG measuring device. Sterman et al [12] discovered through training cats that they too could modulate brain wave activity. As a result of these discoveries, a variety of treatments have been developed to alleviate symptoms of many cognitive disorders, including ADHD, schizophrenia, and many others [13-15].

Due to criticism relating to the efficacy of EEG-NFB in the 1970s, there was a decline in research on the use of EEG-NFB [16]. However, in recent years there has been a reemergence of the use of EEG-NFB globally in many research and clinical settings [10].

One example of a novel EEG-NFB is the adaptive P300 speller for attention training by Arvaneh et al [17]. The P300 speller was first introduced by Farwell and Donchin [18] in 1988 as a tool for patients who could not communicate, such as in the case of patients who have “locked-in” syndrome. In the speller, a matrix of symbols (eg, letters and numbers) is presented to the user. Each row and column in the matrix of symbols is highlighted or flashed in random order. When the user only focuses on the flashes of a target symbol and ignores the other flashes, the BCI can select this target symbol by identifying the row and column that elicited a P300 wave, thus allowing the user to spell words with their mind. In this process, each row and column are flashed several times, so that the signal-to-noise ratio (SNR) of the EEG signals can be increased by averaging. Usually, this number of flashes per row and column is fixed to allow the user to spell words sufficiently well in an acceptable amount of time. However, Arvaneh et al [17] progressively reduced the number of flashes in a training session based on the user’s performance to intentionally decrease the SNR. This makes it more difficult for the user to spell words correctly, thus encouraging them to improve their focus in order to maintain their performance. The researchers demonstrated that a single training session on healthy adults resulted in an increase in performance in a cognitive task, as well as an enhancement of event-related potentials (ERPs) [17].

This study intends to replicate the experiment by Arvaneh et al [17], comparing their adaptation of the number of flashes to a novel adaptation approach based on iterative learning control (ILC).

Framework of ILC

ILC is a type of control engineering that was introduced by Ukiyama [19] in the late 1970s and Arimoto et al [20] in the 1980s. ILC is applied to repetitive processes, where the same tracking task is repeated several times. Examples of traditional application areas of ILC are the control of pick-and-place industrial robots or semiconductor manufacturing [21]. ILC exploits the repetitiveness of processes such as these by learning

XSL•FO
RenderX

from past experiences, thus reducing the tracking error over time, as well as adapting to small changes in the processes. An iterative learning controller is able to learn from past experiences by taking the control input and error of previous iterations into account when determining the control input for the next iteration. The typical framework for ILC is

$$u_{k+1}(\cdot)=f(e_{k+1}(\cdot),\ldots,e_{k-s}(\cdot),u_k(\cdot),\ldots,u_{k-r}(\cdot)), \textbf{(1)}$$

where k is the iteration index, u is the control input, and e is the tracking error. There are different ways to determine the function f in (1). The simplest ILC algorithm is Arimoto et al's [20] algorithm, where the next control input is equal to the control input plus the scaled error of the previous iteration, that is,

$$u_{k+1}(t)=u_k(t)+\gamma e_k(t+1), \textbf{(2)}$$

where t is discrete time, and γ is a scalar controller parameter. ILC algorithms generally take the form

$$u_{k+1}(t)=u_k(t)+Ke_k(t+1), \textbf{(3)}$$

where K is the so-called learning-gain operator, which is often based on a model of the system, such as the inverse-model ILC algorithm [22] or the Adjoint algorithm [23]. The algorithms described in (2) and (3) are so-called P-type ILC algorithms as they use the error from previous iterations. Algorithms that use the derivative of the error instead are known as D-type ILC [24].

While ILC was mostly used in industrial and manufacturing processes in its early days, it has found popularity in other application areas, such as stroke rehabilitation [23] or the control of exoskeletons [25] in more recent years.

Since rehabilitation and training, whether physical or cognitive, are inherently repetitive processes, where the task difficulty needs to change progressively, this application area lends itself nicely to the use of ILC.

Objectives

The primary objective of this study is to accelerate P300-based attention training by progressively and optimally adjusting the task difficulty in a training session to each individual using ILC. The proposed iterative learning controller, which determines the task difficulty based on previous performance and task difficulty level, will be compared to the adaptation algorithm used in a previous study by Arvaneh et al [17]. Thus, we will be able to analyze the replicability of Arvaneh et al's [17] study. A random task difficulty control group will also be used in this study to compare the training effects of personalized approaches with the training effects due to exposure to a range of nonpersonalized task difficulty levels.

While we expect the cognitive enhancements achieved during the training session to be similar among the groups, we expect the experimental group, where the task difficulty is determined by an iterative learning controller, to complete the training session more quickly than the other groups.

Methods

Study Design

In this single-blind, 3-arm randomized controlled trial with parallel-arm design, the effectiveness of different task difficulty adaptation approaches in a P300 speller task will be evaluated and compared. The study involves a single experimental session that lasts no longer than 2 hours (including setup). The experiments will be conducted in an electrically shielded, dark, and quiet room on the Maynooth University campus.

Recruitment

The participants for this study will be recruited from the staff and student community of Maynooth University through an open enrollment process. Study participants will be alerted to the study through advertisement flyers distributed throughout the Maynooth University campus and through email advertisements sent to staff and students.

Participants

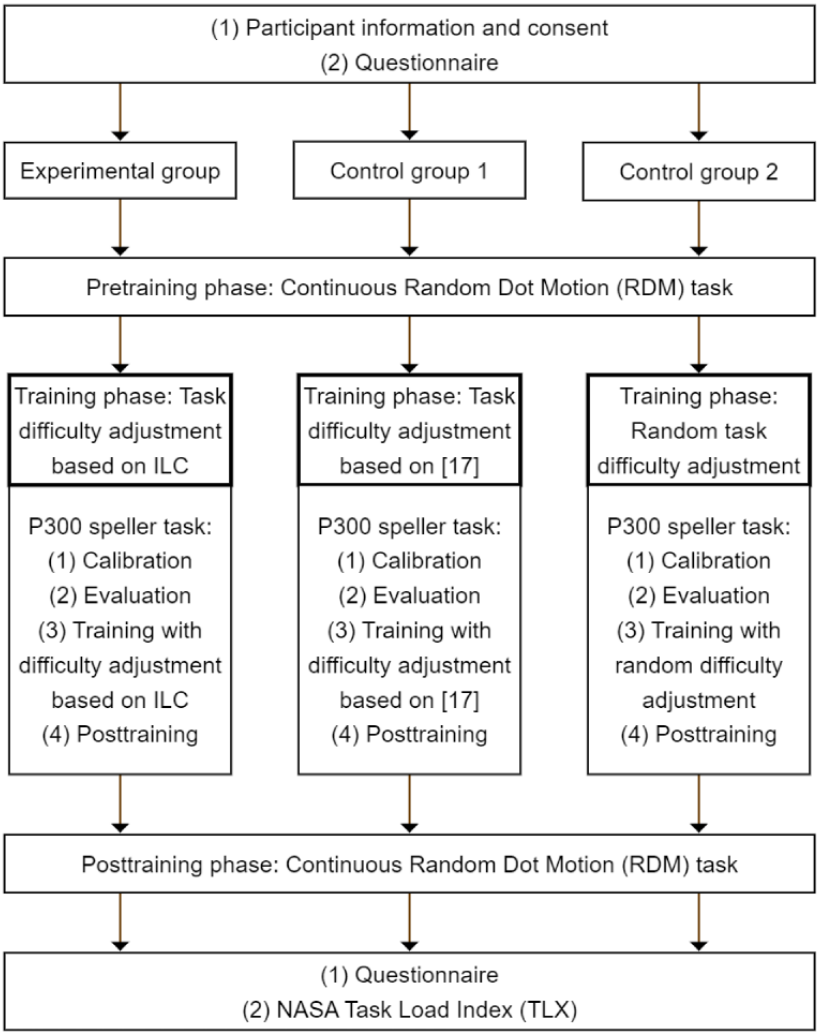
The participants will be healthy individuals aged 18 years or older with no self-reported history of neurological or cognitive illness, and normal or corrected-to-normal vision. Interested participants who do not meet these criteria, have a negative reaction to the electroconductive gel, or who are illiterate will be excluded from the study.

Based on previous work using a P300-based BCI for attention training [17,26], a sample size of 45 participants (15 per group) was determined. Participant recruitment will continue until the sample size is reached. It is expected that around 50 participants will be recruited due to a 10% dropout rate.

Ethical Considerations

This study was approved by the Maynooth University Ethics Committee (BSRESC-2022-2474456) and is registered on ClinicalTrials (NCT05576649). Interested participants who meet the eligibility criteria and give informed consent to study participation, allowing the recording of their performance in the training session and their brain signals, as well as the use of the collected data for this study and future research, will be invited to conduct a patch test to mitigate the risk of allergic reactions to the electroconductive gel. Participants will be advised that they have the freedom to withdraw from the experiment at their discretion at any time throughout the course of the experiment and will not be compensated for their participation in the study. The data from this study will be irreversibly anonymized immediately upon collection.

Procedure



The experimental procedure of this study is based on previous work by Arvaneh et al [17]. An overview of the procedure can be found in Figure 1.

Participants will be asked to fill in a questionnaire at the beginning and end of the experiment. They will then complete a continuous random dot motion (RDM) task, which will serve as a baseline for their cognitive abilities. Afterward, participants will receive attention training using a P300 speller task, where the task difficulty in each run of the speller is either chosen

XSL•FO
RenderX

randomly (control group 2) or adjusted to the participant's performance (control group 1 and experimental group). To analyze improvements in cognitive abilities, participants are asked to complete the RDM task again after the training.

Figure 1. Study procedure based on Arvaneh et al [17]. ILC: iterative learning control.

EEG Data Acquisition

Participants' EEG data will be recorded during the P300 speller training phase of the experiment. EEG data will be collected using the battery-operated ANT Neuro eego rt [27] with a 32-channel waveguard cap [28]. The sintered silver–silver chloride electrodes are located in standard 10-20 positions. Impedances will be maintained below 5 kΩ during recording.

The EEG signals will be acquired in the OpenViBE software [29] at a sampling rate of 500 Hz. All channels will be band-pass filtered (1-20 Hz) and down-sampled by a factor of 4 before further processing.

Offline analysis of the EEG data will be carried out in MATLAB [30] using the EEGLAB toolbox [31]. Since this study is a replication of Arvaneh et al's [17] study, the following offline analysis steps closely follow the steps described in the study. The continuous EEG signals will be rereferenced to Fz, band-pass filtered between 0.5 and 35 Hz and separated into baseline-corrected epochs of 150 milliseconds before the stimulus to 550 milliseconds post stimulus, where the 150 milliseconds prestimulus period is used as the baseline. Epochs with an amplitude of more than 75 µV or those with a voltage step of more than 150 µV within a 200-millisecond window will be excluded from analysis.

Tasks and Stimuli

Questionnaire

Participants will be asked to complete the same 10-point Likert scale questionnaire as in Arvaneh et al [17]. It consists of the four questions: (1) How tired are you now? (2) How alert do you feel? (3) How bored do you feel? (4) Do your eyes feel tired?

This questionnaire will be completed at the beginning and end of the experiment so that responses before and after training can be compared.

In addition, the NASA Task Load Index will be used at the end of the experiment to assess participants' perceived workload of the training [32].

RDM Task

The continuous RDM task is based on Arvaneh et al [17] and Kelly and O'Connell [33]. In this task, the participants will

XSL•FO
RenderX

focus on moving dots on the screen, which transition from incoherent motion to coherent motion. During incoherent motion, all dots will continuously move in random directions, whereas in coherent motion, a significant fraction of the dots will move in one direction, either left or right. The participants will be asked to indicate the direction of the coherent motion by pressing the left or right arrow key once they are sure of the motion direction. In both the pre- and posttraining phases, the main task consists of 40 trials, where the coherence level, that is, the fraction of coherently moving dots, and the motion direction vary in each trial.

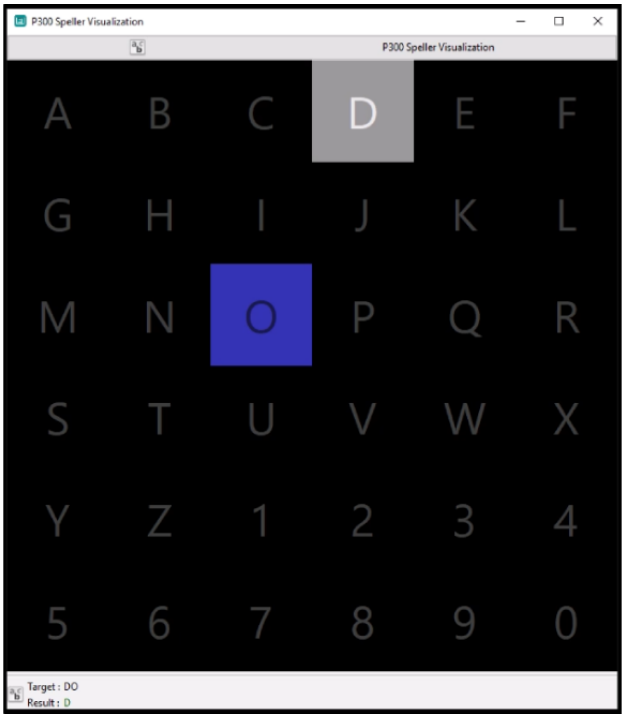
An average of 118 dots, with a size of 6×6 pixels each, are displayed in a circular aperture of 5° at a viewing distance of 70 cm, resulting in a dot density of approximately 10.8%. Each dot is black against a grey background. The dots are moving at a speed of 3.33°/second. The incoherent motion lasts for either 3.1, 4.2, or 5.7 seconds, and the coherent motion always lasts for 1.9 seconds. The coherence level is either 19% or 25%.

To allow participants to understand the task, a practice session will be carried out before the pretraining phase. The practice session consists of 3 blocks of 6 trials each. In the first block, the coherence levels are either 60% or 80%, reducing to 30% or 40% in the second block, and finally reaching 20% or 25% in the last block of the practice session. All other parameters of the task are the same as above. During the practice session, participants will receive verbal feedback on hits, misses, and false alarms.

The code for this task was developed in-house using PsychoPy [34] and the stimuli are presented on a 52.7-cm-wide LED monitor with a refresh rate of 60 Hz and a resolution of 1920×1080 pixels.

P300 Speller Task

Overview



In this study, the P300 speller implementation in OpenViBE [29] is used. This P300 speller uses the xDAWN algorithm [35] to train a spatial filter that enhances the SNR of the P300 ERPs. This reduces the 32 EEG channels to 3 components, which are weighted combinations of all channels. A linear discriminant analysis classifier is used to distinguish target and nontarget trials. It should be noted that the row and column with the highest probability of belonging to the target class are chosen, even if that is below 50%. Both the spatial filter and classifier are trained for each participant using calibration data.

Figure 2 shows the 6 by 6 grid of letters and numbers that is displayed on the screen. The word to be copy-spelled and the identified symbols can be seen below the grid. If the identified symbol is the same as the target symbol, it will be displayed in green. If the identified symbol is in the same row or column as the target symbol, it will be displayed in orange and if it is wrong, it will be displayed in red.

Outside of the training phase, 12 flashes per row and column are used. Each flash lasts 55 milliseconds with an interflash interval of 117 milliseconds. Each target symbol is highlighted in blue for 6 seconds before the flashing begins.

In each run after the calibration phase, the spelling accuracy, that is, the fraction of symbols that were identified correctly, is calculated for all numbers of flashes between 1 and the actual number of flashes used.

Figure 2. OpenViBE [29] implementation of the P300 speller. The next target letter in the word “dog,” “o,” is currently highlighted in blue. The previous letter, “d,” was correctly identified by the speller and is therefore highlighted in grey. The target symbols are displayed below the grid of letters and numbers (“Target:”), and the previously identified symbols can be seen below the target (“Result:”).

XSL•FO
RenderX

Calibration Phase

The calibration phase is used to collect training data for the spatial filter and classifier. The participants will complete 2 runs, where the words “the” and “quick” are copy-spelled without feedback. The recorded EEG signals from both runs are concatenated and then used to first train the xDAWN spatial filter before the linear discriminant analysis classifier is trained. Both target and nontarget trials are separated into epochs ranging from stimulus onset to 600 milliseconds poststimulus. The spatial filter is trained using the continuous EEG signals as well as the target epochs, whereas the classifier uses target and nontarget epochs for training.

Evaluation Phase

Once the spatial filter and classifier are trained, the participants will copy-spell the word “dog.” If at least 2 of the 3 letters are correctly identified by the P300 speller, the participant will move on to the training phase. Otherwise, the spatial filter and classifier will be retrained with the added EEG signals from the latest run. They will then copy-spell the word “fox.” If only 1 of the 3 letters is identified correctly, the participant will be removed from the study.

Training Phase

During the training phase, all participants will copy-spell the word “beautiful” for 5 runs. Ten flashes per row and column are used for the first run of the training phase, for all groups. The number of flashes in all subsequent runs is adapted randomly (control group 2) or based on the participants’ performance in the previous run (control group 1 and experimental group). The participants in all groups will receive feedback but will not be told why the number of flashes varies in each run.

The details of the task difficulty adaptation for each group are described below:

Control group 1: The adaptation algorithm in control group 1 is a replication of the work described in [17]. The number of flashes in each run, N_i, is the average of the minimum number of flashes needed to reach more than 66% spelling accuracy in the previous run, referred to as $N_{(i-1)66}$, and the actual number of flashes used in the previous run, N_{i-1}, that is,

where N_i is rounded to the nearest integer. If the spelling accuracy in the previous run was below 66%, then the number of flashes in the next run is increased by 1, that is,

$$N_i=N_{i-1}+1. \quad \textbf{(5)}$$

Control group 2: The task difficulty adaptation of control group 2 is not based on the participants’ performance. Instead, the number of flashes in each run is chosen at random between 1 and 10 flashes. Choosing the number of flashes in this way will expose the participants in control group 2 to varying task difficulties in an unpredictable way. This allows the authors to compare the personalized adaptation approaches of the other 2 groups to a nonadaptive difficulty adjustment approach under similar conditions. Using a constant task difficulty in this group would potentially lead to differences due to an easier average task difficulty [36] and reducing the number of flashes by the same amount each run would introduce predictability, which the other groups do not have.

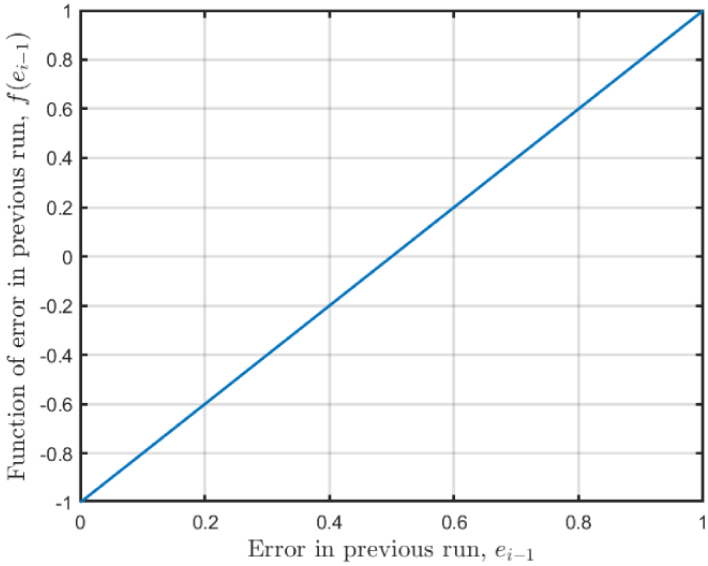
Experimental group: In the experimental group, a P-type ILC controller is used to adapt the number of flashes in the next run, N_i, based on the number of flashes and error in the previous run, N_{i-1} and $e_{i-1}=1-J_{1(\,i-1)}$ (where J_1 is the spelling accuracy). The update law of the controller is

$$N_i=N_{i-1}+f(e_{i-1}), \quad \textbf{(6)}$$

where ε is a controller parameter and

$$f(e_{i-1})=2e_{i-1}-1. \quad \textbf{(7)}$$

Figure 3 shows $f(e_{i-1})$ against e_{i-1}. As can be seen, if only half of all symbols in the previous run were identified correctly, that is, 50% error, $f(e_{i-1})$ will be 0, which means that the number of flashes in the next run will remain the same as that in the previous run. $f(e_{i-1})$ will be –1, if all symbols were identified correctly, and1 if no symbols were identified correctly. This means that the controller parameter is the maximum update step of the number of flashes from one run to the next. ε was tuned in simulation and pilot experiments to the following:



The update law described in (6), (7), and (8) can therefore be simplified to

$$N_i=N_{i-1}(e_{i-1}+0.5). \quad \textbf{(9)}$$

The new number of flashes, N_i, is then rounded up to the next highest integer.

XSL•FO
RenderX

Figure 3. The function of the error in the previous run, f(e_{i-1}), used in the P-type ILC update law, plotted against the error in the previous run, e_{i-1}.

Posttraining Phase

After the training phase, which differs for each group and individual, the participants in all groups will copy-spell the word "dance" with 12 flashes per row and column. This is done to compare any posttraining differences between the groups.

Data Analysis

The offline data analysis steps closely follow the steps described by Arvaneh et al [17] to allow for comparability of results.

Questionnaire

The answers to Arvaneh et al's [17] questionnaire will be analyzed for between-group and within-group differences, using statistical tests, such as repeated measures ANOVA and paired *t* tests.

Similarly, between-group differences in responses to the NASA Task Load Index questionnaire [32] will be analyzed, for example, using a 1-way ANOVA. The raw score of each question will be used for the data analysis.

RDM Task

The change in performance in the RDM task between pre- and posttraining phases will be analyzed in terms of accuracy and response time. The accuracy is the number of correct trials over the total number of trials, and the response time is the elapsed time between onset of the coherent motion until the correct button is pressed before the end of the coherent motion. The response time of incorrect trials will not be considered. The mean response time will be calculated for each participant individually. Statistical tests, such as ANOVA and paired *t* tests, will be conducted to analyze between-group and within-group differences for both the accuracies and mean response times.

P300 Speller Task

Spelling Accuracy

The between-group differences in performance in the P300 speller in terms of spelling accuracy will be analyzed for all participants. Only the evaluation run, the first run of the training phase, and the posttraining run will be considered, as these 3 runs use the same number of flashes per row and column for all participants. Training runs 2-5 are different for each individual as the number of flashes is either determined by their previous performance (control group 1 and experimental group) or chosen randomly (control group 2). This means that the performance during these runs cannot be compared directly.

Length of Training

Since 1 of the objectives of this study is to accelerate attention training, the length of the training will be compared in terms of the total number of flashes used in runs 2-5 of the training phase. A statistical test, such as the 1-way ANOVA, will be carried out to compare between-group differences.

ERP Components

The changes in the ERP components throughout the training will be analyzed. For this purpose, epochs from 150 milliseconds to 550 milliseconds poststimulus onset will be extracted from the EEG data for both target and nontarget trials. Subsequently, the total power across the same centroparietal electrodes as used in [17] (ie, C3, Cz, C4, P3, Pz, and P4) will be calculated for each epoch.

The average total power for all epochs of the calibration and evaluation phases, the training phase, and the after-training phase, respectively, will be calculated. A training-to-calibration ratio of the average power for both target and nontarget trials will be obtained by dividing the average total power during the training phase by the average total power during the calibration and evaluation phases. The same will be done with the average total power during the after-training phase to obtain an after-training-to-calibration ratio.

A ratio of greater than unity indicates an increase in average total power, whereas a ratio of less than unity indicates a decrease in average total power compared to the calibration and evaluation phase. For target trials, an increase in power means that the participant improved their attention, and a decrease in power of nontarget trials can be interpreted as the participant being less distracted by nontarget flashes [17].

XSL•FO
RenderX

Appropriate statistical tests, such as ANOVA, will be conducted to analyze within-group and between-group differences in the aforementioned ratios.

Time-Frequency Analysis

Similarly, to the training-to-calibration and after-training-to-calibration ratios of the average total power, these ratios will be calculated for the power of the alpha rhythm (7-12 Hz) of nontarget trials that are not presented immediately after a target trial. The alpha power will be calculated for the same centroparietal electrodes as before, for a period of 150 milliseconds poststimulus.

The training-to-calibration alpha ratio is the average alpha power during the training phase divided by the average alpha power during the calibration and evaluation stages, and the after-training-to-calibration alpha ratio is the average alpha power during the after-training phase divided by the average alpha power during the calibration and evaluation stages. A ratio of less than unity means that a participant is less distracted by nontarget stimuli compared to the calibration and evaluation phases [17].

Between-group differences of the training-to-calibration and after-training-to-calibration alpha ratios will be analyzed using statistical tests, such as 1-way ANOVA.

Correlation Between EEG and RDM Performance

The potential correlation between the brain activity during the P300 speller phase of the training session and the performance in the RDM task will be investigated with tests, such as the Pearson correlation coefficient or the nonparametric Spearman correlation test. The training-to-calibration and after-training-to-calibration ratios of total power and alpha power will be used as performance metrics during the P300 speller task. Similar ratios will be obtained for the response times and accuracies of the RDM task by dividing the posttraining phase response times and accuracies by the pretraining phase response times and accuracies, respectively.

Results

This study was approved by the Maynooth University Ethics Committee (BSRESC-2022-2474456) and is registered on ClinicalTrials.gov (NCT05576649). Participant recruitment and data collection began in October 2022. We expect to publish the results in 2023. This study is replicating the experimental protocol of Arvaneh et al [17], comparing their task difficulty adaptation approach to a novel approach using an iterative learning controller, as well as random task difficulty levels in each run.

Arvaneh et al [17] showed a significant enhancement of ERP components and performance in the RDM task after the P300 speller training, suggesting that participants' attention improved. We expect such an improvement for all groups in this study, with changes in the length of the training between groups due to the different adaptation approaches.

Discussion

Overview

This study aims to evaluate the use of an adaptive P300 speller as a neurofeedback training tool for attention training. We aim to accelerate the training process using ILC and compare personalized and nonpersonalized task difficulty adaptation approaches. By replicating the experimental protocol of Arvaneh et al [17], who demonstrated the adaptive P300 speller's potential as an easy-to-use and effective neurofeedback training tool, we seek to gather further evidence supporting this application for attention training.

The findings of this study will contribute to the understanding of how different adaptation approaches, both personalized and nonpersonalized, can impact the efficacy of neurofeedback training tools. These insights can guide the design of future BCI-based cognitive training and rehabilitation interventions. Accelerating the training with the P300 speller, without affecting its effectiveness or the users' frustration levels, will make it a more attractive training option for people with cognitive deficits.

Limitations

There are limitations to this protocol. The participants will only receive a single session of the neurofeedback training and therefore the long-term impacts of the neurofeedback training will not be obtained. Due to the short length of the training session, participants may not experience significant cognitive enhancements. The participants for this study will be healthy, and most likely young (due to recruitment in the university community) adults. It can be assumed that these individuals possess close to maximal cognitive abilities, which further limits the significance of the cognitive enhancements of the training.

Conclusions

Due to an aging and growing population, the number of people with cognitive deficits and illnesses is rising. It is therefore important to develop cognitive training and rehabilitation tools that are affordable, easy to use, and effective. The adaptive P300 speller that will be evaluated in this study might have the potential to be an efficient training tool. Positive findings of this study may demonstrate that the adaptive P300 speller, and more broadly BCIs, can be effective tools in cognitive training and rehabilitation.

Acknowledgments

The work described in this manuscript is funded by the Irish Research Council (award GOIPG\2020\692) and Science Foundation Ireland (grant number SFI/12/RC/2289_P2). The authors thank the Hamilton Institute for providing access to the shielded room this study is to be conducted in.

Abstract

Background: Low medication adherence is a common cause of high blood pressure but is often unrecognized in clinical practice. Electronic data linkages between electronic health records (EHRs) and pharmacies offer the opportunity to identify low medication adherence, which can be used for interventions at the point of care. We developed a multicomponent intervention that uses linked EHR and pharmacy data to automatically identify patients with elevated blood pressure and low medication adherence. The intervention then combines team-based care with EHR-based workflows to address medication nonadherence.

Objective: This study aims to describe the design of the Leveraging EHR Technology and Team Care to Address Medication Adherence (TEAMLET) trial, which tests the effectiveness of a multicomponent intervention that leverages EHR-based data and team-based care on medication adherence among patients with hypertension.

Methods: TEAMLET is a pragmatic, cluster randomized controlled trial in which 10 primary care practices will be randomized 1:1 to the multicomponent intervention or usual care. We will include all patients with hypertension and low medication adherence who are seen at enrolled practices. The primary outcome is medication adherence, as measured by the proportion of days covered, and the secondary outcome is clinic systolic blood pressure. We will also assess intervention implementation, including adoption, acceptability, fidelity, cost, and sustainability.

Results: As of May 2023, we have randomized 10 primary care practices into the study, with 5 practices assigned to each arm of the trial. The enrollment for the study commenced on October 5, 2022, and the trial is currently ongoing. We anticipate patient recruitment to go through the fall of 2023 and the primary outcomes to be assessed in the fall of 2024.

Conclusions: The TEAMLET trial will evaluate the effectiveness of a multicomponent intervention that leverages EHR-based data and team-based care on medication adherence. If successful, the intervention could offer a scalable approach to address inadequate blood pressure control among millions of patients with hypertension.

Trial Registration: ClinicalTrials.gov NCT05349422; https://clinicaltrials.gov/ct2/show/NCT05349422

Introduction

Low medication adherence, frequently defined as a proportion of days covered (PDC) of less than 80% [1,2], is associated with increased cardiovascular morbidity and mortality and has a prevalence as high as 30%-50% among patients with hypertension [3-5]. Assessment of adherence in clinical practice is challenging; however, as most objective measures of adherence are of limited use, electronic monitoring is expensive and challenging to scale, while pharmacy claims data are limited to certain insured patients and only available to primary care providers (PCPs) with delays [4,6-8]. However, recent uptake of electronic prescribing from the electronic health record (EHR) to pharmacies offers the opportunity for scalable, real-time measurement of medication adherence that can be used for interventions at the point of care [9]. Despite the recent integration of pharmacy medication fill data into many EHRs, their use in addressing medication adherence at the point of care has not been thoroughly evaluated [10,11].

These limitations in the assessment of medication adherence in combination with the limited PCP time due to competing demands have led to insufficient attention to medication adherence in primary care practice [12]. Prior studies have demonstrated that clinical teamlets comprising PCPs paired with medical assistants (MAs) might be able to improve screening for adherence as well as medication-taking behavior [13-15]. Furthermore, the ability of teamlets to communicate and effectively change behavior can be enhanced through tight integration into the workflow using EHRs. However, the benefits of an intervention that combines teamlets with scalable, EHR-based adherence data and integrated workflows have not been studied.

The purpose of this study is to describe the design and protocol of the Leveraging EHR Technology and Team Care to Address Medication Adherence (TEAMLET) study. This cluster randomized controlled trial will evaluate the effectiveness of a multicomponent intervention on medication adherence and blood pressure control among patients with hypertension who are seen in primary care. The intervention combines a data-driven approach to automatically identify patients with elevated blood pressure and low medication adherence, team-based care to address low medication adherence, and user-centered EHR workflows. We will also evaluate the implementation of the intervention into primary care clinical sites.

Methods

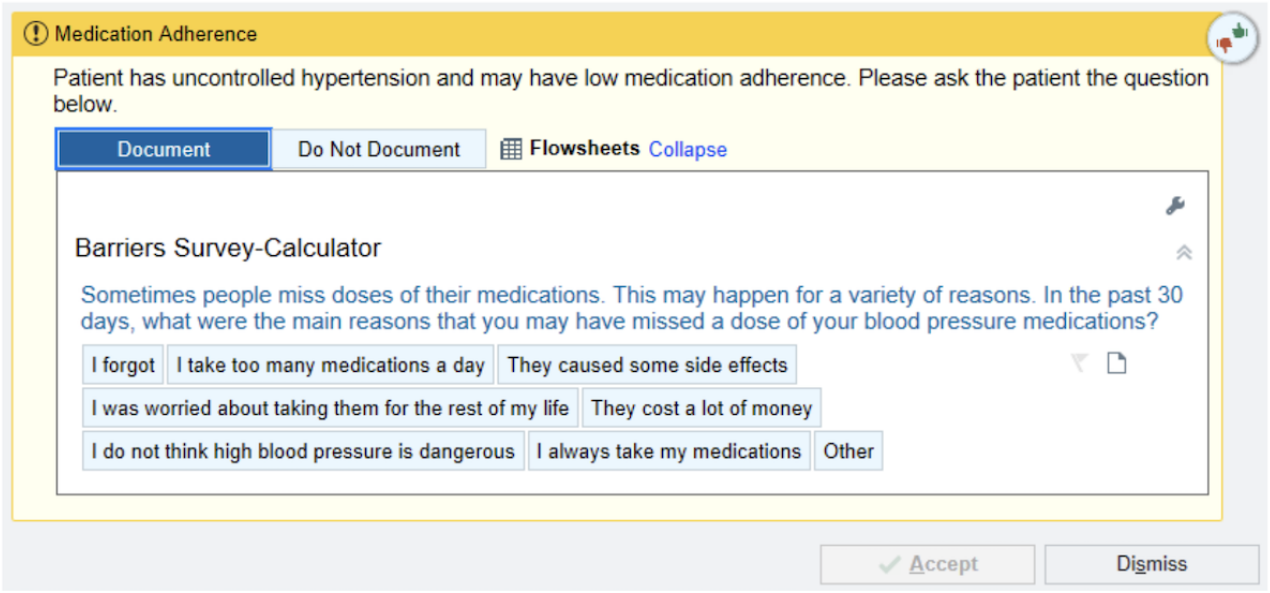
Study Design

A 2-arm hybrid type I effectiveness-implementation pragmatic, cluster randomized controlled trial will be performed to assess the effectiveness of a multicomponent intervention on medication adherence (primary outcome) and systolic blood pressure (secondary outcome) for patients with hypertension. The clusters for randomization are primary care practices in a large health care network. The intervention is guided by the Capability-Opportunity-Motivation Model of Behavior (COM-B) framework, a parsimonious amalgamation of existing theories of behavior change, which has been proven effective for designing programs that help patients improve medication adherence [16]. Our evaluation is based on Proctor Implementation Outcomes Framework, a conceptual framework that guides the evaluation of distinct outcomes that serve as indicators of implementation success [17].

Setting and Eligibility

This study is being conducted at primary care practices in the NYU Langone Health network. NYU Langone Health includes a diverse network of hospital-based practices, community-based practices, and community health centers in New York City and the surrounding areas. The health system includes over 60 distinct primary care practices that all use the same EHR, Epic (Epic Systems). From these practices, we will recruit 10 to participate in the study.

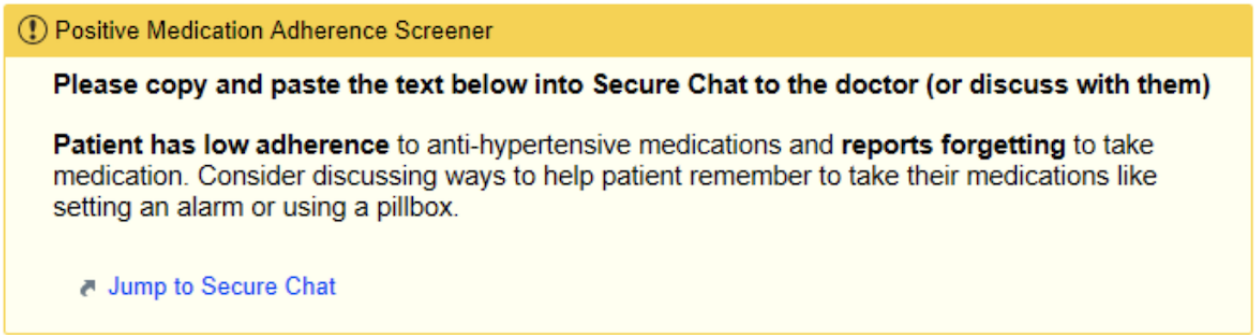
This study will include all adult patients seen at one of the recruited practices who have hypertension, uncontrolled blood pressure, and poor medication adherence. Specifically, we will include patients aged ≥18 years who were seen for a visit at one of the included practices in the study during the first 6 months of the commencement of the trial at that site. Patients with an active order for at least 1 antihypertensive medication will be included. To ensure patients have inadequately controlled hypertension (and mitigate variability associated with clinic blood pressure readings), we will include those with a measured clinic blood pressure ≥140/90 mm Hg on the day of the visit plus a blood pressure reading greater than or equal to 140/90 mm Hg on the previously recorded blood pressure measurement. Low medication adherence will be defined by a PDC <80% during the prior 6 months, where PDC is defined as the proportion of days that a patient had a medication from pharmacy fills while the medication had an active prescription [1,9]; for example, if a medication is initially prescribed at the start of the 6-month period, is not discontinued, and is only filled once for 90 days, the PDC would be 90/180=50%. PDC will be calculated using the algorithm in our EHR, which is based on the Pharmacy Quality Alliance measure [18]. This calculation will include adherence to all antihypertensive medications used in the prior 6 months, even if the medication was no longer active on the day of assessment. For patients on multiple antihypertensive medications, the algorithm considers a patient to be adherent on a given day only if medication fills are available for all medications on that day.



Intervention

The intervention is an EHR-based workflow that consists of four components: (1) identification of patients with poorly controlled hypertension and low medication adherence at the point of care; (2) prompts for the MA to screen for important barriers to medication nonadherence; (3) alerting the PCP of low medication adherence and important barriers, with the intent of facilitating a conversation with the patient regarding medication adherence; (4) clinical decision support (CDS) to assist PCPs in addressing the barriers to medication adherence. These components have been informed through interviews and usability sessions with PCPs and MAs as well as a patient survey [19]. The process for intervention begins when the MA records the blood pressure of a given patient presenting to see their PCP.

XSL•FO
RenderX



If the blood pressure is recorded as ≥140/90 mm Hg, the algorithm within the EHR will automatically screen the patient for the other inclusion criteria. If the patient meets all the criteria, that is, if their age is ≥18 years, the prior blood pressure is ≥140/90 mm Hg, they are taking an antihypertensive medication, and their PDC <80%, the MA will then receive a CDS alert to ask the patient about whether 1 of the 6 barriers contributed to missing medications (Figure 1). These 6 barriers are based on a validated questionnaire and survey of the patient population in our health system [19-21]. After responding to the question, the MA will receive an alert to communicate this result to the PCP, either through secure chat or through another method (Figure 2). The PCP then will receive the secure chat message, which will include a prompt to review the CDS related to medication adherence (Figure 3). Even if the message is not communicated from the MA to the PCP, the passive CDS will still be available to the PCP. The CDS will convey the barrier to medication adherence and provide suggestions to address the barrier (Figure 4). Additionally, the CDS will link to an order set, which will include auto documentation related to medication adherence and barriers, appropriate patient instructions, and an International Classification of Diseases, Tenth Revision (ICD-10) diagnostic code to add to the visit (Figure 5). Ultimately, our goal is for these tools to facilitate a discussion between the PCP and the patient to address barriers to medication adherence.

MA and PCP Training

We will use a multipronged approach to train MAs and PCPs about the intervention. First, individual emails will be sent out to each MA and PCP group alerting them to the study. Included in the email will be an attachment of a tip sheet about the intervention and its components. Second, an in-person or web-based practice site meetings will be presented to include an overview of medication adherence, a walk-through of the intervention components, and suggestions for communication with patients. Third, 3 training videos that contain similar content will be built: the first containing general information about medication adherence, the second describing patient communication, and the third detailing the intervention. These supplemental videos will be accessible to intervention MAs and PCPs at any time if questions arise, although they are not required for the success of the CDS, which stands on its own. Fourth, study staff will be on-site for the first week of intervention to provide support and answer any questions during the implementation period.

Ongoing Support

In addition to the availability of training videos that can be used at any time, site administration, PCPs, and MAs will be provided with study staff's contact information to discuss any questions or concerns, as needed. Study team members will make monthly site visits to offer additional support. Additionally, study team members will be in regular contact with site leadership to learn of any staffing changes and encourage the training of newly hired MAs and PCPs.

Control

MAs and PCPs in the control group will receive individual emails informing them of inclusion in the study. The email will include an overview of medication adherence and will describe current tools available related to medication adherence that are available within the EHR. The first and second training videos available for the intervention group will also be accessible to control group PCPs; these videos contain general information about medication adherence and a description about communication with patients.

Recruitment and Randomization

This study will use a practice-level cluster randomized design, with 1:1 randomization of 10 practices, resulting in 5 per study arm. We will use block randomization of 4 to 6 practices at a time with go-lives occurring approximately monthly to stagger the intervention rollout across the network.

Recruitment will be performed through email outreach to medical directors and practice managers at individual practice sites. The email will contain a brief description of the project, expectations of the practice for participation, and an offer to have a virtual meeting to present the project and answer additional questions.

XSL•FO
RenderX

Enrollment and Follow-up Period

Patients who meet inclusion criteria will be included in the analysis if seen in one of the interventions or control primary care sites in the first 6 months after site enrollment into the trial. The patients will be evaluated for the outcome 12 months after the index clinic visit. The research support staff will support intervention implementation at each site for a total of 18 months to ensure complete 12-month follow-up for all included patients. After this time, we will observe outcomes for an additional 6 months without direct support from the research staff to assess the sustainability of the intervention.

Clinical Outcomes

Clinical outcomes will be based on the data extracted from the EHR. Our primary outcome will be medication adherence assessed at 12 months. Adherence will be measured by PDC as a continuous variable using a lookback period of 6 months. The secondary clinical outcomes will be medication adherence as measured as a binary variable of PDC ≥80% [1,2] and clinic systolic blood pressure assessed continuously. When available, we will use the mean of the last 2 clinic blood pressure measurements within 1 year of the initial clinic visit, in order to increase reliability with multiple blood pressure measurements [22].

Implementation Outcomes

Our implementation measures are guided by Proctor Implementation Outcomes Framework and will include adoption, acceptability, fidelity, cost, and sustainability of the intervention (Table 1). Data for our implementation measures will be obtained from both EHR data and semistructured interviews of PCPs and MAs.

Table 1. Description of implementation outcomes.

Outcome and measure	Data source
Adoption	

• For MAs[a], we will assess:
  • If the MAs completed the survey (yes or no)
  • The percentage of times the MA sent a secure chat to the PCP[c] (yes or no)
  • Assessment of MA participation
• For PCPs, we will assess:
  • If the PCP interacted with the CDS[d] (yes or no)
  • If the orders were placed from the order set (yes or no)
  • If the PCP documented discussion of medication adherence with the patients. (yes or no)
  • Assessment of PCP participation
	• EHR[b]
	• Semistructured interviews

Acceptability	
• We will ask MA and PCP about the acceptability of the intervention	• In-person and email survey • Semistructured interviews
Fidelity	

• Chart review for documentation of discussions MA and PCP self-reported adherence
• For MAs, we will assess:
  • The percentage of times that MAs completed the survey
  • The percentage of times the MA sent a secure chat to the PCP
• For PCPs, we will assess:
  • The number of times PCP interacted with the CDS
  • The number of orders placed from the order set
  • The percentage who documented discussion of medication adherence with the patients.
	• Chart review
	• Semistructured interviews
	• EHR

Cost	
• Time spent by MAs and PCPs on intervention, multiplied by average salary	• EHR • Public salary data
Sustainability	
• Evaluate outcomes at 18 months • Identify factors that influence sustainability and integration	• EHR data • Semistructured interviews

[a]MA: medical assistant.

[b]EHR: electronic health record.

[c]PCP: primary care provider.

[d]CDS: clinical decision support.

XSL•FO
RenderX

Adoption

EHR data will be used to measure the adoption of the intervention by MAs and PCPs. For MAs, we will evaluate the number of MAs that completed the barriers questionnaires and the number that sent secure chat messages (measured as a yes or no dichotomous variable). For PCPs, we will assess if the order set was opened from the CDS and if the autodocumentation and patient handouts were added from the order set (measured as a yes or no variable). A qualitative assessment to understand MA and PCP participation will also be performed.

Acceptability

We will ask the PCPs and MAs about the acceptability of the intervention during interviews and will administer a validated survey, the Acceptability of Intervention Measure at the end of the intervention [23].

Fidelity

To assess fidelity (a metric of implementation success and quality), we will perform a chart review for a sample of eligible patients to determine the frequency of documentation of provider actions to address medication adherence, including discussions with patients and switching to alternative medications for cost or side effect issues. A weekly review will be performed at each site for the first month, then monthly throughout the study period, and provide feedback to sites if medication adherence does not appear to be addressed. The EHR data will also be used to measure the fidelity to the intervention protocol, as intended. For MAs, the percentage of barriers questionnaires completed and the percentage of secure chats sent will be measured. For PCPs, the percentage of times the order set was opened from the CDS and the number of times that auto documentation and patient handouts were added from the order set will be assessed.

Cost

We will evaluate the cost of the intervention by estimating the additional time spent by MAs and PCPs on the intervention and then multiplying this by their average national salaries with fringe. Both self-report and data to estimate the time spent will be used. We will survey MAs and PCPs from the intervention group on how much additional time they spend with each patient for whom they receive the intervention. This value will be compared to the time the MAs spent between receiving the CDS and completion of the survey. For the PCPs, the average time spent in the EHR for intervention patients will be measured and compared to the average time on control patients. We will measure average salaries using publicly available data from the US Bureau of Labor Statistics [24].

Sustainability

During semistructured interviews, we will ask PCPs and MAs about the opportunities to maximize the sustainability of the intervention, and the strategies to optimize continued integration of the intervention into the routine workflow. In addition, to assess the sustainability of the intervention over time, PDC will be measured longitudinally at the following time intervals: baseline, 6 months, 12 months, and 18 months (6 months post completion of intervention). Similarly, if available, blood pressure at these time points will be assessed.

Covariate Measures

The baseline patient characteristics at the time of the initial visit with the PCP in which inclusion criteria are met will be assessed. Demographic characteristics to be collected will include patient age, sex, race, ethnicity, and insurance. Baseline clinical characteristics to be collected will include clinic blood pressure, number of medications, and comorbidities. Additionally, we will assess the number of clinic visits during the follow-up period.

Statistical Methods

Sample Size

Our sample size estimate is based on the clinical outcome of medication adherence after 12 months, which is measured as a continuous variable. We plan on a 6-month enrollment period. Based on the preliminary data from primary care practices in our health system, we estimate a median of 182 eligible patients per practice during this period. Based on our prior work of having MAs perform counseling related to adherence, we anticipate a group difference of at least 20% between the intervention and the control groups [15]. Applying this effect size to our study, and assuming 80% power, 5% type I error rate (α), 30% attrition over the 18-month study period, and an intraclass correlation coefficient of 0.15 to account for clustering of patients within sites, we estimate a necessary sample size of 10 practices in the study. Calculations of sample size were estimated using a standard approach (eg, design effect) for cluster randomized trials [25].

Descriptive Analyses

We will summarize baseline characteristics, clinical outcomes, and quantitative implementation outcomes. Frequencies and percentages will be used to describe categorical variables, and means and SDs will be used to characterize continuous outcomes. Medians and IQRs will be reported for continuous variables that exhibit skewness.

Analyses of Primary and Secondary Outcomes

The analysis of all outcomes will follow the intention-to-treat principle. For the intention-to-treat approach, all participants randomly assigned to one of the 2 arms will be included in the analysis under their assigned group, regardless of compliance. The primary study outcome will be PDC, which can take on values ranging from 0% to 100%. We will develop a generalized linear mixed model with PDC as the dependent variable. The model will include a categorical indicator variable for the randomized study arm (control as reference), a variable corresponding to time (baseline as reference), and the interaction of the 2, representing the primary independent variable. The primary study end point will be at 12 months, with secondary end points measured at 6 and 18 months; these secondary end points will be used to assess sustainability. We will also adjust for any sociodemographic or clinical covariates imbalanced at baseline, as well as the number of clinic visits per patient to assess the frequency of exposure to intervention. The model will include practice-level random effects to account for

XSL•FO
RenderX

clustering of patients within clinics during randomization. Prior to analyzing the data, we will compare dropout and missing data across the 2 arms and examine whether any patient characteristics were associated with the missing data. If necessary, additional analyses utilizing multiple imputation methods will be conducted.

The secondary study outcome will be blood pressure, also measured as a continuous variable using a similar generalized linear mixed model approach. Exploratory outcomes will include subgroup analyses to identify individual components of the intervention that may be influential on the clinical outcomes and other EHR-based measures.

Qualitative Collection and Analyses

Semistructured interviews of PCPs and MAs will be conducted toward the end of the trial to identify emerging themes related to Proctor implementation outcomes. The interview guide, informed by the implementation outcomes, will consist of 10-15 questions regarding acceptability, adoption, fidelity, and sustainability, with an emphasis on barriers and facilitators to implementing the intervention. This qualitative data collection will be complemented by quantitative data collected in the study.

Qualitative analysis will include both semistructured interviews with PCPs and MAs as well as narrative reports to assess adherence. Interviews will be audio-recorded and transcribed verbatim by an outside vendor. Qualitative data will be analyzed using thematic analysis [26]. We will begin with open codes and progressively group and refine codes into categories. In addition to identifying key a priori codes based on our framework, coders will initially review a selection of interviews and develop codes to describe the content for the initial code list. The codebook will be updated and revised throughout the review process. Once all interviews are coded, the investigative team will meet to discuss and identify code clusters, relationships between codes, and common themes.

In addition, we will follow the National Institutes of Health's best practices for mixed-methods research [27] in synthesizing quantitative results and qualitative themes by constructing a joint display for statistics-by-theme and side-by-side interpretation of the qualitative data [28]. The mixed methods approach will allow us to integrate the qualitative findings with quantitative results, providing a comprehensive understanding of the impact of the intervention, and identify the best practices for implementation.

Ethics Approval

This study was approved by the institutional review board at NYU Langone Health (#21-00133). Verbal consent was obtained at the practice level from the medical director in addition to the ambulatory system and enterprise EHR leadership at each primary care practice. We have obtained a waiver of consent from the institutional review board at NYU Langone Health for patients included in the trial.

The Data and Safety Monitoring Board will be responsible for monitoring the study. The Data and Safety Monitoring Board will receive information specific to the intervention and control arms to evaluate the progress of the trial, including periodic assessments of data quality and timeliness; participant recruitment, accrual; and retention; participant risk versus benefit; the performance of trial sites; and other factors that can affect the study outcome.

Results

As of May 2023, we have randomized 10 primary care practices into the study, with 5 practices assigned to each arm of the trial. Enrollment for the study commenced on October 5, 2022, and the trial is currently ongoing. We anticipate patient recruitment to go through the fall of 2023 and the primary outcomes to be assessed in the fall of 2024.

Discussion

Medication nonadherence is a major contributor to inadequate blood pressure control [29]. However, health care providers underestimate the frequency of patient nonadherence to antihypertensive medications [30]. Relatedly, medication nonadherence is not well addressed in clinical practice: 40% of primary care visits do not include discussions about medication adherence among patients with elevated cardiovascular risk [31]. Even when these conversations do occur, they amount to a very brief discussion [32]. Lack of resources, inadequate skills, and insufficient system-level supports are the most common barriers expressed by PCPs for the lack of integration of adherence counseling into routine practice [12].

The TEAMLET intervention was developed to provide system-level support and resources to address medication nonadherence. In this study, we will conduct a cluster randomized controlled trial of this multicomponent intervention on medication adherence and blood pressure control among patients with hypertension. The intervention draws on 2 innovations to address the gaps in screening for and addressing medication nonadherence. First, the intervention uses a data-driven approach to automatically identify patients with low medication adherence and high blood pressure. Our medication adherence measure will use EHR-based pharmacy fill data, which is a scalable and reliable measure of adherence that is available in real-time clinical care [4]. To date, few studies have used these data for real-time adherence measurement and most used cases have been limited to a closed health system that includes a pharmacy [10,11]. Conversely, our study is within a health system that includes patients with various insurance providers or who are uninsured and that interfaces with hundreds of pharmacies. The second innovation of the intervention is that it relies on teamlets in primary care to address medication adherence [33]. Specifically, we will give MAs the tools to assess barriers to medication adherence and then relay this information to providers during regular clinical practice. This will allow PCPs to focus their limited time on the patient's specific issue related to adherence and deliver tailored health coaching.

Our study has potential limitations. First, medication adherence is based on PDC from pharmacy fills; as such, it is not a direct measure of medication adherence. While PDC is commonly used in the literature to assess medication adherence, it is subject

XSL•FO
RenderX

to misclassification. Nonetheless, PDC from pharmacy fill data has been shown to be well correlated with medication continuity, biomarkers, and clinical outcomes, and there is evidence that improvement in PDC leads to improvement in clinical outcomes [4,34-36]. We are also examining a clinically meaningful secondary outcome of blood pressure. Second, patient-level inclusion in the intervention and our secondary clinical outcome are based on clinic-based blood pressure measurement, which may be subject to misclassification due to issues including white coat hypertension [37]. As a result, we use a conservative definition for patients with hypertension that includes multiple high readings and a cutoff of 140/90, which is endorsed by some guidelines [38,39] but considered conservative by others [40]. Third, the study will be conducted in 1 health care system that uses 1 EHR platform. Nonetheless, Epic is the most commonly used EHR platform in the United States [41] and the intervention workflows can be generalized to most health systems and EHRs.

In this protocol, we describe a clinic-based, cluster randomized controlled trial of the TEAMLET intervention. We hypothesize that the intervention will lead to improved medication adherence among patients with hypertension being seen in primary care clinics. If shown to be true, we believe that this intervention, which is centered on data available in many EHRs and teamlets typically available in primary care settings, can be easily scaled to help address inadequate blood pressure control.

Data Availability

In order to prioritize participant privacy and confidentiality, we will not be sharing any electronic health record data or qualitative data from this study due to ethical concerns regarding the sensitivity and potential reidentification risks associated with these data. However, any high-level aggregate data sets generated and analyzed in the randomized controlled trial will be made available upon reasonable request from the corresponding author.

Conflicts of Interest

Abstract

Background: Obesity is an increasing problem worldwide. The effective treatments for obesity mainly include diet, physical activity, behavioral intervention, pharmacotherapy, and bariatric surgery, which all have certain limitations. As a specific type of acupuncture therapy, acupoint catgut embedding (ACE) has gained substantial attention in the management of obesity in recent years. Previous studies suggested that ACE may be an effective obesity treatment. However, the evidence for the efficacy of ACE in abdominal obesity (AO) remains inadequate due to the paucity of high-quality studies.

Objective: This study aims to investigate the difference in the effectiveness of catgut embedding at acupoints and catgut embedding at nonacupoints in patients with AO and to further validate the efficacy and safety of ACE for AO.

Methods: This is a multicenter, double-blind, 16-week randomized controlled trial. A total of 92 eligible participants with AO will be randomly divided into 2 groups (1:1 allocation ratio). The ACE group will receive catgut embedding at acupoints and the control group will receive catgut embedding at nonacupoints. The intervention will be performed every 2 weeks for a total of 6 sessions. Follow-up will be performed every 2 weeks for a total of 2 visits. The primary outcome is waist circumference. Secondary outcomes include body weight, BMI, hip circumference, and the visual analog scale of appetite. Upon the completion of the trial, we will evaluate the effect of catgut embedding at acupoints or nonacupoints on obesity indicators in patients with AO. For treatment outcomes, an intention-to-treat analysis will be performed.

Results: The start of recruitment began in August 2019 and is expected to end in September 2023.

Conclusions: Although studies have been conducted to demonstrate the effectiveness of ACE in the treatment of obesity, the evidence for the efficacy of ACE in AO remains insufficient due to the quality of the studies. This rigorous normative randomized controlled trial will verify the effect of catgut embedding at acupoints or nonacupoints in patients with AO. The findings will provide credible evidence as to whether ACE is an effective and safe treatment for AO.

KEYWORDS

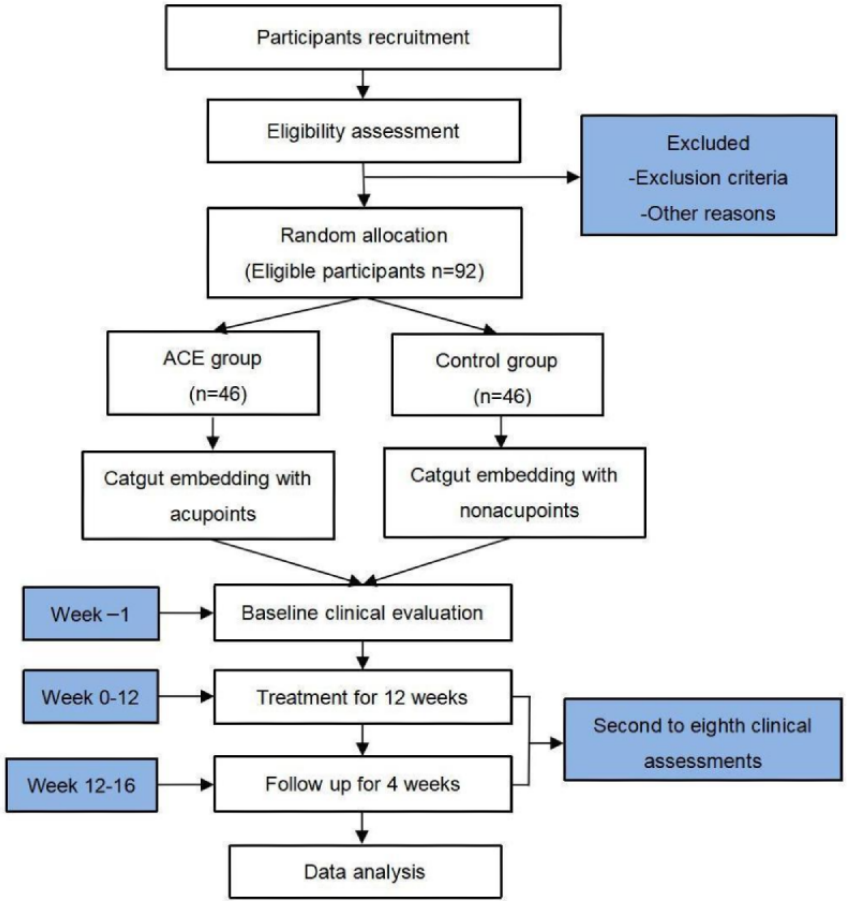
acupoint catgut embedding; nonacupoints; abdominal obesity; randomized controlled trial; protocol; waist circumference

Introduction

Obesity has become a global health issue regardless of race, region, and age [1]. Globally, the prevalence of obesity in adults was approximately 13% (603.7 million). There were approximately 107.7 million children and adolescents who were obese [2,3]. The prevalence of obesity was about 20% or more in the United States, the Middle East and North Africa, the Caribbean, Polynesia, and Micronesia [4]. The increase of adults who are obese has leveled off in several high-income countries, but the incidence is dramatically on the rise in most low- and middle-income countries, particularly in urban regions [1,5]. As a major type of obesity, the prevalence of abdominal obesity (AO) in adults was 29.1% (28.6% in men and 29.6% in women) in China [6]. Obesity is a worldwide problem and a burden in many diseases [2,7,8]. Studies have demonstrated that obesity may lead to diabetes, subfertility, chronic spontaneous urticaria, nonalcoholic fatty liver disease, Alzheimer disease, cardiovascular diseases, and even cancer [2,9-18]. In addition to diseases, obesity can also affect disability-adjustment life-years and generate a large economic burden [4,19-21]. Obesity is also a persistent problem, where most children who are obese will remain obese in adolescence [22].

The effective treatments for obesity mainly include diet, physical activity, behavioral intervention, pharmacotherapy, and bariatric surgery [23-29]. Diet and physical activity require great self-discipline and enough time, which are difficult to adhere to. The effect of behavioral intervention for obesity is typically limited [30]. Side effects such as abdominal pain, vomiting, nervousness, insomnia, headache, dizziness, dysgeusia, and insomnia may accompany pharmacotherapy [31]. Pharmacotherapy could not be used for patients who are obese with complicated active cardiovascular disease, glaucoma, uncontrolled hypertension, anorexia, thyroid, and many other diseases [32,33]. For pregnant individuals and children, the safety of pharmacotherapy is still not guaranteed currently [34]. Bariatric surgery requires a high level of medical technology and may increase the risk of fractures [35-37]. Alternative therapies such as acupuncture, moxibustion, acupoint catgut embedding (ACE), and massage are increasingly used for the treatment of obesity [38-42].

ACE is a special acupuncture therapy that combined the absorbable surgical suture and acupoint, and the effective stimulation of every ACE treatment could persist for 2 weeks. Previous studies indicated that ACE was an efficient treatment for obesity, but the risk of bias was significantly high [43]. Therefore, this rigorous and normative randomized controlled trial (RCT) study is designed to verify the efficiency of catgut embedding at acupoints and nonacupoints in participants with AO. The findings will provide credible evidence as to whether ACE is an effective and safe treatment for AO.



Methods

Study Design and Setting

This multicenter, double-blind, 16-week RCT will be conducted from August 2019 to September 2023 in 4 clinical centers: The Second Affiliated Hospital of Yunnan University of Chinese Medicine, The Sports Trauma Specialist Hospital of Yunnan Province, Kunming Hospital of Traditional Chinese Medicine, and ShengAi Hospital of Traditional Chinese Medicine. A total of 92 eligible participants with AO will be assigned to 1 of 2 groups (catgut embedding at acupoints or nonacupoints) using central randomization (1:1 allocation ratio). Every participant will receive a 12-week intervention period and a 4-week follow-up. The flowchart of this study is shown in Figure 1.

Ethics Approval

This protocol is in line with the Declaration of Helsinki and has been approved by the Hospital Ethics Committee of The Sports Trauma Specialist Hospital of Yunnan Province (2018CK-001) in June 2018. The study has been registered in the Chinese Clinical Trial Registry (ChiCTR1800016947). This protocol is compliant with the principles of the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials; see Multimedia Appendix 1) and CONSORT (Consolidated Standards for Reporting Trials) guidelines [44]. The SPIRIT checklist is presented in Multimedia Appendix 1 and the schedule is shown in Table 1.

[b]BW: body weight.

[c]WC: waist circumference.

[d]HC: hip circumference.

[e]VAS: visual analogue scale.

[f]AE: adverse event.

Participants

Participants who meet all the following criteria will be included: (1) aged between 18 and 60 years with simple obesity; (2) BMI ≥28 kg/m^2 and waist circumference (WC) ≥90 cm for male participants and ≥85 cm for female participants; (3) agreed to participate in this study and signed written informed consent for this trial and catgut embedding therapy; and (4) did not participate in other trials within past 3 months. Participants will be excluded if they meet any one of the following criteria: (1) secondary obesity, such as obesity caused by endocrine disease (Cushing syndrome, thyroid disease, hypothalamic disease, pituitary disease, gonadal disease, etc) and medication (glucocorticoid or antipsychotics); (2) pregnancy, lactation, and childbirth within the past 6 months; (3) heart disease; hematopoietic system, liver, kidney, and other important organ diseases; and hypertension that is not effectively controlled; (4) severe mental and neurological diseases where the patient is unable or unwilling to cooperate; (5) allergy to alcohol and animal protein or immune diseases; and (6) received other weight loss treatment within the past 3 months.

Criteria for Elimination From the Study

Those who meet the following criteria should be eliminated from the study: (1) misdiagnosis and misrepresentation; (2) poor treatment tendency; (3) involvement with other treatments after being selected; and (4) participants' withdrawal before the first test recording.

Recruitment and Randomization

All participants with eligible AO will be recruited from the 4 hospitals and the community. Recruitment methods mainly include posters, public notice boards, and WeChat public numbers in hospitals and communities. The randomization sequence will be generated by the Clinical Research Center of Yunnan University of Chinese Medicine using a computerized random number generator and placed in opaque envelopes. Stratified randomization will be performed for the 4 clinical centers. To ensure allocation concealment, randomization will be performed by an independent researcher. The research assistant will open the envelope when the participant begins treatment to determine the assigned group and will not disclose grouping information under any circumstances. The acupuncture therapist will be responsible for manipulation only.

XSL•FO
RenderX

Blinding and Informed Consent

Participants will be informed that they have a 1 in 2 chance of being assigned to 1 of 2 treatments: catgut embedding at acupoints or nonacupoints. The procedure and stimulation of the catgut embedding at acupoints are identical to catgut embedding at nonacupoints. Therefore, participants will be blinded to their treatment assignment. Both groups of participants will be assigned to different treatment rooms to prevent intercommunication. In addition, the acupuncturist, outcome assessor, and those involved in data collection and statistics will be blinded to treatment assignment throughout the trial. Research assistants with knowledge of grouping information will be asked not to communicate with participants or outcome assessors regarding treatment procedures and responses. All patients will be fully informed about the study (including the purpose of the trial and possible risks, etc) prior to participation in the trial, and they have the right to withdraw from the trial at any time without giving a reason. They will sign a written informed consent for voluntary participation prior to enrollment.

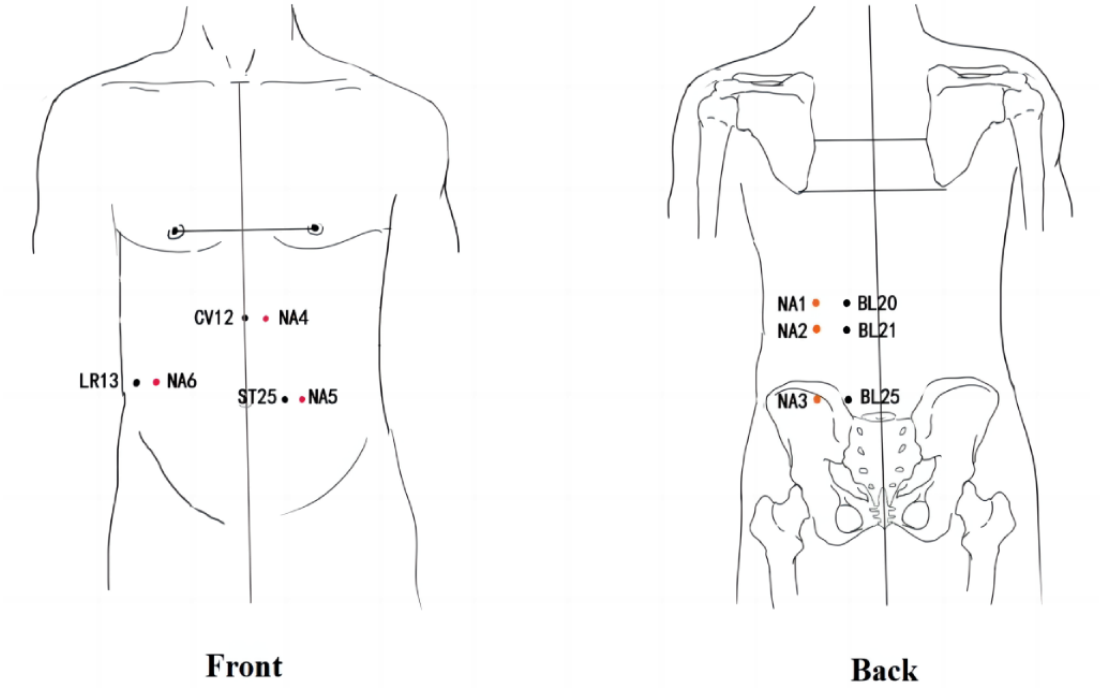
Sample Size Calculation

According to the existing literature [45], the mean BMI of simple obesity was 32.30 kg/m^2, whereas after 12 weeks and 6 treatment of acupuncture combined with a low-energy diet, the mean BMI was 30.98 kg/m^2, and the improvement value was 1.32 kg/m^2. In contrast, the improvement value was 1.02 kg/m^2 in a control group with a variation from 32.74 kg/m^2 to 31.73 kg/m^2 when treated by sham acupuncture combined with a low-energy diet, and the SD of the 2 groups was 0.31 kg/m^2. In this project, the expected improvement value of the mean BMI of the Shu-Mu acupoints embedding group after treatment is 1.14 kg/m^2 and that of the nonacupoints embedding group is 0.9 kg/m^2, with the SD of each group being 0.31 kg/m^2. The significant level is α=.05, and the power of a test is $1 - \beta = 0.95$. The sample size is 84 as calculated by German G*power software 3.1 [46]. According to the 10% dropout, the total sample is 92 cases, and 46 cases will be assigned to each group.

Interventions

All catgut embedding manipulations will be performed by an acupuncturist with national medical qualifications. The participants will receive treatment every 2 weeks for a total of 6 sessions.

ACE Group



The selection of acupoints for treatment in the ACE group will be based on the theory that obesity is closely related to the spleen, stomach, and large intestine in traditional Chinese medicine and the Shu-Mu acupoints allocation method commonly used in the current clinical treatment of obesity. The acupoint prescription includes BL20 (Pishu), BL21 (Weishu), BL25 (Dachangshu), RN12 (Zhongwan), ST25 (Tianshu), and LR13 (Zhangmen). All acupoints except Zhongwan are selected bilaterally, for a total of 11 acupoints. The locations of these acupoints are shown in Table 2 and Figure 2.

Table 2. The locations of acupoints.

Acupoints	Location
BL20 (Pishu)	In the upper back region, at the same level as the inferior border of the spinous process of the 11th thoracic vertebra (T11), 1.5 B-cun lateral to the posterior median line
BL21 (Weishu)	In the upper back region, at the same level as the inferior border of the spinous process of the 12th thoracic vertebra (T12), 1.5 B-cun lateral to the posterior median line
BL25 (Dachangshu)	In the lumbar region, at the same level as the inferior border of the spinous process of the fourth lumbar vertebra (L4), 1.5 B-cun lateral to the posterior median line
CV12 (Zhongwan)	On the upper abdomen, 4 B-cun superior to the center of the umbilicus, on the anterior median line
ST25 (Tianshu)	On the upper abdomen, 2 B-cun lateral to the center of the umbilicus
LR13 (Zhangmen)	On the lateral abdomen, inferior to the free extremity of the 11th rib

Figure 2. Locations of acupoints and nonacupoints (NAs). Acupoints: BL20: Pishu, BL21: Weishu, BL25: Dachangshu, CV12: Zhongwan, LR13: Zhangmen, and ST25: Tianshu.

Control Group

The acupoints in the control group will be selected based on the acupoints in the ACE group by moving each acupoint 2-3 cm outward horizontally in the median line (CV12 to the left side only) as a nonacupoints (not located on or overlapping with other meridians). They are labeled NA1, NA2, NA3, NA4, NA5, and NA6, respectively, for a total of 11 acupoints. The locations of these acupoints are shown in Table 3 and Figure 2, marked as red points.

Table 3. The location of nonacupoints (NAs).

Nonacupoint	Location
NA1	The sitting position of the patient, in alignment with BL20 and the midpoint of the first and second lateral line of the bladder channel
NA2	The sitting position of the patient, in alignment with BL21 and the midpoint of the first and second lateral line of the bladder channel
NA3	The sitting position of the patient, in alignment with BL25 and the midpoint of the first and second lateral line of the bladder channel
NA4	The supine position of the patient, in alignment with RN12 and the midpoint of the left kidney and stomach channel
NA5	The supine position of the patient, in alignment with ST25 and the midpoint of the stomach and spleen channel
NA6	The sitting position of the patient, in alignment with LR13; a vertical line is made from Zhangmen to the spleen channel and the midpoint of the vertical line

Operation Instruments

The thread-embedding needle used in this study is an 8# disposable needle (Jiangxi Glance Medical Equipment Co Ltd Production), and the medical protein string is an absorbable collagen line with the specification of 2-0, 2 cm × 20 length (Jiangxi Longteng Biotechnology Co, Ltd).

Manipulation

The specific manipulation is as follows: participants are instructed to be placed in an appropriate position; the separate research assistant marks the acupoints or nonacupoints and routinely disinfects the skin around them; and a sterile sheet is spread, leaving only the buried area. Then, acupuncturists, who are unaware of the group allocation, take a sterile protein cord 1-2 cm long (the length depends on the location of the acupoints), place it on the front end of the trocar, connect the needle core, lift the partial skin with the thumb and forefinger of one hand, and pierce the needle with the other hand. When the piercing reaches the desired depth, apply appropriate push-and-twist techniques, push the needle core and remove the needle tube, and implant the sterile protein string in the subcutaneous tissue or muscle layer of the acupoints. After removing the needle, press the needle hole with a dry cotton ball for half a minute to stop the bleeding. Meanwhile, check that there is no thread residue exposure and no bleeding and then paste a bandage to protect the needle hole. It will be

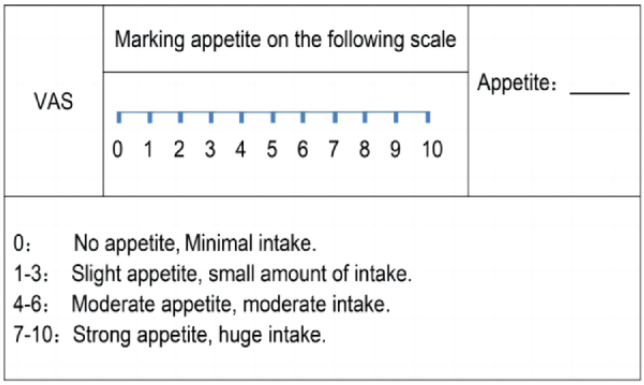
XSL•FO
RenderX

recommended that patients do not take a bath for 24 hours and keep the embedding place dry.

Outcomes and Assessment

Primary Outcome

The primary outcome is the change of WC every 2 weeks, from baseline to end points. To collect the measurements, participants will stand their body upright, feet at shoulder width. An inelastic, 1-mm minimal tapeline will be used, set on the midpoint between the upper border hipbone and lower border 12th rib of the right midaxillary line. At the end of normal exhalation, they will be measured around the abdomen in the horizontal direction and without pressing the skin. The WC will be measured in millimeters (mm) and accurate to 1 mm.



Secondary Outcomes

The following secondary outcomes will be assessed:

1. The change of body weight (BW) will be measured every 2 weeks, from baseline to end points. Participants will be fasting 2 hours before the assessment. Shoes will be taken off, and only light clothing should be worn in a warm room while standing upright in the middle of the calibrated scale. BW will be measured in kilograms (kg) and accurate to 10 g.
2. The change of BMI will be measured every 2 weeks, from baseline to end points: *BMI = BW (kg) ÷ height2 (m2)*. Height will be measured after the weight measurement, with the participants standing upright and close to the measuring stick. Height will be measured from the top of the head to the bottom of the feet in meters (m) and accurate to 1 mm.
3. The change of hip circumference (HC) will be measured every 2 weeks, from baseline to end points. HC is the circumference of the most prominent point of the pelvis. Participants will stand upright, feet at shoulder width. The circumference at the end of the normal exhalation will be measured in millimeters (mm) and accurate to 1 mm.
4. The visual analog scale (VAS) of appetite will be scored every 2 weeks, from baseline to end points. Appetite will be assessed by VAS as reported in Doucet et al [47] (see Figure 3): no appetite and minimal intake (score of 0), slight appetite and a small amount of intake (score of 1-3), moderate appetite and moderate intake (score of 4-6), and strong appetite and huge intake (7-10 score of 7-10).

All of the above measurements and evaluations will be performed by a separate researcher in the morning, with the patient coming to the hospital without eating breakfast.

Figure 3. The visual analogue scale (VAS) of appetite.

Safety Evaluation

Due to puncture injury and protein wire stimulation, participants may experience local sterile inflammatory reactions such as redness, swelling, fever, pain, or small amounts of exudate within 1-5 days, which are normal, generally do not require treatment, and are kept under close observation. If there is more exudate from the acupoints; localized redness; swelling; increased pain; increased temperature; or even protein line spillage, wound fat liquefaction, or nerve damage, treatment will be suspended when these adverse reactions occur. Participants will be treated aggressively until they have fully recovered and reported to the study center for evaluation by a medical professional to see if the trial can continue. Serious or unexpected adverse events will be verbally reported within 24 to 48 hours. All information will be classified as a safety event.

Data Management and Quality Control

The outcome evaluator will complete the initial data in the case report form and enter it into a Microsoft Excel spreadsheet. The protocol will be reviewed several times by an acupuncturist with the title of director and a statistical expert. To ensure the smooth conduct of the study, the study leader shall provide uniform training to all study personnel before the start of the study and provide detailed operational training on the project implementation protocol and observation indicators to familiarize them with the study process and specific implementation details to ensure the reliability of the study results. The project leader shall supervise and check the entire study process to confirm that all study data and case report forms are recorded and reported truthfully, accurately, completely, and consistently with the original data. Any deviation from the protocol will be reported to the ethics committee of The Sports Trauma Specialist Hospital of Yunnan Province, which will ultimately decide whether we must change the protocol or terminate the trial. To ensure participant compliance, all treatments and tests will be provided free of charge.

XSL•FO
RenderX

Statistical Analysis

All data will be analyzed by SPSS statistical software (version 19.0; IBM Corp). The clinical outcomes and baseline characteristics are based on the intention-to-treat population, which will include participants who have received at least one treatment. Continuous variables will be shown as the mean and SD, whereas the nonnormally distributed variables will be presented as the median and IQR. Categorical variables will be described as numbers and percentages. The normality of continuous variables will be determined using the Shapiro-Wilk test, Kolmogorov-Smirnov test, skewness, and kurtosis. The homogeneity of continuous variables will be determined by *F*-test, Brown-Forsythe, and Bartlett tests. Comparisons between groups will be made using independent samples 2-tailed *t* tests or nonparametric tests (Mann-Whitney *U* test). Repeated measures within groups (≥3) will be analyzed using one-way ANOVA or nonparametric (Friedman) tests. Paired 2-tailed *t* tests or nonparametric tests (Wilcoxon test) will be used for within-group pre-post comparisons. For categorical data, the chi-square test will be used to assess the significance of differences. Values of $P<.05$ will be considered significant using a 2-sided test.

Results

The start of recruitment began in August 2019 and is expected to end in September 2023.

Discussion

Expected Findings

In the past, obesity was considered a problem in high-income countries. However, recent studies reported that the prevalence of obesity is rapidly increasing in low- and middle-income countries [4,48-50]. As a type of obesity, AO is also related to cardiovascular diseases, cancer, and many other diseases [51-54].

ACE is a traditional Chinese medical practice that has been used in clinical practice since the mid-1960s. Compared with other treatments, ACE has the advantages of a short single-treatment time, long effective stimulation time, low impact on daily life, as well as being time-saving and low cost and having few side effects, which are well suited for the fast-paced modern society and become gradually favorable to patients who are obese. As a specific type of acupuncture therapy, ACE has gained substantial attention in the management of obesity in recent years. Research has demonstrated that ACE has a certain impact on obesity. First, it can reduce BW by regulating appetite and food intake. ACE stimulates specific acupoints, promoting the release of neurotransmitters and hormones to regulate feelings of hunger and satiety and ultimately reducing food intake [55]. Second, ACE can improve metabolic function. Studies have shown that acupoint stimulation can affect various physiological processes, including the endocrine, nervous, and immune systems, thus regulating energy and fat metabolism, improving insulin sensitivity, and enhancing blood lipid levels [41]. Additionally, ACE may also have positive effects on obesity by improving psychological well-being and sleep quality, among other factors [56]. However, current research has some limitations, including small sample sizes and inconsistent study designs [57]. Therefore, to better assess the effectiveness and safety of ACE treatment, further high-quality studies with larger sample sizes are needed.

The decrease of several indicators such as BW, WC, BMI, HC, and appetite is not only beneficial to personal health but also helps people who are obese to reshape their bodies [58]. Among them, BMI is the most commonly used indicator in obesity research, but it mainly reflects total body fat and cannot distinguish between fatty obesity and muscular obesity. HC is affected by both sex and age, and changes in abdominal fat cannot be accurately reflected promptly [59]. WC can directly reflect abdominal fat, so we use WC as the main outcome indicator and other related indicators as secondary outcome indicators. According to the classification adopted by the Chinese Medical Association of China in 2019, the inclusion criteria was set as WC ≥90 cm for male individuals and ≥85 cm for female individuals, rather than those of other Asian countries (WC ≥102 cm for male individuals and WC ≥88 cm for female individuals or WC ≥ 90cm for both male and female individuals) [6,60].

The combination of Shu and Mu acupoints is one of the classical methods of acupuncture and is mainly used in clinical practice to treat metabolic diseases of the viscera. According to the identification theory of traditional Chinese medicine, obesity is mainly caused by the dysfunction of the spleen, stomach, and large intestine, so we chose the Shu and Mu acupoints of these 3 internal organs as the treatment prescription. Our preliminary analysis of 175 obesity ACEs in the early stage also found that the existing high-frequency acupoints for obesity ACEs were mainly Shu and Mu acupoints of the spleen, stomach, and large intestine [61].

Strengths and Limitations

First, this study is a multicenter RCT designed to investigate the efficacy and safety of ACE in AO with a relatively long study period, and the results will provide powerful evidence for the clinical application of ACE in the treatment of obesity. Second, participants' diet and exercise will not be intervened, which will allow participants to maintain their original lifestyle habits throughout and maximize the efficacy of ACE. Finally, to maintain the success of the double-blind method, contact between participants from different groups will be avoided. The acupuncturist, data evaluator, and statistician will also be hidden from the group assignment, which will minimize possible bias in the results.

Limitations of this study are as follows. First, the relatively short follow-up period of this study may not be comprehensive enough to assess the durability of ACE efficacy. Second, the selection of nonacupuncture acupoints as an intervention in the control group in this study may inevitably produce some efficacy as well [62,63]. Third, only patients with AO are selected as the study population in this study, and further studies on different types of obesity will be conducted at a later stage.

XSL•FO
RenderX

Conclusions

In summary, our trial aims to investigate the difference in the effectiveness of catgut embedding at acupoints and catgut embedding at nonacupoints in patients with AO. This finding will provide reliable evidence to support whether ACE is an effective and safe treatment for AO.

Acknowledgments

All authors are grateful for the support of all participants or participants who will join the trial, as well as the support of other institutions.

This study is funded by Youth Special of Yunnan Province Ten-thousand Plan (YNWR-QNBJ-2019-257) from the Human Resources & Social Security Department of Yunnan Province; "Liang Fanrong Expert Workstation" of Yunnan Province—Yunnan Provincial Science and Technology Plan Project (202305AF150072); Yunnan Provincial Science Plan Project—Joint of Traditional Chinese Medicine (2019FF002-021) from the Science & Technology Department of Yunnan Province; and "Liu Zili Famous Doctor" special talent program of the Yunnan Provincial Xing Dian Talent Support Program (Yunnan Party Talent Office [2022] No. 18). The funding agencies do not play any role in the design, collection, analysis, or writing manuscripts of the study.

TG and XZ (doczhangxh@163.com) are cocorresponding authors for this manuscript.

Data Availability

The data sets generated or analyzed in this study will not be publicly available. Consent and ethical approval for this study do not include a provision for the sharing of data from this study.

Authors' Contributions

TG and XZ are the principal investigators and were primarily responsible for the conception and design of this study; QL and GH wrote the original manuscript; RY, ZL, XP, XT, RZ, and YH participated in the implementation of the study and acquisition of data; XZ was primarily responsible for the analysis of the data; and CX provided ethical approval. All authors contributed to the revision and approved the final manuscript.

Abstract

Background: There is a lack of studies on internet-based interventions in inpatient settings. This is especially true for studies of internet-based interventions in acute psychiatric inpatient care. Internet-based interventions in this specific setting may provide benefits such as patient empowerment and overall improved treatment outcomes. However, there may also be specific barriers to their implementation that are unique due to the complexity of acute psychiatric inpatient care.

Objective: The aim of this study is to examine the feasibility and preliminary evidence for effectiveness of a web-based emotion regulation intervention provided as an add-on to acute psychiatric inpatient care.

Methods: The goal is to randomly allocate 60 patients with a range of different diagnoses in a 1:1 ratio to either treatment as usual (TAU), which consists of acute psychiatric inpatient treatment, or to the intervention group, which will receive TAU plus access to a web-based intervention that focuses on reduction of emotion regulation difficulties and improvement of emotion regulation skills. The primary outcome is symptom severity, assessed with the short form of the Brief Symptom Inventory at baseline, after 4 weeks, after 8 weeks, and at hospital discharge. Secondary outcomes include 2 emotion regulation parameters, intervention use, usability, patient satisfaction, and reasons for patient loss to follow-up.

Results: Participant recruitment started in August 2021 and as of March 2023 was ongoing. First publication of study results is expected in 2024.

Conclusions: This study protocol describes a study that intends to examine a web-based emotion regulation intervention in acute psychiatric inpatient care. The study will provide information on the feasibility of the intervention and possible effects on symptom severity and emotion regulation. The results will provide new insights on blended treatment, in this case the combination of a web-based intervention and face-to-face psychiatric treatment, in an understudied patient group and setting.

Introduction

Internet interventions are efficacious and effective for treating various mental health disorders [1-3]. In recent years, the combination of internet intervention and face-to-face treatment (blended treatment [4,5]) has been examined. Several studies point to the efficacy and effectiveness of blended treatment approaches in the outpatient setting for patients with depression [6-9]. Studies have also been conducted on outpatient blended treatment for anxiety disorders [10] and substance dependence [11,12]. Moreover, blended treatments with a more explicit transdiagnostic focus have also been examined in the outpatient setting. Examples include a treatment for emotional disorders [13] and transdiagnostic treatments with an emotion regulation focus [14]. However, only a few studies on blended treatment have been conducted with adult inpatients.

Several studies have focused on web-based and mobile-based interventions as aftercare after an inpatient stay [15-20]. For example, 2 studies evaluated aftercare interventions for eating disorders [16,17]. The first found a therapist-guided smartphone-based intervention showed high acceptance rates but nonsignificant effects on BMI and eating disorder symptoms [16]. The second found that a web-based program for women with bulimia nervosa applied as aftercare led to a significantly lower frequency of vomiting episodes but no significant differences in abstinence rates compared to treatment as usual (TAU) [17]. Another study investigated the effect of a self-help smartphone app on self-esteem among inpatients with depression after discharge from a psychiatric hospital [15]. While there was no significant improvement in the primary outcome (self-esteem) or secondary outcomes (depressive symptoms and quality of life), there was a small positive effect on self-competence in favor of the intervention group. Schlicker et al [18] examined a text message–based maintenance intervention for depression and determined whether individualized messages would lead to better outcomes than standardized messages that target emotion regulation. The results of the study suggested that standardized messages with an emotion regulation focus led to a significantly smaller increase in depressive symptoms than a waitlist condition. This was not the case for the condition with the individualized messages.

Regarding transdiagnostic interventions applied as aftercare in samples with mixed diagnoses, a study by Ebert et al [19] examined an internet-based maintenance intervention after inpatient treatment and found the intervention to be more effective than TAU with regard to the long-term outcomes of inpatient psychotherapy. Furthermore, a study by Zwerenz et al [20] was able to show that a group that received a psychodynamic web-based intervention provided after inpatient psychotherapy had improved depressive symptoms, quality of life, and emotional competence compared to a waitlist control group. However, completion rates for the program were low.

Regarding internet interventions applied during an inpatient stay, a few studies have focused on the feasibility of these types of interventions. Dorow and colleagues [21] examined an internet-based self-management program for depression, focusing on user acceptance and chances and barriers from both the patient and medical expert perspectives. User acceptance was reported to be moderate to high. Experts mentioned some aspects to be relevant barriers, such as technical problems, the severity of the course of depression, and the ability of patients to concentrate. Patients mentioned positive aspects of the intervention, such as ease of use and flexible availability, but also negative aspects, such as the design and structure of the program. Schwarz and colleagues [22] examined the feasibility of a tool for depressive disorders in inpatient care. They reported feasibility of the intervention but also low use rates. Moreover, general attitudes toward and acceptance of internet interventions by mental health professionals working in psychiatric hospitals have also been examined [23,24]. For example, a study by Sander and colleagues [23] showed that participants had little experience or knowledge about internet-delivered interventions. Their attitudes toward these types of interventions in inpatient care were indifferent. Participants mentioned benefits, such as optimized treatment structure and patient empowerment. They also mentioned anticipated barriers, such as patient symptom severity and insufficient technical equipment.

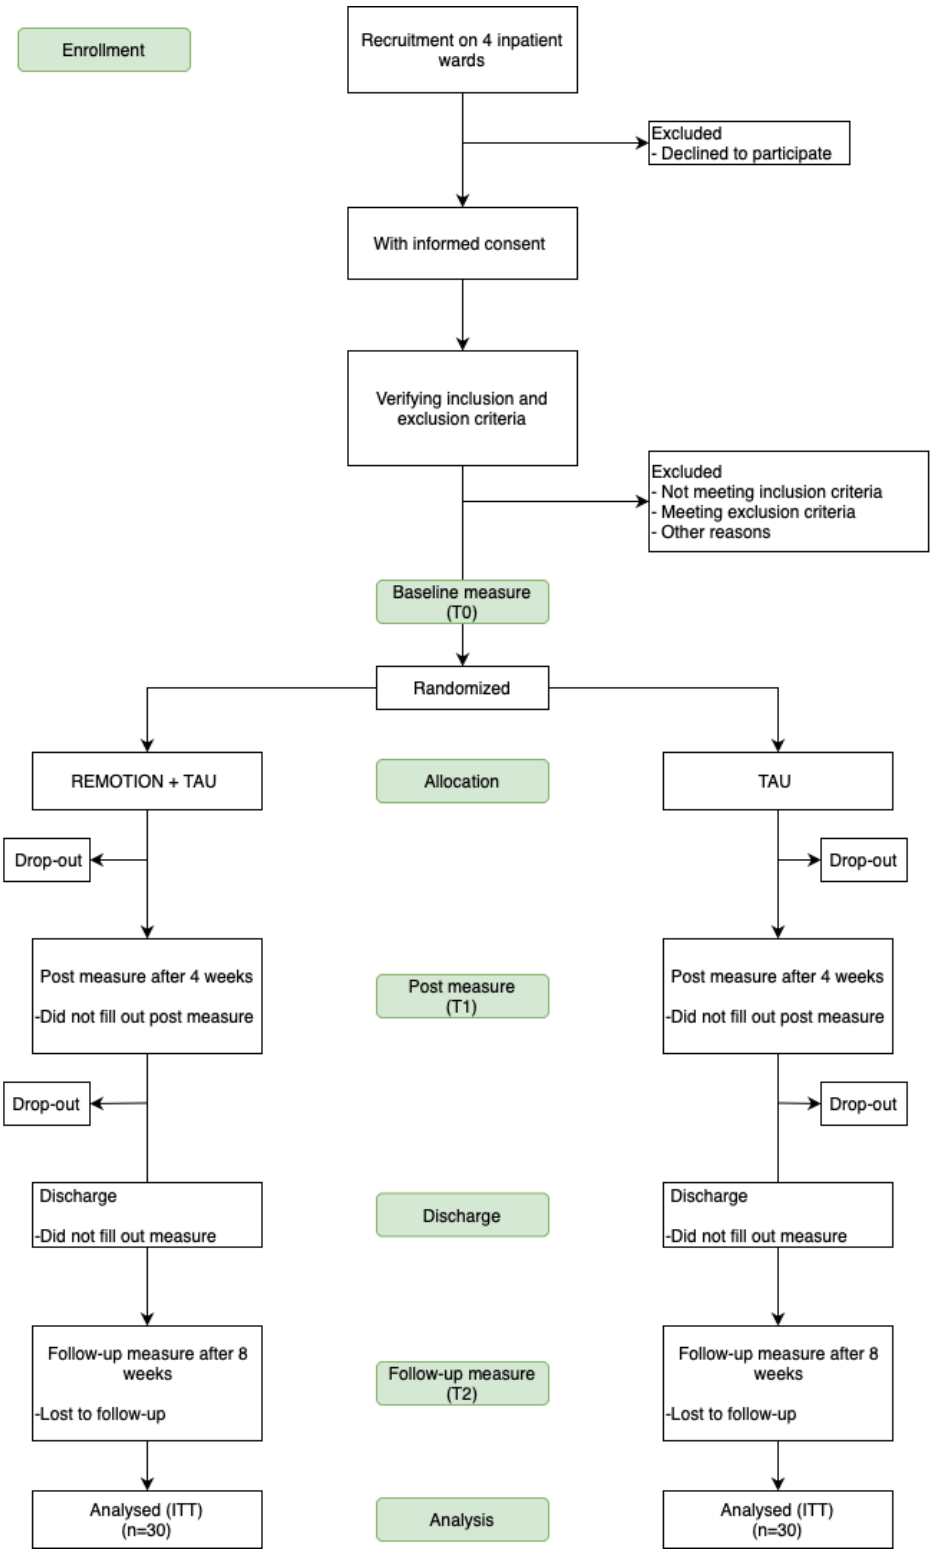
Even fewer studies have focused on the effectiveness of internet interventions during inpatient treatment. Zwerenz and colleagues [25,26] examined an internet intervention in an inpatient setting where patients with depression received the self-guided program as an addition to psychodynamic psychotherapy. The study showed a positive effect of the intervention (inpatient stay plus access to the internet intervention) on depressive symptoms with small to medium effect size at the end of the intervention (d=0.44) [25] and a medium effect size (d=0.58) at a follow-up assessment compared to an active control group [26]. Richter and colleagues [27] examined the same program that was investigated by Zwerenz and colleagues [25,26] but in a routine psychiatric inpatient setting with guidance added for the program. They found a medium-sized effect (d=–0.73) in favor of the intervention group, which received TAU plus access to the guided internet intervention, compared to the TAU group at the 12-week assessment timepoint and earlier discharge for patients who received access to the internet intervention compared to patients in the TAU condition. Finally, Bendig and colleagues [28] examined the feasibility of blended group training for social skills in inpatient acute psychiatric care. The blended treatment lasted 4 weeks and consisted of 4 face-to-face group sessions and 3 online modules. In the 1-group trial without a control group, the effect on social skills was not statistically significant, but the blended group training was deemed feasible for use in an acute inpatient setting.

Implementing an internet intervention in an acute psychiatric inpatient setting may offer benefits. On the one hand, the addition of an internet intervention to standard care or TAU may improve overall treatment effects, as has been demonstrated previously in outpatients and in studies focusing on inpatient treatment [6,25-27]. An internet intervention may thus provide a useful complement to treatment, one that is easily accessible during the inpatient stay, where patients may have idle timeslots during the treatment program. The few studies on an internet intervention in acute or routine psychiatric inpatient settings point toward the feasibility of such interventions [27,28].

XSL•FO
RenderX

However, implementing an internet intervention in acute psychiatric care may also come with specific barriers and complexities. Individuals in acute psychiatric inpatient care often enter treatment in acute crisis with severe disorders and with one or more comorbidities. A recent study by Becker and colleagues [29] showed that the number of diagnoses and symptom severity were associated with active or inactive participation in an online intervention during and after inpatient and day-clinic psychotherapeutic treatment. A lack of motivation due to symptom severity was also a reason for patients to decline participation in an inpatient study on e–mental health implementation by Van Assche et al [30]. According to Wentzel and colleagues [31], crisis risk and psychosocial problems are important factors to consider for a fit for blended treatment. Moreover, stays in acute wards are nowadays often short [28], and during this time, inpatients may already be saturated with other treatment components (eg, medication, psychotherapy, ergotherapy, and physiotherapy), making it difficult for patients to focus on an additional internet intervention. Wentzel and colleagues [31] also mention that having a private place to work is an important condition for blended treatment. This may not be available in an acute inpatient ward. Finally, all the different stakeholders involved in acute inpatient treatment may also make the implementation of such an intervention more complex [28].

The aim of this randomized controlled pilot trial is to investigate an internet-based intervention in acute psychiatric inpatient care. To this end, a web-based emotion regulation intervention (REMOTION; an acronym for “Regulate Emotion”) will be provided as an add-on to acute inpatient treatment in public psychiatric care at a university hospital. Different feasibility parameters will be recorded, including specific intervention parameters, such as use of the program and adherence, usability, satisfaction with the intervention, and reasons for patient loss to follow-up. Effects of the intervention will be assessed by comparing patients that receive access to REMOTION in addition to TAU to patients who receive TAU only on general symptom severity and emotion regulation difficulties and skills.



Methods

Study Design

Sixty patients will be randomized in a 1:1 ratio to 2 trial arms: REMOTION plus TAU and TAU alone. Assessments will take place at baseline, after 4 weeks, after 8 weeks, and after discharge from inpatient stay (Figure 1). Assessments will take place irrespective of inpatient stay duration. The planned duration of the study is approximately 2 years, to reach 60 individuals. Since external validity and the generalizability of the results to acute inpatient care settings play an important role, the inclusion and exclusion criteria are broadly defined.

XSL•FO
RenderX

Figure 1. Planned study flow. Discharge can take place at any time after randomization. ITT: intention to treat; TAU: treatment as usual.

Setting

The setting for the study is the acute inpatient psychiatric wards at the University Hospital of Psychiatry and Psychotherapy, Bern, Switzerland. The University Hospital of Psychiatry and Psychotherapy is part of the Universitäre Psychiatrische Dienste (UPD), Bern. The UPD guarantees psychiatric care in the Bern region, including adult and geriatric psychiatry, as well as child and adolescent psychiatry for the entire canton [32]. The University Hospital of Psychiatry and Psychotherapy treats patients with a variety of mental health diagnoses. For the study, patients are recruited from 4 different acute inpatient wards at the University Hospital of Psychiatry and Psychotherapy.

Sample Size

Based on recommendations in the literature [33], the aim is to recruit a minimum of 30 participants per group during the trial.

XSL•FO
RenderX

No power analysis is performed, as is commonly the case with randomized controlled pilot trials.

Eligibility Criteria

To take part in the study, patients should fulfill the following criteria: (1) be older than 18 years, (2) be in acute inpatient treatment, (3) have access to the internet, and (4) provide written informed consent. The exclusion criteria include (1) participation in another specific intervention for emotion regulation; (2) a current episode or a history of psychotic disorders or bipolar disorder, intellectual disability, or organic mental disorders; (3) acute suicidality; and (4) not being fluent in German.

Procedure

After consultation with the individual ward team at the weekly interdisciplinary ward meeting, individual patients are asked about study participation. Information on the study is provided and patients are asked if they would like to participate. Once written informed consent is provided, the inclusion and exclusion criteria are checked. Eligible patients are asked to complete the baseline questionnaires online. This takes approximately 15 to 20 minutes. Randomization occurs after baseline assessment. A computerized randomization procedure concealed from the study team is used to randomize patients. Patients randomized to the intervention group receive immediate access to REMOTION. Patients in TAU are informed that they can have access after the 8-week assessment, per request. There is no blinding implemented in the study. During the study period, the ward staff is informed about a patient's designated trial arm. Patients receive a reminder to work on the program, either face-to-face from the study team if still on the ward or by telephone or email if discharge has already occurred, once a week for 4 weeks. For individuals who fail to complete follow-up assessments, interviews on reasons for loss to follow-up will be performed via telephone. Prior to study initiation, all 4 acute ward teams are informed in detail about the study, including the provision of a 1-hour workshop on the REMOTION intervention for each ward.

Interventions

Control Group (TAU)

The active control group in this study receives TAU, comprising acute psychiatric inpatient treatment at the University Hospital of Psychiatry and Psychotherapy. This treatment consists of integrative, psychiatric-psychotherapeutic treatment. Depending on the individual conditions, it includes pharmacotherapy informed by current guidelines and adapted to individual needs, psychotherapy, contact with psychiatric nursing, specialist therapies such as occupational therapy or music therapy, and contact with social workers. The ward teams are informed not to talk about REMOTION content with patients in the control group. Individuals in the control group receive access to the intervention on request after the 8-week mark.

Intervention Group (REMOTION and TAU)

Patients in the intervention arm are given access to REMOTION in addition to TAU on the acute inpatient ward. The web-based intervention REMOTION was developed at the University of Bern by authors LLB and TB with input from author FM. It is structurally based on the extended process model (EPM) of emotion regulation [34]. It is currently also being examined as an add-on to outpatient psychotherapy in a different study [35] and is being examined in a large, randomized, controlled, 3-armed outpatient trial in Germany that focuses on effectiveness [36]. It has never been examined in an inpatient setting up to this point. The intervention contains an introduction module and 5 further modules: psychoeducation, identification, selection, implementation, and monitoring/flexibility [35]. The intervention's aim is to reduce symptom severity and improve patient emotion regulation. As such, it does not target specific mental health disorders but is meant to be applied transdiagnostically, across disorders. Such an intervention may be of particular interest for inpatient populations, where comorbidity is likely highly prevalent [37]. A full overview of the intervention content for each module can be found in Table 1 and has also been published in 2 previous publications [35,36]. REMOTION is only available in German. The intervention runs on a server from the University of Bern and access is strictly password protected. Individuals in the intervention group immediately receive access to REMOTION and are asked to work on content for 4 weeks (1 to 2 modules a week). The study team reminds patients to work on the content once a week face-to-face if patients are still on the ward or by telephone or email if already discharged. Patients on the 4 wards have access to their smartphones, laptops, and tablets during their inpatient stay. Moreover, each ward is equipped with a ward computer that patients can use to engage with the program throughout their stay, if desired.

Table 1. REMOTION modules and content. Note that this entire textbox is adapted from tables already published in previous publications by Bielinski et al [35] and Trimpop et al [36], which are published under Creative Commons Attribution 4.0 International License [38].

Module	Content of module
Introduction	This module provides information on the content of the intervention and instructs patients on how to use the intervention.
Psychoeducation	This module provides psychoeducational content on emotions, their function, and types of emotional experience. It also introduces the concept of emotion regulation and its relationship to mental illness.
Identification	Emotional awareness (the perception substep of the identification stage of emotion regulation [34]) is explored in this module. The value of emotion regulation and information on if and when to regulate emotions is provided in this module.
Selection	In the selection module, patients learn about the types of emotion regulation strategies that are available. Situation selection or modification, attentional deployment, change of cognition, and response modulation are introduced to patients [39]. Furthermore, strategies specific to over- and underregulated states [40-42] are described.
Implementation	In the implementation module, patients learn how the strategies from the previous module can be implemented. Exercises are introduced for every emotion regulation strategy, and application of strategies in daily life is discussed.
Monitoring/flexibility	In the monitoring/flexibility module, patients are motivated to flexibly use emotion regulation strategies. Modifying strategies, maintaining, switching, and stopping [34,43] are discussed. Patients are encouraged to apply strategies to different contexts, to practice, and to try sequences or blends of strategies.

Measures

Overview

All measures will be assessed via the internet, except for patient diagnoses at intake and medication at discharge, which will be retrieved from the hospital's patient records. Interviews with patients will be conducted via telephone, and interviews with ward teams will be conducted face-to-face or via telephone. At baseline assessment, several demographic and other items will be assessed. These include questions on age, gender, nationality, mother tongue, highest degree of education, employment status, civil status, household size and composition, income, previous inpatient stays, previous experience with emotion regulation interventions, current involvement in an emotion regulation intervention, current involvement in other online therapy interventions, and frequency of use of online media. Study feasibility parameters, such as number of individuals approached for written informed consent, number of individuals with written informed consent, number randomized, and number of patients who completed all questionnaires, will be recorded for the study flow and presented in the main outcome paper to inform other institutions on the feasibility of the study design.

Primary Outcome Measure

The short version of the Brief Symptom Inventory (BSI-18) [44-46] is used to assess the primary outcome: general symptom severity. The BSI-18 contains the Global Severity Index (GSI), including all 18 items, as well as the three 6-item scales Somatization, Depression, and Anxiety [45]. The internal consistency is considered good for all 4 scales: Somatization (α=.82), Depression (α=.87), Anxiety (α=.84), and GSI (α=.93) [45]. The items are assessed on a 5-point Likert scale ranging from 0="not at all" to 4="very strong." The BSI-18 is presented to patients at baseline assessment, after 4 weeks, at discharge, and after 8 weeks.

Secondary Outcome Measures

Emotion Regulation

Emotion regulation is assessed with 2 different questionnaires at baseline, after 4 weeks, after 8 weeks, and at discharge. One of the two questionnaires is the Emotion Regulation Skills Questionnaire (Fragebogen zur standardisierten Selbsteinschätzung emotionaler Kompetenzen; SEK-27) [47]. The questionnaire assesses emotional skills and includes a total of 27 items. The items are assessed on a 5-point Likert scale ranging from 0="not at all" to 4="almost always." Studies have found good reliability and validity for the German and English versions of the questionnaire [48,49]. The Cronbach α is between .68 and .81 for the subscales and .90 for the total scale [47].

The second questionnaire is the Difficulties in Emotion Regulation Questionnaire (DERS) [50]; the study uses the German version by Ehring et al [51]. The DERS was developed to assess emotion regulation difficulties. It includes 6 subscales: lack of emotional awareness (Awareness), lack of emotional clarity (Clarity), nonacceptance of emotional responses (Nonacceptance), limited access to emotion regulation strategies (Strategies), difficulties engaging in goal-directed behaviors (Goals), and impulse control difficulties (Impulse) [50]. These subscales and the overall DERS score have high internal consistency (α=.93) [50].

System Usability

The System Usability Scale (SUS) is a 10-item scale giving a global view of subjective assessments of system usability [52]. The questionnaire asks users to rate their level of agreement with statements covering a range of usability characteristics, such as the complexity of the system and any support or training participants feel they need to use the system effectively. The evaluation of the questionnaire results in a usability score in the range of 0 to 100. Values greater than 68 typically indicate good usability [53]. The questionnaire will be provided to individuals in the intervention group after 4 weeks, after 8 weeks, and at discharge.

Patient Satisfaction

Patient satisfaction will be assessed with the Client Satisfaction Questionnaire (CSQ-8 [54]; the German version is the Fragebogen zur Patientenzufriedenheit; ZUF-8 [55]). Eight items are used to measure general satisfaction with aspects of the treatment received. The CSQ-8 is suitable for economic

XSL•FO
RenderX

screening of patient satisfaction The CSQ-8 consists of 8 items that are formulated as questions; each has 4 predefined answer options without a neutral position (eg, excellent, good, less good, and poor) [55]. The CSQ-8 proves to be a reliable (Cronbach α=.90) 1-dimensional scale [56] and has validity regarding detailed quality assessment of the service and treatment outcome [56]. For this study, the CSQ-8 was adapted for an internet intervention (as has been done in previous studies [57,58]). The questionnaire will be provided to individuals in the intervention group after 4 weeks, after 8 weeks, and at discharge.

Program Use

Program use will be assessed by number of modules completed at 4 weeks and 8 weeks, number of exercises completed at 4 weeks and 8 weeks, and time spent in the program at 4 weeks and 8 weeks. These use parameters will be assessed for the intervention arm only.

Interviews With Patients Lost to Follow-Up

Telephone interviews are conducted with patients who are lost to follow-up. The purpose is to explore reasons why patients have not continued with the intervention and have not completed the questionnaires. The authors designed questions specific to the study. Interviews with patients lost to follow-up will be conducted by phone and audio recorded.

Other Measures

Interviews With Acute Inpatient Ward Staff

During the study, interviews with staff members from 3 of the 4 acute ward teams will be conducted. These interviews will occur at the earliest a few months after study commencement for teams to have sufficient experience with the intervention. Purposive sampling will be applied. A minimum of 1 member of the following stakeholder groups per ward will be interviewed: physicians, psychologists, and nurses, and if applicable, social workers and other stakeholder groups. Ward staff will provide written informed consent, fill out a short demographic data questionnaire, and be interviewed using a semistructured interview developed specifically for the study. Interview questions focus on expectations and attitudes toward blended treatment in acute inpatient care, specific experiences with the web-based intervention examined in this study, and the implementation of internet-based interventions in acute inpatient care. The analyses of these interviews will be published in a separate publication to the main outcome publication.

Planned Analysis

Feasibility parameters (use, usability, and patient satisfaction) will be analyzed descriptively. Means, SD, and CIs will be reported for continuous data and counts or percentages will be reported for nominal data. The recorded interviews of patients lost to follow-up will be transcribed according to rules specified by Dresing and Pehl [59]. Patient interviews will then be analyzed with a content analysis approach [60]. The focus will be on the coding process to build categories where similarities and differences between patients will be explored [60]. MAXQDA (2022 version; VERBI Software) will be used for the analysis.

To examine the effects of the intervention, means and SDs for the primary and secondary outcomes will be reported at baseline (T0), at the end of the intervention (4 weeks; T1), at inpatient discharge, and at follow-up after 8 weeks (T2). Within- and between-groups effect sizes will be calculated using guidelines specified by Cohen [61].

Data will also be examined using inferential statistics. An intention-to-treat approach will be used. All patients who were initially assigned after randomization will be included. In a first step, baseline differences between the intervention group and the control group will be examined for all relevant variables. For metric variables, this is done using a 2-tailed *t* test for independent samples. For nominally scaled data, the chi-square test is used. In case of meaningful differences, those variables will be included in further analyses and controlled accordingly. In a second step, mixed models with “group” as the between-group factor and “time” as the within-group factor will be used to examine differences between groups. In a first analysis, a model including the study timepoints (eg, baseline, after 4 weeks, and after 8 weeks) will be calculated. In addition, an analysis including the discharge timepoint in the model will also be calculated. Specifically, the interaction between time and group will be of interest. The significance level is set at 5%.

Interviews with ward staff members will be audio-recorded and then transcribed using the guidelines specified by Dresing and Pehl [59]. Transcripts will be analyzed using thematic analysis [62] to examine ward staff experiences with the REMOTION intervention. MAXQDA software will be used for the analysis.

All quantitative analyses will be performed with the most current versions of R (R Core Team) and SPSS (IBM Corp).

Ethical Considerations

The study has been approved by the Ethics Committee of the Canton of Bern, Switzerland (2020-01139). Informed consent is obtained from all participants. The trial is registered with clinicaltrials.gov (NCT04990674). The study will be conducted according to local regulations and the Declaration of Helsinki. The CONSORT-EHEALTH (Consolidated Standards of Reporting Trials for e-Health) [63] checklist will be followed in reporting the trial. Participants receive no compensation for taking part in the trial.

Results

Recruitment for the study started in August 2021. As of March 2023, it was still ongoing. Results for the study are expected in 2024.

Discussion

Expected Findings

While a few trials on blended treatment in inpatient care exist, patients in the acute psychiatric inpatient setting are understudied, and there is a need for the examination and evaluation of internet-based interventions in this specific setting. This randomized controlled pilot trial explores a web-based emotion regulation intervention in this treatment setting. The

XSL•FO
RenderX

study is designed to obtain information on the feasibility of the intervention. It is also designed to provide estimates of the effectiveness concerning reduction of symptom severity and improvement of emotion regulation. The study will inform future trials on blended treatment (ie, the combination of internet-based interventions with face-to-face treatment) in acute psychiatric inpatient care and thus provide evidence on the potential added value of a web-based intervention in this specific setting.

Limitations

This is a randomized controlled pilot trial, and the targeted sample size is small. All estimations of possible effects on symptom severity and emotion regulation are thus preliminary only. The focus of the study lies with feasibility. As there are only a few studies on internet interventions in acute psychiatric care, the study is inherently exploratory. Several components of the specific acute psychiatric inpatient care setting may be challenging for study feasibility: recruitment of more severely impaired patients, fast turnaround on wards, the possibility of conversations between patients from different trial conditions on one ward, and multiple stakeholders being involved in treatment. We have tried to consider these factors by providing an adequate study duration; informing ward staff in detail about the study prior to commencement, including the fact that the TAU group should not receive information on REMOTION content; and by incorporating weekly reminders to work on the intervention, even if patients have been discharged.

Conclusion

This randomized controlled pilot study is the first to examine a web-based emotion regulation intervention, REMOTION, in acute psychiatric inpatient care at a public university hospital. This type of blended treatment is grossly understudied. The results of the study will provide information on the potential added value of such an intervention for patients with severe mental health disorders in acute psychiatric care.

Acknowledgments

We would like to thank all the patients and all the inpatient ward teams for taking part in the study. We would like to thank Anna Lange, Lena Demel, Elianne von Känel, Raël Brechbühler, Jessica Duschén, and Milena Fischer for their support of the recruitment process. This study is funded by the University Hospital of Psychiatry and Psychotherapy, Bern, Switzerland, and by the Department of Clinical Psychology and Psychotherapy, University of Bern. Open access funding was provided by the University of Bern and swissuniversities.

Data Availability

The data sets generated and analyzed during the study described in this protocol will be available from the corresponding author on reasonable request.

Authors' Contributions

LLB and GW drafted the first version of the manuscript. FM, TB and CN provided critical revision of further drafts of the manuscript. LLB, FM, TB and CN contributed to conceptualization of the study. FM is the principal investigator of the study.

Conflicts of Interest

CN is a member of the advisory boards of Idorsia and Lundbeck. The other authors have no conflicts of interest to declare.

Abstract

Background: Cancer continues to be the leading cause of mortality in high-income countries, necessitating the development of more precise and effective treatment modalities. Immunotherapy, specifically adoptive cell transfer of T cell receptor (TCR)-engineered T cells (TCR-T therapy), has shown promise in engaging the immune system for cancer treatment. One of the biggest challenges in the development of TCR-T therapies is the proper prediction of the pairing between TCRs and peptide-human leukocyte antigen (pHLAs). Modern computational immunology, using artificial intelligence (AI)-based platforms, provides the means to optimize the speed and accuracy of TCR screening and discovery.

Objective: This study proposes an observational clinical trial protocol to collect patient samples and generate a database of pHLA:TCR sequences to aid the development of an AI-based platform for efficient selection of specific TCRs.

Methods: The multicenter observational study, involving 8 participating hospitals, aims to enroll patients diagnosed with stage II, III, or IV colorectal cancer adenocarcinoma.

Results: Patient recruitment has recently been completed, with 100 participants enrolled. Primary tumor tissue and peripheral blood samples have been obtained, and peripheral blood mononuclear cells have been isolated and cryopreserved. Nucleic acid

XSL•FO
RenderX

extraction (DNA and RNA) has been performed in 86 cases. Additionally, 57 samples underwent whole exome sequencing to determine the presence of somatic mutations and RNA sequencing for gene expression profiling.

Conclusions: The results of this study may have a significant impact on the treatment of patients with colorectal cancer. The comprehensive database of pHLA:TCR sequences generated through this observational clinical trial will facilitate the development of the AI-based platform for TCR selection. The results obtained thus far demonstrate successful patient recruitment and sample collection, laying the foundation for further analysis and the development of an innovative tool to expedite and enhance TCR selection for precision cancer treatments.

Introduction

Overview

Cancer has been recognized as a leading cause of death in high-income countries [1]. Currently, cancer treatment is based on 1 of the 3 available modalities: surgery, radiotherapy, and/or chemotherapy. However, recent research advancements in the field of cancer molecular biology have contributed to the development of novel tumor treatment approaches, such as targeted therapies and immunotherapies [2].

Immunotherapy uses the immune system against cancer cells by using monoclonal antibodies, tumor vaccines, or adoptive cell transfer (ACT). In 2013, immunotherapy was announced as the breakthrough technology of the year by the prestigious journal *Science*, while in 2018, two immunologists, James P Allison and Tasuku Honjo, were awarded the Nobel Prize in Medicine and Physiology for the discovery of the so-called immune checkpoints: programmed death receptor 1 and cytotoxic T cell antigen 4 [3,4]. They have shown that antibodies blocking these receptors, known as immune checkpoint inhibitors, cause reactivation of T cells, thus allowing them to attack and eradicate cancer cells. The first immune checkpoint inhibitor (ipilimumab) was approved by the US Food and Drug Administration (FDA) in 2011 to treat metastatic melanoma [5]. Recognition of immunotherapy as a cancer treatment modality paved the way for further studies and the development of other immunotherapeutic strategies.

Advancements in ACT for Cancer Treatment

ACT is a type of immunotherapy where tumor-reactive immunocytes are infused into a patient with cancer to eradicate tumor cells and maintain durable immune responses. To date, T lymphocytes are the most commonly used immune cells in ACT. T cells are responsible for a specific recognition of tumor neoantigens and subsequent destruction of malignant cells. The idea that tumor-reactive T cells can be used for cancer treatment evolved from early studies in 1991 by van der Bruggen et al [6] who showed that melanoma cells express antigens presented by the human leukocyte antigen (HLA)-A1 molecule and are specifically recognized by cytotoxic T cells. Importantly, the authors underlined that the presented antigen was not found in the panel of healthy tissues, which raised the possibility of the development of a targeted immunotherapy for patients with melanoma. Further studies and the subsequent discovery of tumor antigens, such as melanoma antigen recognized by T-cells 1 (MART-1), glycoprotein 100, or New York esophageal squamous cell carcinoma 1 (NY-ESO-1), proved that T cells are able to specifically recognize tumor antigens [7].

Initially, ACT treatment was based on tumor-infiltrating lymphocytes (TILs) that were isolated from the tumor lesion and expanded in vitro. However, one of the major limitations of this approach was associated with the fact that it only applied to resectable tumors and to tumors that were infiltrated by T cells. Furthermore, ex vivo expansion of TILs was proven to be problematic and time-consuming [8,9]. To bypass these limitations, an approach using blood-derived T cells, engineered ex vivo to recognize tumor antigens and then infused back into the patient, was introduced as an alternative.

Chimeric Antigen Receptor and T Cell Receptor T Cells

Currently, there are 2 main approaches to retarget T cells: chimeric antigen receptor (CAR)- and T cell receptor (TCR)-based. Despite the fact that both approaches involve redirecting T cell specificity, their mechanisms of action are different.

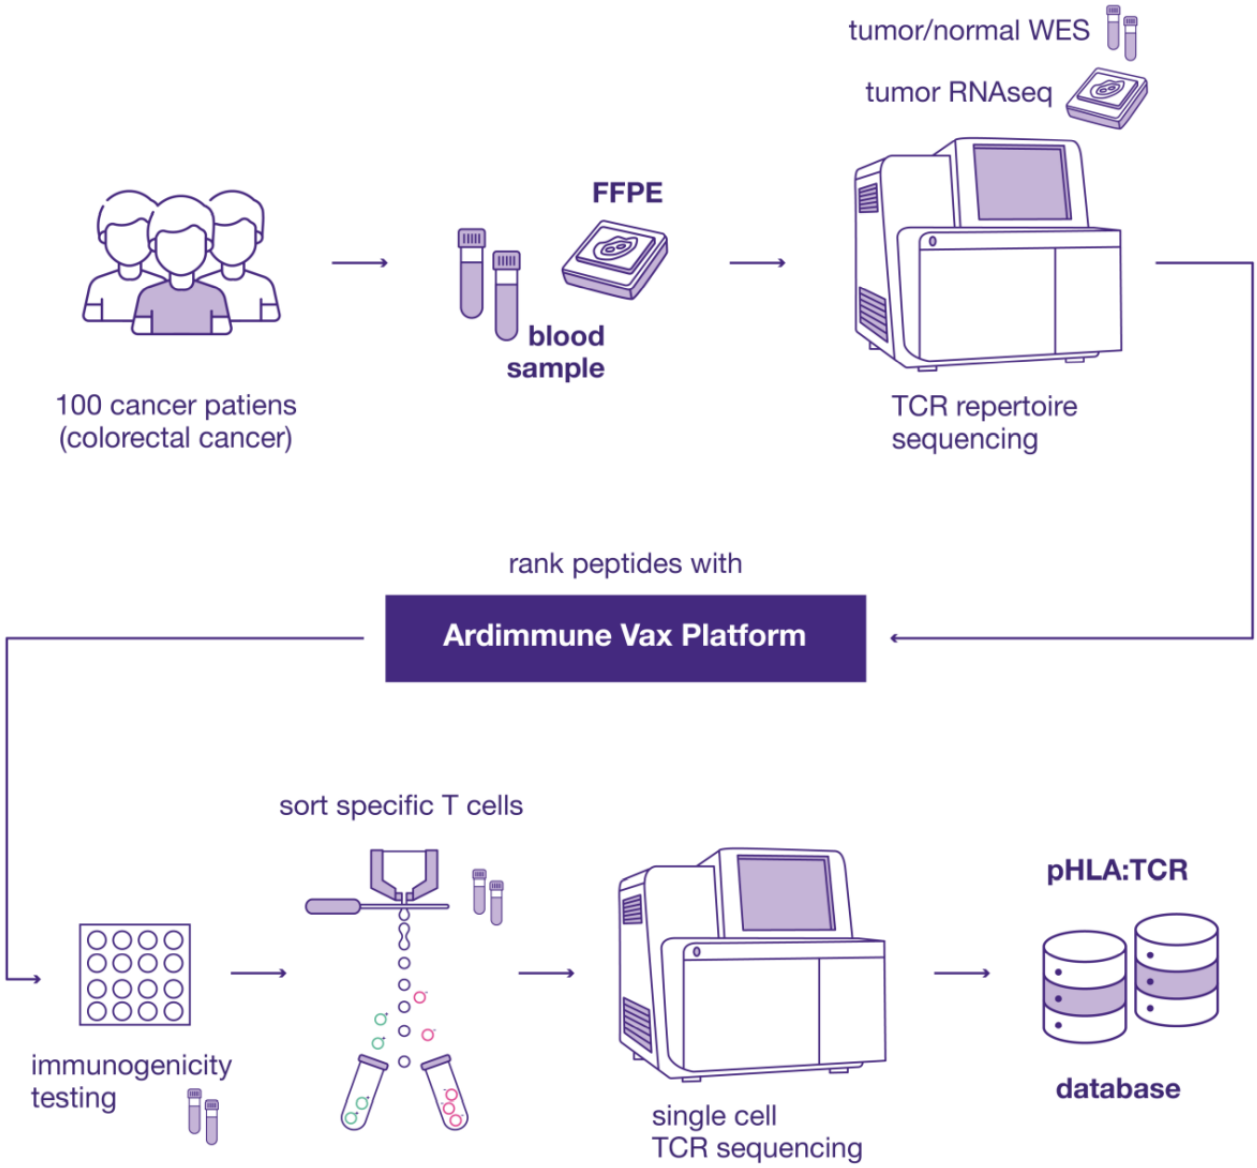
CAR-T cells use a single-chain fragment variable from monoclonal antibodies to specifically recognize tumor antigens that are expressed on the cell surface [10]. Spectacular results were achieved when CAR-T cells were used against the cluster of differentiation (CD) 19 molecule, leading to a complete remission in many patients with B-cell acute lymphoblastic lymphoma (B-ALL). This resulted in the first FDA-approved genetically engineered cell therapy in 2017 [11].

On the other hand, TCR-based technology uses heterodimers of α and β chains that recognize peptides in the context of HLA. The major advantage of this technology over CAR-T cells is that TCRs recognize intracellular antigens that are presented by major histocompatibility complex molecules [10,12]. In 2006, Morgan et al [13] demonstrated that ACT treatment using autologous TCR-engineered T cells (TCR-T) to specifically recognize the MART-1 antigen mediated a durable regression of metastatic melanoma lesions. Similarly, phase I and II clinical trials with TCR-engineered autologous lymphocytes

XSL•FO
RenderX

reprogramed to express high-affinity TCR against NY-ESO-1 and L-antigen 1, cancer-testis antigens, showed clinical response in 80% of patients with advanced myeloma with 70% demonstrating a complete response to the treatment [14]. These results not only showed that autologous T cells can be redirected by introducing TCR with defined specificity and affinity against tumor antigens, but also provided hope for the treatment of incurable metastatic disease. Despite the promising results, TCR-based technology faces several drawbacks associated with (1) finding a good antigenic peptide presented by HLA, (2) screening for a TCR that binds a given peptide-human leukocyte antigen (pHLA), (3) optimizing affinity and avidity of the pHLA:TCR complex, and (4) performing safety evaluations, all of which require extensive laboratory work. This is why a search for artificial intelligence (AI) models to address these issues has been gaining substantial interest in the past few years.

TCR-T Therapy With a pHLA:TCR Database



The use of AI in medicine has been gaining momentum in recent years. There have been successful attempts at applying AI in clinical histopathology [15,16], mammogram analysis [17], and immuno-oncological studies involving checkpoint inhibitors [18]. Furthermore, recent studies have shown that deep learning can be successfully applied for the prediction of TCR-peptide binding specificity [19-21] at least for some of the possible validation scenarios (eg, the scenarios single peptide binding, TCR peptide pairing-I to TCR peptide pairing-III [20]), with the general problem (predictions for pHLA complexes and TCRs unseen by the AI models during training) being still challenging for the current methods [21].

In TCR-T cell therapies, a reliable approach for predicting pHLA:TCR binding is of great importance although it presents challenges, which should be properly addressed. One of the major obstacles concerns the data available in the public domain to train such models, which is often limited or incomplete. In many cases, these data describe only 1 chain, mainly the β chain of TCR, while data on the α chain are missing. This is a major drawback to screening for antigen-binding TCRs, since the complementarity determining region 3 loops sequences of both α and β chains determine the TCR binding specificity [20]. It is important to emphasize that currently, there are no available solutions that allow for in silico predictions of TCR sequences binding a specific, novel peptide in the context of HLA. The algorithms that are used for TCR sequencing data analysis do not provide data regarding matched pHLA complexes. Similarly, bioinformatics tools for the prediction of TCR antigen binding for human TCRs offer results for a limited number of known epitopes. Additionally, the evaluation of possible toxicities associated with TCRs requires extensive and expansive in vitro experiments.

Herein, we present the study protocol for collecting patient material necessary to build a pHLA:TCR database for training and validating AI technology that can be used for screening and optimizing TCRs for TCR-T cell therapies (Figure 1). As highlighted above, the current lack of proper data training for AI-based pHLA:TCR interaction prediction models poses a major limitation in the discovery of specific TCRs. Therefore, in our opinion, creating a comprehensive database is the first and most fundamental step in building an efficient AI model for TCR discovery. We believe that the incorporation of AI technology will not only accelerate and advance the entire process relating to the identification of specific TCRs but will also provide a new approach to personalized cancer treatment using therapeutic T cells.

Methods

Study Design and Objectives

This is a multicenter observational study performed by the surgical oncology departments in Poland: the Maria Sklodowska-Curie National Research Institute of Oncology in Cracow, Brothers Hospitallers of Saint John of God Hospital in Cracow, Ludwik Rydygier Memorial Hospital in Cracow, St Raphael Hospital in Cracow, Voivodeship Multi-Specialist Center for Oncology and Traumatology in Lodz, Holy Cross Cancer Center in Kielce, J Struś Multispecialist Municipal Hospital, and Heliodor Swiecicki Clinical Hospital in Poznan. The overall objective of this study is to create a pHLA:TCR database to aid the development of an AI-based platform for the selection of specific TCRs used in cancer immunotherapy. This aim will be achieved by collecting high-quality blood and tissue samples from patients with colorectal cancer (CRC) that can be used for next generation sequencing, single-cell, and bulk TCR repertoire sequencing. The sequencing data will be processed with Ardigen (Ardigen SA)-developed platforms to generate a pHLA:TCR database.

Ethical Considerations and Regulatory Approvals

This study has been approved by the Maria Sklodowska-Curie National Research Institute of Oncology, Gliwice branch (KB/430-87/21). It was carried out in accordance with the Declaration of Helsinki and the Good Clinical Practice guidelines issued by the International Conference on Harmonization (ICH-E6, 17/07/1996). The enrolled participants were evaluated based on the inclusion and exclusion criteria. The selected participants provided written informed consent before the start of all experimental procedures. All the participants were provided with a thorough explanation of the proceedings planned in the study with an emphasis on the type and quantity of biological samples that will be collected from them. Furthermore, the participants were informed on the type of experiments that will be performed and how the samples will be stored. Generated data reports will be confidential and stored safely at a repository at Ardigen.

XSL•FO
RenderX

Patient Selection

All the patients with CRC admitted to the surgical oncology wards of the participating hospitals were evaluated for their study eligibility. All the participants were required to be older than 18 years with a diagnosed and histopathologically confirmed advanced resectional CRC adenocarcinoma in active stage II, III, or IV. Participants were excluded from the study if they were unwilling to sign the informed consent form; had a history of inflammatory bowel disease, mucinous adenocarcinoma of the colon, cancer of the anal canal and verge, or adenocarcinoma of the appendix; had a histopathological diagnosis other than adenocarcinoma; were undergoing neoadjuvant and radiotherapies; were pregnant; had HIV infection or active hepatitis B or C infections; or had a leukocyte (white blood cell) levels <4000/mm^3. Qualified participants agreed to make the formalin-fixed paraffin-embedded (FFPE) tissue from the primary tumor available for research as well as to have their blood drawn.

Study Procedure

After the selection process, the enrolled participants underwent medical history review and physical examination by a medical doctor of the research team. Once completed, tissue samples of the primary tumor and blood were obtained from the participants. The tissue samples were provided in the form of FFPE blocks with a total area of embedded tissue of at least 100 mm^2 or alternatively as a minimum of 10 histopathological slides, the quality of which was confirmed by a pathologist. Blood sample collection was performed twice by qualified medical personnel (ie, a nurse or medical doctor) after which the sample was secured for further processing.

Study participants had the option of terminating their participation in the study at any given time. The participants could have also been withdrawn from the study at the discretion of the investigational team.

Sample Processing

Sample Collection

Biological samples that were obtained from the study participants included FFPE blocks of the primary tumor tissue or histopathological slides derived from it and their peripheral blood samples. The FFPE blocks and histopathological slides were provided by the hospital laboratory or department of pathomorphology of the participating institution. Peripheral blood samples were collected into heparin-containing tubes in 2 blood draws, 40 mL each. Additionally, at the first venipuncture, 2.5 mL of peripheral blood was collected per 1 PAXgene Blood DNA and 1 PAXgene Blood RNA tube (Thermofisher) for DNA and RNA isolation, respectively. If an insufficient number of peripheral blood mononuclear cells (PBMCs; <50 million) was obtained after the first 2 draws, an additional 40 mL of blood was collected from eligible participants (eg, those who had not yet started chemotherapy) after receiving their consent. Samples were transported to the Biobank Lab at the Head Department of Oncobiology and Epigenetics, Faculty of Biology and Environmental Protection, University of Lodz, according to the standard operating procedures. For long-term storage, the samples in PAXgene Blood DNA and PAXgene Blood RNA tubes are stored at –80 °C, and FFPE blocks and histopathological slides are stored at 2-8 °C.

PBMC Isolation

Blood collected into heparin-containing tubes was used for PBMC isolation. The isolation procedure for all samples started within 3 hours after venipuncture and was performed under sterile conditions according to standard density gradient centrifugation protocol. Briefly, blood samples were diluted with a phosphate-buffered solution in a 1:1 ratio at room temperature (RT) and layered onto Histopaque-1077 reagent (Sigma-Aldrich) in 50 mL test tubes. Next, the samples were centrifuged according to the manufacturer's instructions (at 400*g* at RT for 30 minutes without braking or acceleration). After centrifugation, the leukocyte phase was transferred into new tubes and washed with phosphate-buffered saline followed by centrifugation at 300*g* at RT for 10 minutes. To remove erythrocytes, the cell pellet was treated with a red blood cell lysis buffer according to the manufacturer's instructions. The viability of the isolated PBMCs was assessed using trypan blue staining. If applicable, the PBMCs were resuspended in fetal bovine serum with 10% of dimethyl sulfoxide and cryopreserved in liquid nitrogen for long-term storage.

DNA and RNA Isolation

DNA and RNA were isolated from tumor FFPE block samples after macrodissection and evaluation of corresponding hematoxylin and eosin (H&E)-stained slides with tumor area distinctly labeled by a pathomorphologist.

For DNA and RNA extraction from blood samples collected in the PAXgene Blood DNA and PAXgene Blood RNA tubes, the PAXgene Blood DNA and PAXgene Blood RNA kits (Qiagen) were used, respectively, according to the manufacturer's protocol.

Next Generation Sequencing

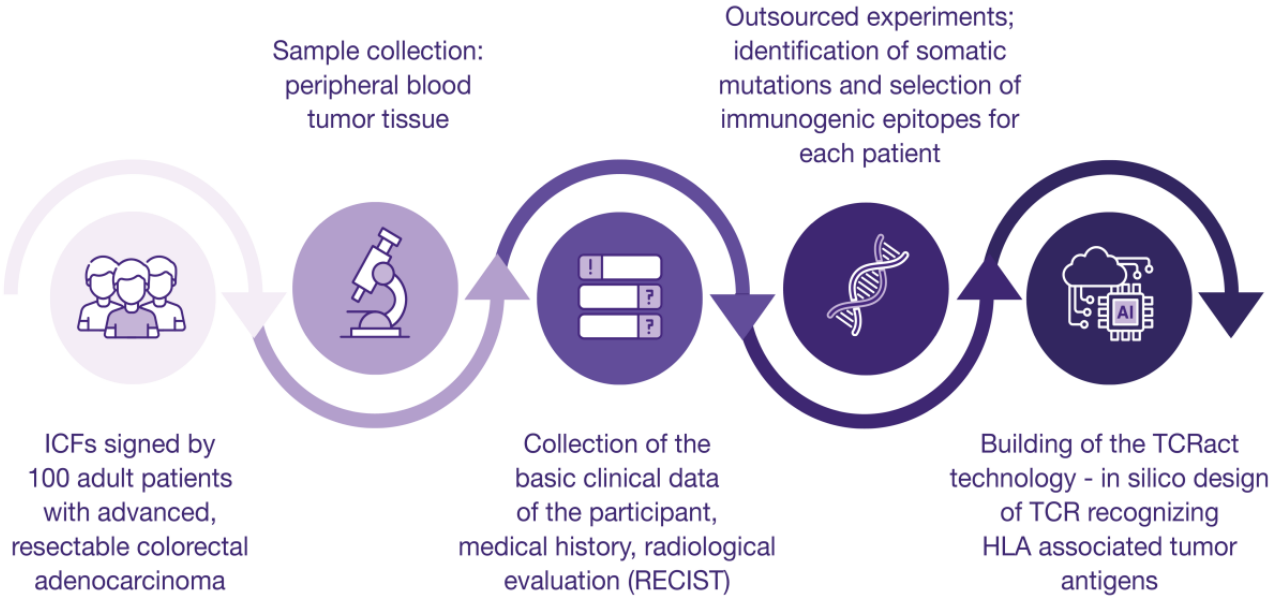
Isolated DNA from both FFPE blocks and peripheral blood was prepared for whole exome sequencing (WES) sequencing with commercial kits for 100 bp paired-end read lengths. The RNA isolated from FFPE blocks was used for RNA library preparation for paired-end sequencing with read lengths of 100 bp. The quality of prepared libraries was checked with Fragment Analyzer and sequenced on an Illumina sequencer with expected depth for DNA of 150x and 300x for PBMC and FFPE samples, respectively. RNA sequencing was set to obtain at least 100 million reads for each sample.

Identification of Immunogenic Peptides and Sequencing TCRs That Bind Them

ARDesign (previously called ArdimmuneVax) is an Ardigen-developed platform that uses in-house created AI models to design off-the-shelf and personalized peptide-based cancer vaccines and target identification for TCR-based therapies [22,23]. ARDesign platform includes ARDitox, the ARDisplay—presentation model, Ardimmune—immunogenicity model, and Meta-model, which considers the output of these models and other metrics. DNA sequences will be aligned to

XSL•FO
RenderX

the reference genome and both somatic and germline mutation will be called, which will constitute one of the inputs for the ARDesign platform. Expression profiles derived from RNA sequences will comprise the other input for the platform.



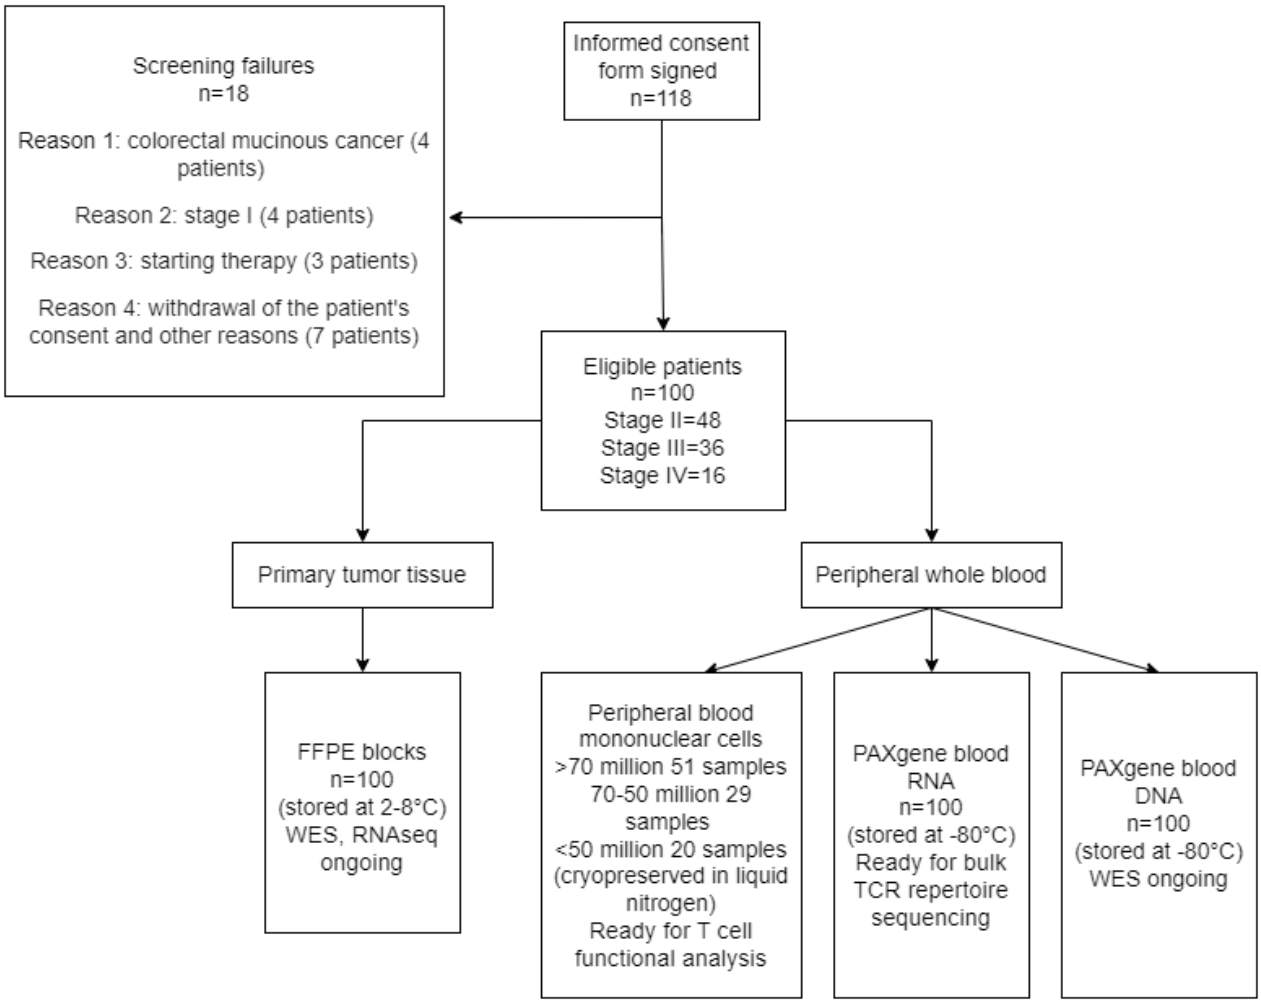
Next, based on ARDesign results, peptide immunogenicity can be validated by in vitro functional assays (ie, ELISpot), and fluorescently labeled pHLA multimers can be synthesized and applied for the isolation of reactive T cells with a flow cytometry cell sorting methodology. For that purpose, the isolated, biobanked PBMCs will be stained with fluorescent pHLA multimers and a panel of antibodies allowing the gating of pHLA-specific $CD8^+$ T cells.

Sorted $CD8^+$ T cells will be analyzed using the 10x Genomics (10x Genomics, Inc) single-cell technology to obtain paired α and β sequences of the TCRs with information about the pHLA that they bind.

Additionally, RNA isolated from the peripheral blood collected into PAXgene Blood RNA tubes will be used for bulk TCR repertoire sequencing to enable profiling of TCR repertoire diversity and clonality and to help to prepare negative training data sets for the pHLA:TCR database.

Altogether, the gathered results can serve as the basis to generate a reliable pHLA:TCR database that includes validated TCRαβ-paired sequences of a known peptide specificity. The overall process of the proposed pHLA:TCR database generation is presented in Figure 2.

Figure 2. Overview of creating an artificial intelligence–based technology (TCRact) for T cell receptors (TCRs) design and optimization. HLA: human leukocyte antigen; ICF: informed consent form; RECIST: response evaluation criteria for solid tumors.



Results

Participant recruitment and sample collection started in October 2021 and was completed at the end of 2022. To date, primary tumor (FFPE blocks) and peripheral blood samples have been obtained from 100 participants. Isolation of PBMCs from peripheral blood has been performed for all 100 patients. On average, 74 million PBMCs were isolated from 80 mL of blood with average cell viability of 93%. All the isolated PBMCs were cryopreserved and are being stored at the Biobank Lab, University of Lodz.

To date, 85 participants have had their DNA and RNA extracted from both FFPE and peripheral blood samples. In 57 cases, WES was performed to analyze the occurrence of somatic mutations. Altered gene expression analysis was done for 57 participants using the RNA sequencing method. Additionally, RNA samples (isolated from blood) will be undergoing bulk TCR repertoire sequencing to enable profiling of TCR repertoire diversity and clonality. In all of the cases mentioned above, the obtained sequencing data (DNA and RNA) were incorporated into the ARDesign platform to rank the immunogenic potential of tumor peptides. Final study results are expected to be analyzed by September 2023. For further information regarding the progress of the study refer to the study flowchart presented in Figure 3.

Discussion

Overview

This study describes a protocol of a trial for creating a comprehensive database containing pHLA-TCR sequences with paired α and β chains of TCRs. The generated database will be used for the development and testing of an AI-based platform designed for the prediction and optimization of TCR sequences that specifically recognize tumor antigens. These types of platforms are of great interest, especially for the development of antitumor immunotherapies using TCR-T cells. ACT trials using TCR-T cells or CAR-T cells have shown that complete and durable eradication of tumor cells in the primary tumor is possible [24]; however, there are also reports suggesting that this type of immunotherapy might be effective in the treatment of metastatic disease [25,26], which is a major challenge for current treatment modalities. A great example of ACT efficacy against neoplastic disease is a therapy involving CD19 CAR-T cells in the treatment of relapsed or refractory B-ALL and relapsed or refractory diffuse large B-cell lymphoma in adult patients. This therapy was approved by FDA in 2017, and in 2018 it was authorized by the European Medicines Agency, which underlines that these technologies are highly promising for the treatment of neoplastic diseases [27]. Nevertheless, despite the spectacular effect of CAR-T cells in the treatment of some blood cancers, these types of cells are not as effective in the treatment of solid tumors [28]. TCR-T cell therapy appears to be a better approach for the treatment of solid tumors [29], which make up the majority of all cancer cases. Furthermore, unlike CAR-T technology, TCR-T cells are able to recognize mutated intracellular proteins, which make up a much larger part of cellular proteins than surface antigens by themselves [30,31]. In other words, the range of potential antigen targets is larger in the case of TCRs than CARs. Thus, the development of TCR-T technology might offer hope for “universal” cancer treatment. For this reason, many pharma and biotech companies are involved in the development of TCR-based therapies and clinical trials involving patients with cancer. Nevertheless, the advancement of TCR-T technologies had been slowed down by several drawbacks. The main obstacle with TCR-engineered ACT is associated with finding the appropriate TCRs that specifically recognize tumor antigens and do not show “on-target, off-tumor” toxicities at the same time. Another challenge is finding a TCR with proper avidity for the target. Currently, the development of TCR-T cells for therapeutic purposes is based on extensive lab work, which is time-consuming, labor-intensive, and very expensive.

XSL•FO
RenderX

For this reason, our study aims to develop a platform for faster TCR selection and simultaneous prediction of potential toxicities. Our platform is intended not only to accelerate TCR identification but also to reduce the cost of the entire process. One of the main stages of TCRact platform development is to create a unique pHLA:TCR database. Currently, high-throughput TCR sequencing enables deep analysis of the TCR repertoire, which allows for comparison between different tissues and individuals. Currently, several databases of TCR sequences are available, such as VDJdb, McPAS-TCR, and IEDB, and subsequently, algorithms that allow for TCR specificity prediction have also been developed (ie, TCRdist and TCRex) [32-36]. It has to be stressed that the available databases are often incomplete and, in many cases, provide a sequence of only one of the TCR chains, or both α and β chains that are not paired. Furthermore, in many cases, they lack information about the cognate peptides and HLA types involved in peptide presentation. Hence, the function of only a minor fraction of TCRs is known, especially in the context of TCR-peptide-HLA interactions. Recently, Zvyagin et al [37] pointed out this problem by concluding that there is a lack of studies and protocols that allow for good prediction of TCRs and epitopes based on their sequences.

To build the database with a size that is comparable to the publicly available data set, we are aiming to use samples from approximately 100 patients [38]. Notably, our database will be based on the data obtained from the primary tumor and blood samples of patients with cancer. This approach is more specific (as tumor neoantigens are highly similar to self-antigens, unlike viral or bacterial antigens) for the identification of the TCR-peptide-HLA complex in the context of neoplastic disease in comparison to TCR data obtained from infectious diseases or vaccine monitoring studies [15,34,39,40]. Our approach helps to populate the database with a unique set of sequences that may be invaluable in the context of immuno-oncological therapies using TCR-T cells. For this reason, close cooperation with clinical sites guaranteeing the highest quality of the collected biological specimens together with complete clinical data is essential for the completion of this project's goals.

In this study, an AI-based platform is being developed as a tool for designing a precise and safe immunotherapeutic approach in tumor treatment. Adopting this type of approach would allow oncogenic, personalized immunotherapy to be widely accessible to the general public.

Limitations

Although we strongly believe that TCR-T therapies developed with the aid of AI-based platforms, such as the one discussed in this study, will become more accessible for cancer treatment with time, there are still a number of limitations that need to be addressed. The first major obstacle concerns the sharedness of the target (ie, neoantigen and tumor-specific antigen) for such therapies. There is a limited number of defined shared peptide targets. Furthermore, the method for creating the pHLA:TCR database described in this study will mainly provide data for personal neoantigens (specific to a given patient) and the TCRs that bind them. However, we believe that including neoantigens in the database might address the key limitation in pHLA:TCR binding prediction with AI models and the limited diversity of pHLAs in the training set. Another limitation to consider involves the number of patients in the study cohort itself and the number of pHLA:TCR pairs that it can potentially generate. Our cohort is composed of 100 patients, and we plan to choose 1 pHLA per patient. However, it is difficult to predict what number of different T cell clones per pHLA will be identified in our experimental approach, as the number can differ greatly depending on epitope sequence, clonal diversity, and clone size. In summary, the pHLA:TCR database that we plan to build using the approach described in this study may turn out to be of modest size. However, we believe that it will make a significant contribution to the field because our data set will provide information about specific cancer antigens that are currently underrepresented in public databases.

Conclusions

The results of this study provide the basic information for the development of an innovative platform that allows for fast and safe in silico prediction of TCRs to be used in cancer immunotherapy.

Acknowledgments

This work was part of a project Creation of an Innovative TCRact Based on AI (Artificial Intelligence) In Silico Technology to Launch a New Service of Designing and Optimizing T Lymphocyte Receptors (TCR) For Use in Cancer Immunotherapy, cofunded by the European Regional Development Fund (ERDF) as part of Smart Growth Operational Programme 2014-2020 (Project No. POIR.01.01.01-00-0019/20).

Data Availability

The data sets generated and analyzed in this study are available from the corresponding author on reasonable request.

Authors' Contributions

SK supervised the recruitment of patients and the course of clinical study and consulted the study protocol. JB and KW drafted the manuscript. ASD, AB, and M Balawejder conceived, designed, and wrote the study protocol and manuscript. RS and A Kociniak reviewed and corrected the manuscript. AB and M Balawejder conceived and designed the study and patients' recruitment, coordinated clinical study, and reviewed the manuscript. ZO, JW, GT, MJ, T Kucharczyk, LW, M Borys, HS, MW, M Kayser,

Abstract

Background: Alzheimer disease (AD) and Parkinson disease (PD) are the 2 most common neurodegenerative diseases affecting millions of people worldwide. The *Personalized Integrated Care Promoting Quality of Life for Older People* (PC4L) project proposes an integrated, scalable, and interactive care ecosystem that can be easily adapted to the needs of several neurodegenerative and chronic diseases, care institutions, and end user requirements.

Objective: The study protocol developed within the framework of the PC4L project aims to iteratively test the integrated platform and its modules, and focuses primarily on assessing the impact of the proposed solution (ie, the PC4L platform) on patients' quality of life, as well as its usability and feasibility on a large-scale sample size in 3 different scenarios (home, neurorehabilitation, and day care centers).

Methods: A prospective multicenter clinical study is conducted in 5 European countries (Germany, Italy, Portugal, Romania, and Spain) at 6 different pilot centers, for 3 months, in patients with PD, Parkinsonism, AD, and other dementias (ODs). Patients were randomized in a ratio of 1:1 to the intervention group (use of the PC4L system) or the control group (no intervention). The PC4L system consists mainly of a wristband for monitoring parameters such as steps and levels of physical activity, and the PC4L app, which includes different engaging functionalities. Both groups are assessed through baseline and end-of-study clinical evaluations, including assessment of quality of life through the EQ-5D-3L scale.

Results: The study protocol is part of a project approved and funded by the European Commission Horizon 2020 (grant agreement number 875221). The ethics committees of all involved centers reviewed and approved the study protocol. The study began with the recruitment phase in September 2022, and enrollment ended in February 2023. Recruitment is now closed (April 2023). The results of this study are expected to be published in summer 2023. A total of 558 patients, 279 per study group, were recruited. The results will allow to clarify the impact of PC4L on quality of life, will assess the empowerment of patients and the medical resources use, as well as the usability of the final version of the PC4L system. It will also provide information on the support of the system as a tool to facilitate the decision-making process.

Conclusions: The PC4L project intends to test a technology-based, integrated, scalable, and interactive care platform on patients with neurodegenerative diseases and proposes a good coordinated care model between all involved actors. Future developments

XSL•FO
RenderX

of the PC4L solution may involve caregivers and socio-health professionals in the decision-making process in order to facilitate efficient communication between all stakeholders and ensure reliable and protected access to data within Europe.

Introduction

Background

There is an urgent need to increase the efficiency and sustainability of health and social care systems across Europe, as there is a growing trend in public spending, which is expected to reach 14% of gross domestic product by 2030 [1]. The aging of the population, accompanied by an increase in chronic diseases, including cardiovascular diseases, diabetes, asthma, mental and physical disorders, and neurodegenerative conditions, represents the main cause of this situation [2,3]. In fact, the existence of comorbidities and the confluence of several chronic diseases are progressively more frequent in older adults, which increases the need to develop models and tools to improve integrated health care systems.

The aging of the population has also led to major reforms in long-term care policy and systems in many European Union (EU) countries, raising the necessity for alternatives. This implies the need for help with household tasks or other practical errands, transport to hospital/clinic visits or social visits, social companionship, emotional guidance, or organizing professional care. In most European countries, much of the care for people older than 60 years is based on informal care [4].

Among the most common chronic diseases in older adults, neurocognitive disorders, such as dementia, Alzheimer disease (AD), and Parkinson disease (PD), are the most disabling. Today, more than 10 million Europeans live with neurocognitive impairment disorders at different stages of dementia.

In recent years in Europe, digitalization is recognized as a powerful tool to achieve many potential benefits such as improving quality of life and putting patients at the center of the care process [5].

Therefore, the current situation can be improved by the creation of an integrated care platform, capable of establishing correlations between comorbidities, investigating the use of polypharmacy, mitigating potential health risks, studying the social variables involved, and promoting unified treatment procedures or social services. This solution could help patients, caregivers, and social health professionals to better monitor several diseases, while also considering the social context [6-8]. Besides, according to a recent work [9], the inclusion of a web platform for monitoring signs and symptoms of older persons by health care professionals over time has proved to be an important resource.

In addition, people with chronic diseases experience difficulties in their daily lives and require specialized care services as well as treatments, imposing high burdens on the public budget: this requires special attention to adequately address the sustainability of the social health system in Europe.

Personalized Integrated Care Promoting Quality of Life for Older People (PC4L) is a European Commission Horizon 2020 project (grant agreement number 875221) that proposes an integrated, scalable, and interactive care ecosystem, and can be easily adapted to the reality of several chronic diseases, care institutions, and end user requirements, benefiting all the involved actors, from patients to caregivers and health professionals. Its main contributions consist of the following:

- Building an integrated, scalable, and interactive care ecosystem for neurodegenerative diseases and adaptable to other chronic conditions
- Finding the best actions and measures from a medical and social point of view that can facilitate an improved quality of life, awareness, and care management for senior users with neurodegenerative and other chronic diseases
- Providing a personalized recommendation and interaction model, which can support the user through gamification techniques, with the final goal of adopting healthy habits, maintaining a good daily routine, and following the prescribed actions by the professionals
- Enabling multidisciplinary communication between all involved stakeholders, facilitating better time management for social and health professionals, and contributing to a cost-efficient, flexible, and highly adaptable solution for senior users with short- or long-term conditions

By adopting a user-centered design approach starting from the early stages of the project [10], the inclusion of the needs and requirements of the end users has been crucial toward the PC4L platform development and implementation [11] and the current outline of the protocol presented here. In fact, through the work performed during the first part of the project, we identified the more important factors from the personal, social, and health points of view that are able to influence the daily lives of the end users and reflect on their expectations regarding the PC4L solution.

Aims

This study represents the third, and last, phase (pilot 3) of large-scale pilots aiming to gradually co-design and iteratively test the PC4L integrated platform and modules.

While pilot phases 1 and 2 focused on technical feasibility and patients' satisfaction, this protocol focuses on the following objectives:

XSL•FO
RenderX

- To assess the impact of using the PC4L platform on patients' quality of life
- To compare the metrics generated by the PC4L platform in real-life conditions with the clinical outcome measures
- To evaluate the feasibility and safety of measuring disease progression and patient health status through the global functioning of the PC4L system
- To assess and compare the feasibility and usability of 2 different versions of the PC4L system (fully equipped version vs cloud-based solution)
- To increase patients' safety and empowerment

As the primary outcome, the study will provide:

- The difference in quality of life between groups (experimental vs control group), measured by the EQ-5D-3L scale at the end of the study

The following secondary outcomes will also be acquired:

- The correlation coefficient of the PC4L platform metrics (eg, steps and physical activity levels, sleep, number of falls, cognitive scores) with the clinical outcome measures (eg, motor clinical evaluation, sleep questionnaire, Falls Efficacy Scale-International [FES-I], cognitive evaluations) measured at baseline, end of the study, and the values of change from baseline
- System usability assessment, measured through the System Usability Scale (SUS), at the end of the study
- Users' satisfaction with the PC4L system, measured through a 5-point Likert Scale, the mHealth User Satisfaction Questionnaire, and the participants' answers to open questions, at the end of the study
- Changes in patients' satisfaction and empowerment, measured by the Patient Assessment of Chronic Illness Care (PACIC) and the Short Assessment of Patient Satisfaction (SAPS) scales, respectively, at baseline and at the end of the study
- Change in patients' use of medical resources (number of admissions and number of days spent in health institutions) in the last month, measured at baseline and at the end of the study

Methods

PC4L Platform

Instrumental Setup

The PC4L ecosystem consists of the following:

- Wearable sensors that are used by the patient for monitoring disease-related parameters in passive and interactive paradigms (eg, simple biomeasurements such as heart rate or complex biomeasurements such as motor behavior; passive measurement if initiated automatically, and interactive measurement if initiated by the patient). The wearable sensor used is the smartwatch Fitbit Versa 2 (Google LLC). Patients will wear the sensor in the dominant arm
- The PC4L app for processing data directly from the smartphone (Samsung A20 or another similar model) inertial measurement unit sensors and GPS and directly from users. In particular, the data collected will be anthropometric data and symptoms, as well as data related to medication uptake, which are to be provided directly by the patient or the caregiver, via short questionnaires and annotations. Data related to motor behaviors through GPS and inertial sensors
- Depth camera that will be deployed in the clinical centers (rehabilitation) for monitoring motor parameters of the patients. In principle, cameras will collect both 2D and 3D images to facilitate the extraction of events (eg, falls, loss of balance, wandering episodes), point trajectories, and "skeleton" data from patients for extraction of different motor behaviors and movements (eg, freezing, festination). The selected camera is the Intel RealSense depth camera (model D435)
- Tablet or computer to collect data related to cognitive abilities of the patients: the cognitive games app includes 6 different games about short-term memory, visual recognition, understanding, semantic memory, vocabulary, and mathematics. This app collects not only the results of the games, but also information related to the user interaction with it
- A local computer collects data from the patients via the sensorial ecosystem, which includes several fixed and dynamic sensors such as wearables, sensors, and cameras

In addition, the PC4L integrated care platform (accessible via internet browsers) provides an electronic health record or personal information sheet (fed with data provided by the PC4L ecosystem) and complex interface for personalized interaction and communication between patients and health care professionals.

PC4L Mobile App

The PC4L app includes a prescription dashboard, which monitors drug compliance; questionnaires on health status and physical activity, to be filled periodically; a symptom diary, which registers the symptoms experienced by the patient (ie, falls, freezing, loss of balance); physical activity recommendations; and daily personalized notifications on physical activity, hydration, and nutrition.

Decision Support System

As part of the decision support system, the PC4L platform includes a recommendation component. This component collects information from different sources available (directly from sensors, from the cognitive games, from the patients' and users' questionnaires, and from the multimodal fusion engine), and under clinical and health care professional guidance, after the assessment of the potential improvement or worsening of the patients' conditions, issues personalized recommendations to address the problems identified. Recommendations are related to the following major areas: physical activity, sleep, cognitive, nutrition, social support, and stress management (for informal caregivers).

These recommendations are sent generally to the PC4L app installed on the patients' mobile, where they appear as pop-up notifications when received. In most cases, the content of the

XSL•FO
RenderX

notifications is readily available in the app in case the patient wants to check it again at a later time.

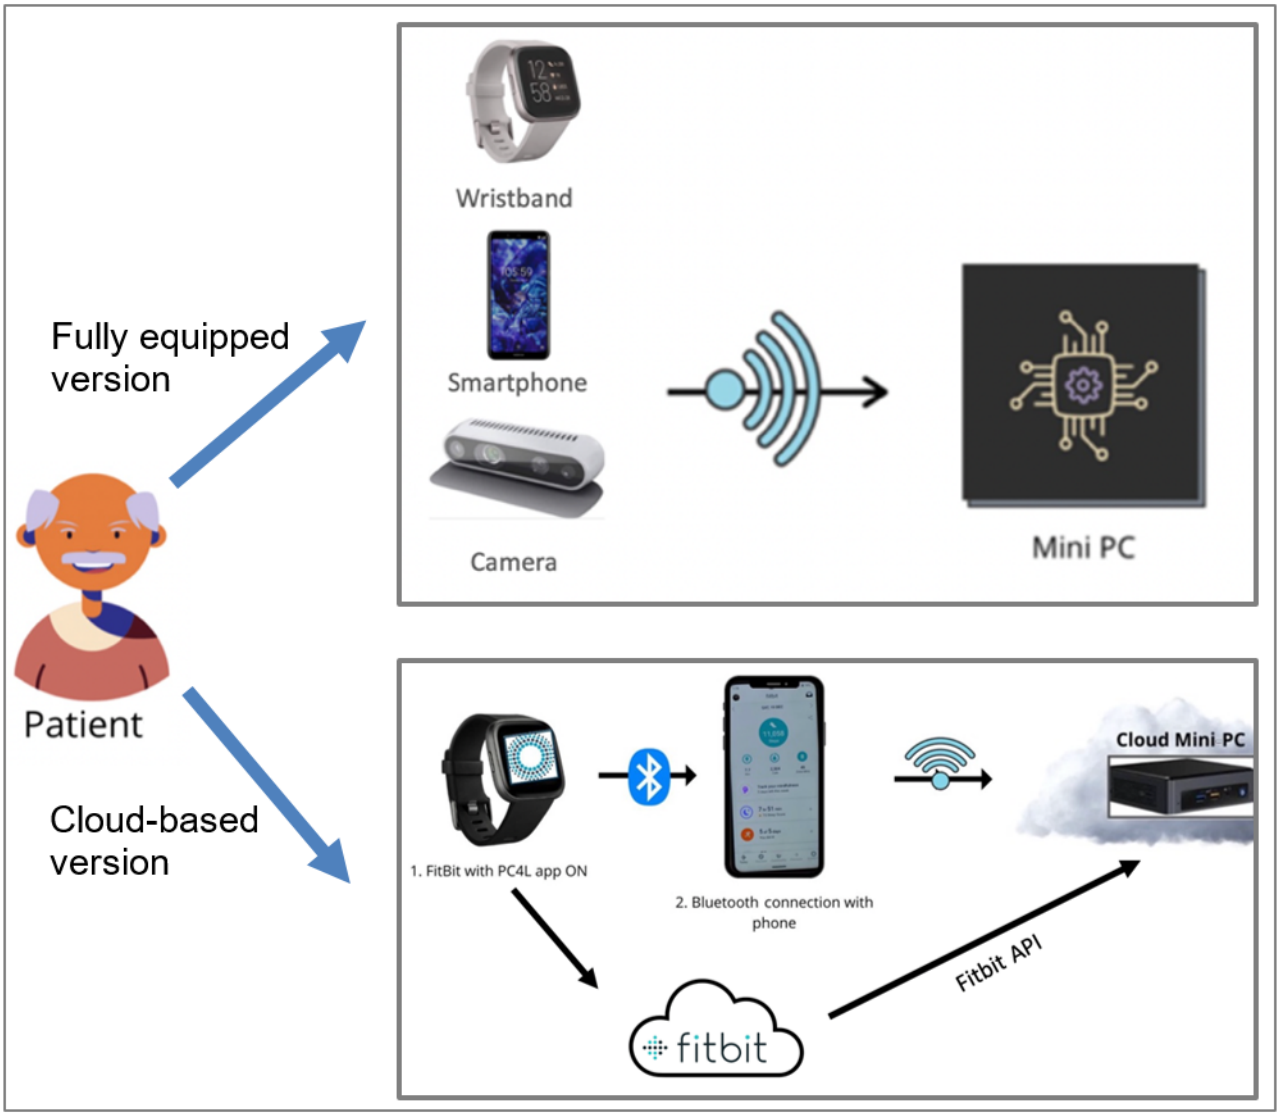
Under clinical supervision, the decision support system will indicate scores' impacts and the contributions to either the improvement or the worsening of the patients' health conditions. Finally, these decisions lead the recommender engine to provide personalized recommendations such as physical activity, nutrition, social support, and stress management. Additionally, reminders for therapy adherence to improve patients' quality of life can be integrated.

Multimodal fusion aims to predict deviations from patients' daily/normal routines, taking into consideration the input modalities (ie, cognitive state, medication intake, motor symptoms, sleep, physical activities, comorbidities, and patient's profile). It focuses on detecting deviations in motor functions, cognitive abilities, sleep routines, and physical activities. The fusion approach benefits from domain knowledge and uses it in a computational framework to fuse the input modalities and detect the probability of deviations in the patient's condition to support them. The multimodal fusion brings together the input modalities to enhance decision-making and gives stronger inferences using dynamic and personalized fusion through Bayesian networks. In the fusion approach, health care professionals use the patients' profile information and the static scores to incorporate their knowledge regarding a patient into the fusion algorithm. In other words, the multimodal fusion algorithm utilizes the long-term analysis of the behavioral analysis modalities to gather broader insights into the deviations in patients' health conditions and routines.

Metrics

During the monitoring period, specific metrics (Table 1) are collected, continuously and passively, through the PC4L system.

Table 1. Metrics and related devices used during patients' monitoring.



Metrics	Devices
Walking parameters	Wristband and phone
Bradykinesia	Wristband and phone
Loss of balance	Cameras
Falls	Cameras and wristband
Festination	Wristband and phone and camera
Physical activity	Wristband
Freezing	Wristband and phone and camera
Inactivity	Wristband
Compliance with medication	App
Sleeping pattern	Wristband
Interaction patterns with the devices	Platform or app
Usage of the physical activity recommendation services	Number of clicks per week of the different services

PC4L System Versions

Two different versions of the PC4L system were used (Figure 1): a fully equipped version, with all the devices enumerated above provided to the patients, and a cloud-based system that only requires a smartphone and a wearable sensor. Of those patients using the PC4L system, 25.1% (70/279) used the fully equipped version, whereas the remaining ones (209/279, 74.9%) used the cloud-based system.

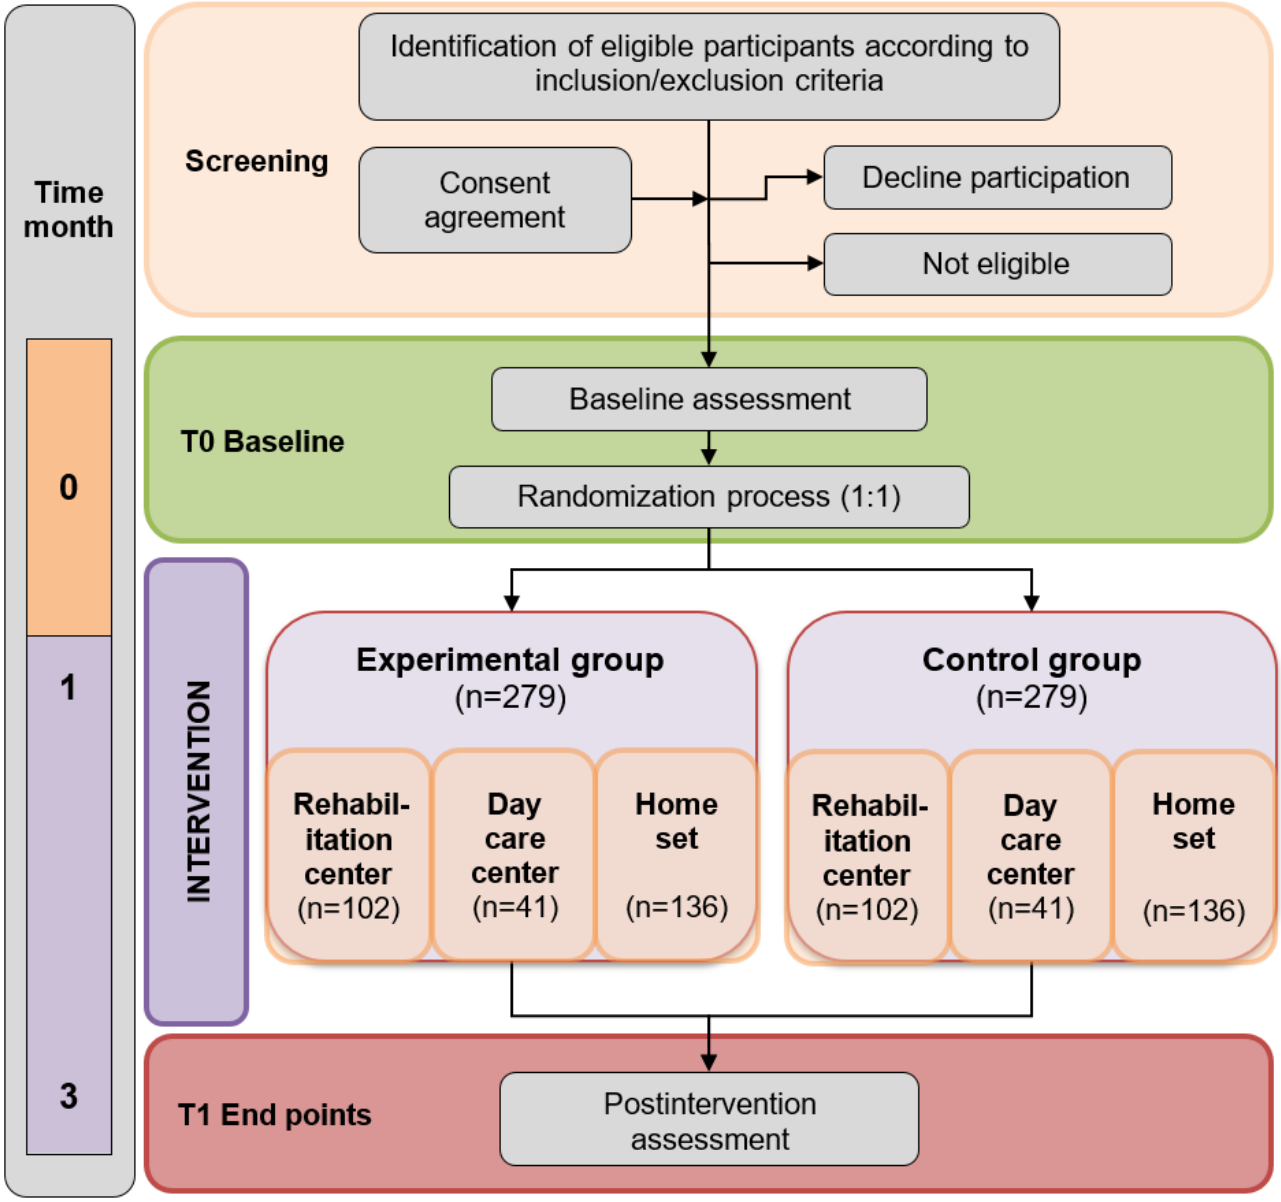
Study Design

A prospective multicenter clinical study is conducted in 5 European countries: Germany, Italy, Portugal, Romania, and Spain (also including 6 pilot centers).

The pilot sites are (1) Asociacion Parkinson Madrid (APM), Madrid (Spain); (2) Casa di Cura del Policlinico (CCP), Milano (Italy); (3) Campus Neurológico Sénior (CNS), Lisbon (Portugal); (4) University and Emergency Hospital of Bucharest (UHB), Bucharest (Romania); (5) University of Medicine and Pharmacy (UMF), Bucharest (Romania); and (6) Wohlfahrtswerk für Baden-Württemberg (WBW), Stuttgart (Germany).



There are also 3 different scenarios: (1) rehabilitation center (inpatients and outpatients); (2) day care centers; and (3) home set (ie, patients' home).

The duration per patient, at home and in the day care center, will be up to 3 months. Participants in the rehabilitation center participated during the period of their stay in the center (not exceeding the 3 months).

A specific route diagram is presented in Figure 2 in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines. The protocol of this study was developed in accordance with the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) guidelines (Figure 3) [12]. The schedule of enrollment, interventions, and assessments is presented in Figure 3.

Selection Criteria

The inclusion and exclusion criteria of participants are shown in Textbox 1.

XSL•FO
RenderX

Textbox 1. Participant inclusion and exclusion criteria.

Inclusion criteria

- For patients with Parkinson disease (PD) and Parkinsonism:
  - Patients diagnosed with PD according to the Movement Disorder Society (MDS) criteria
  - Hoehn and Yahr stages between II and IV assessed in the "on" state
- For patients with Alzheimer disease (AD) or other dementia (OD):
  - Clinical diagnosis of AD or OD
  - General inclusion criteria
  - Willing to participate
  - Aged 65 years or older
  - Willing to interact with technology devices
  - Willing and able to provide written informed consent to participate in the study or having a legal representative responsible for signing

General exclusion criteria

- Clinically significant and severe cognitive decline or intellectual disability that may compromise their ability to use a mobile phone or other electronic devices
- Fever or acute infection such as COVID-19 or influenza
- Life-threatening coexisting disease with life expectancy

Additional criteria regarding the different scenarios

- Home set scenario: Living at home with or without caregiver
- Rehabilitation center scenario: Enrolled in a rehabilitation program with or without caregiver
- Day care center scenario: Being in the day care center program with a caregiver

Recruitment

Patients with PD and other parkinsonian syndromes, AD, or ODs were invited to participate from the clinical centers involved in the study. Each participant organization was assigned to recruit a number of participants related to their skills, experience, number of researchers involved, and access to users (Table 2).

Table 2. Distribution of participants per clinical center and scenario.

Scenario/clinical center	Rehabilitation (n=204), n	Day care (n=82), n	Home (n=272), n	Total (N=558), n

[a]APM: Asociacion Parkinson Madrid.

[b]N/A: not applicable.

[c]CCP: Casa di Cura del Policlinico.

[d]CNS: Campus Neurológico Sénior.

[e]UHB: University and Emergency Hospital of Bucharest.

[f]UMF: University of Medicine and Pharmacy.

[g]WBW: Wohlfahrtswerk für Baden-Württemberg.

To reach the planned number of recruits, many strategies were implemented: participants were contacted through online webinars; through brochures placed in specific centers such as pharmacies, leisure centers, and medical offices; and through patients' associations. Further, regular updates were posted via online newsletters on different websites, such as the PC4L

XSL•FO
RenderX

website and end users organizations' websites. In addition, information about the PC4L pilot 3 study was shared during national and international conferences. Recruitment was also promoted in a collaborative way thanks to partners from other European projects. Finally, participants were recruited in person when accessing the medical facilities and via phone contact or emails after searching local databases.

Patients who discontinue the study participation because of medical conditions (ie, infections, falls, medical emergencies) or unwilling to participate any longer for other reasons (ie, difficulty with technology, loss of interest) will be considered dropouts.

Randomization

Patients were randomized in a ratio of 1:1 to the intervention group (use the PC4L system) or the control group (no intervention) by an independent, nonclinical partner of the project consortium.

Patients allocated in the intervention group were randomized in a ratio of 3:1 to the "cloud-based solution" and the "fully equipped" PC4L system version.

Blinding

Participants and intervention delivery facilitators could not be blinded to group allocation. Evaluators conducting the clinical assessments were blinded to group allocation.

Interventions

Overview

All participants that fulfil inclusion criteria were invited to participate. Information about objectives, duration, procedures, and voluntariness was given to patients and informed consent was obtained. None of the procedures of the study started before the informed consent had been signed by the participants.

Control Group

The patients allocated in the control group, after the baseline assessment, received general written recommendations on the aforementioned major areas (physical activities, sleep, cognitive, and nutrition; social support and stress management for caregivers). At the end of the study period, patients performed end-of-study evaluations.

Intervention Group

The patients recruited and assigned to the experimental group received specific instruction in using the project platform, but without any specific program concerning the activities.

Specifically, patients, after the baseline assessment, received the instrumental setup and indications on its functionalities. Patients were instructed about the use of the Fitbit, the PC4L app, and the cognitive games on a tablet or computer. Patients were also provided with manuals.

Specifically, according to the study approach detailed by Biehl et al [9], the patients were instructed to complete the following questionnaires in the app during the first week and during the last week of the study period: the 10-item Eating Assessment Tool (EAT10) [13] for evaluation of dysphagia; the Edmonton Symptom Assessment System (ESAS) [14] and the Patient Global Impression (PGI)—Severity [15] for evaluation of symptoms; and the International Physical Activity Questionnaire (IPAQ) [16] for evaluation of physical activity. In addition, during the last week of using the app, patients were requested to complete the SUS [17], via the app, for evaluation of usability.

The platform was installed in each scenario with the assistance of the project research staff (ie, bioengineers).

A total of 2 versions of PC4L systems were installed: while the cloud-based system (which only required a smartphone and a wearable sensor) was used in all scenarios, a fully equipped version was implemented only in the rehabilitation scenario.

The patients received the same directions in all 3 scenarios.

At the end of the study period, patients performed end-of-study evaluations and returned the instrumental setup.

Study Assessments

In-person assessments took place at baseline and at the end of the study (3 months follow-up or at discharge from the rehabilitation program).

Specifically, the sample characterization and clinical evaluation of the participants (both experimental and control group patients) were performed at baseline. The clinical evaluation with specific tests and scales was repeated at the end of the study.

At the beginning and at the end of the study, all patients were assessed on quality of life through a specific scale (EQ-5D-3L).

Only for patients assigned to the intervention group, their experience with the PC4L platform was assessed in terms of usability at the end of the experimental period.

Figure 3 and the "Data Collection and Analysis" section report specific outcomes that will be used.

Data Collection and Analysis

Clinical Assessment

Evaluators (ie, medical doctor, physical therapist, and neuropsychologist), at the beginning and at the end of the study, conducted the following clinical evaluation scales and tests:

- The Movement Disorder Society-Unified Parkinson Disease Rating Scale (MDS-UPDRS) [18] will be used to objectively quantify the motor and nonmotor aspects of PD. Changes in the MDS-UPDRS score will be investigated, with higher scores meaning worse outcome
- The Clinical Dementia Rating Scale (CDRS) [19] will be used to assess the cognitive status of AD and OD. It yields a single score on a scale of 0-5, with higher scores indicating worse outcome. Change in the CDRS score will be measured at baseline and at the end of the study
- The FES-I will be used to evaluate the subjective fear of falling of the patients. It yields a single score on a scale of 16-64, with higher scores indicating worse outcome
- The Pittsburgh Sleep Quality Index (PSQI) [20] will be used to evaluate the quality of sleep. Change in the PSQI score will be measured at baseline and at the end of the

XSL•FO
RenderX

study. It yields a single score on a scale of 0-21, where higher scores mean worse outcome
- The State-Trait-Anxiety-Inventory (STAI) [21] will be used to assess the anxiety status (trait and state). Change in the STAI score will be measured at baseline and at the end of the study. It yields a single score on a scale of 20-80, where higher scores mean worse outcome
- Presence of festination, dysphasia, wandering episodes, and nonprogrammed medical resources use in the last month will be assessed (eg, access to emergency room)
- The Barthel Index (BI) is an ordinal scale used to measure performance in activities of daily living (ADLs) [22]. Each performance item is rated with a given number of points assigned to each level or ranking. It uses 10 variables describing ADL and mobility and yields a single score on a scale of 0-100, where higher scores mean better outcome
- The PACIC will be used to determine the involvement of the patient in his/her care plan. Change in the PACIC score will be measured at baseline and at the end of the study. It yields a single score on a scale of 0-5, where higher scores mean better outcome
- Similarly, the SAPS was used to evaluate the user's satisfaction with respect to the medical treatment received. Change in the SAPS score will be measured at baseline and at the end of the study. It yields a single score on a scale of 0-28, where higher scores mean better outcome
- The Cumulative Illness Rating Scale-Geriatric (CIRS-G) [23] is used to include the presence of comorbidities in the clinical profile. Change in the CIRS-G score will be measured at baseline and at the end of the study. It yields a single score on a scale of 0-56, where higher scores mean worse outcome

In addition, patients' characterization in terms of demographic and clinical data (age, gender, level of education, professional activity, social support, and previous use of technology) was performed.

Demographic and clinical data were aggregated, extracted, and analyzed using dedicated spreadsheet files (Microsoft Corporation).

Quality of Life Assessment

The primary outcome of the study will be the difference in quality of life between groups, measured by the EQ-5D-3L scale [24], before and after the experimentation.

The EQ-5D-3L descriptive system comprises 5 dimensions, namely, mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. Each domain was scored by patients through 3 levels: no problems (1), some problems (2), and extreme problems (3) in the execution of the specific item.

Quality of life data were analyzed using dedicated spreadsheet files.

Usability and Satisfaction Assessment

At the end of the experimental period, patients allocated to the experimental group performed the usability evaluation of the PC4L platform solution by means of the SUS [17], Global Satisfaction and mHealth User Satisfaction questionnaires, adverse events reporting, and end-of-study open questions.

The SUS is used to measure how easy or difficult the proposed system is to use. We will compare the usability of 2 different versions of the PC4L system (fully equipped and cloud-based solutions). The overall SUS score will be calculated and assessed consistently with the literature: a score of 100 corresponds to the best imaginable usability, while acceptable usability is defined by an SUS score above 68 points [17,25].

The Global Satisfaction Questionnaire is used to assess the overall level of satisfaction or dissatisfaction with the platform experience.

The mHealth User Satisfaction questionnaire is used to measure user satisfaction and usability of the recommendation component of the solution [26].

As a completion of end-of-study assessment, an adverse events report and end-of-study open questions of preferred and less preferred aspects of the platform, as well as suggestions for improvements, will be collected for each user.

Sample Size

According to published evidence [27], the minimal clinically important difference using the EQ-5D-3L in patients with PD is 5.23 points. The sample size calculation was based on these values and on the data provided in a previous study [28] in the PD field that compared the quality of life of 2 groups of patients, resulting in 10% of difference between groups, corresponding to 6 points. It was estimated that 558 patients, 279 per study group, are necessary to improve 10% in the EQ-5D-3L score, with 95% power. Dropouts were not considered in the calculation. Based on this result, the number of participants was distributed among clinical centers, according to their recruitment capacity (Table 2).

Statistical Analysis

Descriptive analysis will be performed for all variables to characterize the sample. For continuous variables, mean, SD, median, and range values will be calculated. For categorical variables, absolute and relative frequencies will be used to describe the data [29-31].

Normality will be studied using the Kolmogorov-Smirnov and Shapiro-Wilk tests. The effect of using the PC4L system will be analyzed by applying the paired-sample *t* test (2-tailed) and the Wilcoxon signed rank test to each variable (statistical significance will be set at $P<.05$).

The Pearson and Spearman correlation tests will be used to validate the PC4L systems metrics (statistical significance will be set at $P<.05$).

Data Collection and Management

The information will be handled confidentially to prevent participant names or other directly identifiable information from appearing in any report, publication, or other disclosure of results. Data (eg, name, age, length of illness) are collected and stored in separate folders. The investigator will enter the pseudonymous data into a database for statistical analysis.

XSL•FO
RenderX

Essential documents shall be archived in such a way as to ensure that they are readily available, on request, to the competent authorities.

The collected data of the PC4L components are only made available in a pseudonymized form in the secure cloud "Amazon Web Services," which is located within Europe [32]. The patient will therefore be assigned a code to ensure the pseudonymity of his/her data. The data on the cloud are only accessible to the project partners, with whom a data processing agreement was made.

The data processing agreement was stipulated as an agreement between the data controller (partner 1, ie, clinical partners collecting the data) and a data processor (partner 2, ie, partner responsible for data analysis) within the consortium, with the purpose of regulating the processing of any personal data collected. In the context of joint controllers, partner 1 is responsible for the processing of personal data in a conventional form from participants (health data and medical data set derived from patients involved in the user requirements phase and in the pilots, data from caregivers, professionals, and other stakeholders). Partner 2 is—within the framework of joint controllers—responsible for the processing of personal data in device data and annotations (social and medical data set/audiovisual).

The data obtained will be used only for the purposes of the research and not for other purposes. The results of the research will be shared more widely, for example, through publications and conferences, but no personal information will be displayed. The processing, communication, and transfer of personal data will be carried out in accordance with the provisions of Regulation (EU) 2016/679 [33] and Law 3/2018 [34], of 5 December, on the Protection of Personal Data and the Guarantee of Digital Rights. In accordance with the legislation, the participant may exercise his/her rights of cancellation, opposition, portability, limitation, access, and rectification by contacting the professional who informed the participant about the project. Likewise, the consortium adheres to the principles of the General Data Protection Regulation (GDPR; legality, equity and transparency; purpose limitation; minimization of data; accuracy; storage limitation; integrity and confidentiality; and responsibility).

Any inaccuracy regarding the functioning of the system will be promptly reported to the technical partners of the project who will intervene in correcting them. The interruption of operation of 1 or more components of the PC4L system will not have any kind of feedback/effect on the participant.

Ethics Approvals

Study Approval

The study protocol was reviewed and approved by the local ethical committees in Germany [number 2022-29-MB-FA4, Ethical committee of Westfälische Wilhelms-Universität (WWU), Münster], Italy (number 734-2022bis, Comitato Etico Milano Area 2), Portugal (number 6-2022 R, CNS Ethic Committee), Romania (numbers 7/19.07.2022, Comisia de Etică a Cercetării din Spitalul Colentina and 36432, Comitetul local de etică SUUB/ Spitalul Universitar de Urgen ă Bucure ti), and Spain (number 22/392-E, Ethical committee of Hospital Clinico San Carlos – Salud Madrid). The institutional review board of all centers approved the study and will receive study reports during mid-study and at the end of the study, and will monitor the study implementation and data collection. Any deviations from the protocol will be promptly notified to the ethics committees and applied only after its approval.

The randomized controlled trial has been registered at ClinicalTrials.gov (identifier NCT05538455).

The study is conducted in accordance with the principles of the Declaration of Helsinki.

The results of this study will be disseminated through peer-reviewed journals and national and international academic conferences only by the professionals directly involved in the clinical trial.

Patient's Informed Consent

After the study had been fully explained to the patient, written informed consent was obtained prior to any study-related proceedings. The method of obtaining and documenting the informed consent and the contents of the consent comply with ICH-GCP (International Conference on Harmonisation good clinical practice), all applicable regulatory requirements, and legal requirements.

In case the patient is unable to read or sign, a legal guardian is allowed to sign the informed consent, only after confirming that the study has been comprehensively explained to the patient by the research team.

Security and Adverse Event Reporting

Any adverse event (serious or nonserious) and any other abnormal clinical, personal, social finding will be recorded in the patient's case report form. For all adverse events, sufficient information will be pursued to permit the following:

- a determination of a temporal relationship;
- an adequate determination of the outcome of the event (ie, whether the event should be classified as a serious adverse event); and
- an assessment of the casual relationship between the adverse event and the study requirements.

An abnormal result finding will be classified as an adverse event if 1 or more of the following criteria are met:

- the result finding leads to a discontinuation of patient participation in the research study and
- the result finding is considered an adverse event by the researcher.

Withdrawal of Participants

Participation in this study is voluntary. Patients may withdraw from the study at any time, without giving reasons and without disadvantage in terms of the quality of care they would receive if they did not participate. After the withdrawal, no further data will be collected or taken into consideration for statistical purposes.

XSL•FO
RenderX

Results

The recruitment began in September 2022, and enrollment ended in February 2023. Recruitment is now closed (April 2023). The results of this study are expected to be published during the summer 2023.

The results of this study will be presented at national and international patients' organizations and to the public.

The study protocol is part of a project (grant agreement number 875221) approved and funded by the European Commission in the framework of Horizon 2020 action.

The results of pilot 3 will allow clarification of the usability of the final version of the PC4L system, its impact on patients' and caregivers' quality of life, empowerment, and use of medical resources. It would also provide information on the support of the system as a tool to facilitate the decision-making process.

At the time of the deployment of this study, as for the previous protocols, issues due to the COVID-19 pandemic in European countries were managed to avoid safety-related risks.

Discussion

PC4L recognizes that today in health care an integrated care process should be adopted for harmonizing health models with social services from a holistic perspective [35]. Therefore, the project intends to develop and test a technology-based, integrated, scalable, and interactive care platform by involving patients with neurodegenerative diseases, such as PD and dementias. The principal aims of this project are to improve the quality of life of patients and to enable active living and better disease management. These aims will be achieved through large-scale assessments across Europe (in 5 countries and 6 end user organizations), with the final scope to validate the reliability of the overall system in a real-life context.

Eventually, the main advantage of the PC4L project is to propose a system that can be easily adapted to the reality of various chronic diseases, care institutions, and end user needs, thus benefiting all actors involved.

To assess the impact on quality of life and usability, we decided to adopt a randomized controlled trial model because it minimizes selection bias and allows reaching an adequate sample size to achieve power.

In the context of improved technologies and digitalization strategies, the use of wearable sensors and smartphone apps has the advantage of providing objective, longitudinal, and precise information about the status of the patients in their own home environment, as highlighted by Klucken et al [36], especially in cases of neurodegenerative diseases.

Based on the extensive literature on the benefit of physical activity in neurodegenerative diseases [37-46], we expect an improvement in quality of life. This is also facilitated by the early detection of signs and symptoms (eg, falls) through proactive monitoring.

Moreover, in terms of digital health, the inclusion of participants is a crucial part [47]. Based on our recent work, we considered that the ICT-integrated care platform should not promise functionalities that are too complex for too many users [11]. Instead, we focused on selection and restriction to fewer but essential aspects. Users and other stakeholders have in fact been involved in these decisions by being considered active actors from the early stages of the project. Notably, the clinical study here described is conducted in 3 different real-life scenarios, providing relevant information on the everyday life of the patients.

Regarding the home scenario, the primary advantage of implementing this scenario is the ability to monitor patients at home, measuring their general health condition, asking about their perceived state, and detecting their symptoms (eg, gait disturbances or falls). The acquisition of these data will enrich patients' perception of their own condition and will allow the comparison between their insight and the clinical and instrumental data. Health professionals, from their perspective, can take advantage of all these data by adapting the prescribed therapy in a highly personalized manner. Thus, patient-doctor communication will be improved, facilitating patients' engagement with their own health care process.

Central to the study is also the implementation of the PC4L solution in the rehabilitation centers, as such controlled environments involve patients in different kinds of activities, under the supervision of a multidisciplinary team. Here, patients perform personalized treatments in dedicated rooms, such as motor training and exercises connected to ADL, as well as cognitive exercises to improve memory and attention. The main advantages of PC4L in this scenario are (1) the possibility to provide objective information to professionals to study the evolution, treatment personalization, and rehabilitation suggestions; (2) to check the communication between professionals, patients, and caregivers, especially exercise recommendations based on the evolution of patient's movement skills; and (3) to design a decision support tool taking into account the patient's personal and health condition.

Finally, in the third scenario of day care centers, patients perform activities connected to ADL like at home, but under the supervision of professionals (day care center workers). Additionally, the participation of caregivers in this scenario can support the patients. The benefits are to check the communication between professionals and the caregiver, who does not live in the same house with the patient, and to monitor the patient's evolution.

In this pilot study, as already reported by Espay et al [48], low digital skills could be a limitation to the appropriate use of the PC4L solution and, therefore, the correct monitoring of the participants. The consortium mitigated this risk by adopting simplified age-appropriate questionnaires and tools.

Another risk could be the completion of the recruitment of the patients: for this purpose, the consortium of PC4L has adopted several mitigation measures (described earlier).

Trying to provide a balance between an acceptable benefit-to-burden ratio and the delivery of reliable, clinically

XSL•FO
RenderX

relevant insights, through mobile health (mHealth) technologies, as suggested by Espay et al [49], the main solution of PC4L includes the continuous use of the wristband for monitoring parameters such as steps and levels of physical activity, and the PC4L app, which includes easy but engaging functionalities.

The final goal of the PC4L project is to obtain a good coordinated care model between all involved actors. Future developments of such projects might dwell into the active involvement of caregivers and socio-health professionals and into the support of professionals in the decision-making process, to facilitate efficient communication between all stakeholders and ensure reliable and protected access to data within Europe [8].

Acknowledgments

The authors thank the patients, caregivers, and professionals who agreed to participate in this study; the researchers from the study sites; and all the consortium members of the Personalized Integrated Care Promoting Quality of Life for Older People (PC4L) project. PC4L is funded by the European Commission via the Horizon 2020 program (grant agreement number 875221).

Data Availability

The data sets generated during or analyzed during this study will be available from the corresponding author on reasonable request.

Abstract

Background: According to the World Bank, Malaysia reported an estimated 97 tuberculosis cases per 100,000 people in 2021. Chest x-ray (CXR) remains the best conventional method for the early detection of pulmonary tuberculosis (PTB) infection. The intervention of artificial intelligence (AI) in PTB diagnosis could efficiently aid human interpreters and reduce health professionals' work burden. To date, no AI studies have been evaluated in Malaysia.

Objective: This study aims to evaluate the performance of Putralytica and Qure.ai software for CXR screening and PTB diagnosis among the Malaysian population.

Methods: We will conduct a retrospective case-control study at the Respiratory Medicine Institute, National Cancer Institute, and Sungai Buloh Health Clinic. A total of 1500 CXR images of patients who completed treatments or check-ups will be selected and categorized into three groups: (1) abnormal PTB cases, (2) abnormal non-PTB cases, and (3) normal cases. These CXR images, along with their clinical findings, will be the reference standard in this study. All patient data, including sociodemographic characteristics and clinical history, will be collected prior to screening via Putralytica and Qure.ai software and readers' interpretation, which are the index tests for this study. Interpretation from all 3 index tests will be compared with the reference standard, and significant statistical analysis will be computed.

Results: Data collection is expected to commence in August 2023. It is anticipated that 1 year will be needed to conduct the study.

Conclusions: This study will measure the accuracy of Putralytica and Qure.ai software and whether their findings will concur with readers' interpretation and the reference standard, thus providing evidence toward the effectiveness of implementing AI in the medical setting.

Introduction

Tuberculosis is a contagious disease that leads to substantial morbidity and mortality worldwide. It is caused by the *Mycobacterium tuberculosis* bacteria (MTB). Tuberculosis is spread from infected people to others through the air. Even though tuberculosis is curable and preventable, the World Health Organization (WHO) estimated that 10 million people contracted tuberculosis and 1.6 million people died from it worldwide in 2021 [1]. In Malaysia, the incidence of tuberculosis is alarming, where 21,186 cases were reported in 2021 with an estimated 97 cases per 100,000 people, which is growing at an average annual rate of 1.96% [2].

The diagnosis of active tuberculosis is made either by skin test, blood test, chest x-ray (CXR), sputum acid-fast bacilli (AFB) smear and culture, polymerase chain reaction, or a combination of these tests. CXR remains the best conventional method for early detection of pulmonary tuberculosis (PTB) infection and the most recommended method for tuberculosis prevalence survey due to its high sensitivity [3]. The specificity of CXR for PTB could be more significant than evaluating symptoms alone, depending on how the CXR is read. Triage using CXR will also help to minimize the number of individuals undergoing bacteriological tuberculosis testing without reducing the detection of true tuberculosis cases [4]. Despite numerous advantages, the lack of qualified radiologists who can interpret CXR images, especially in high–tuberculosis burden countries, and the high inter- and intrareader variability are among the substantial drawbacks of implementing CXR as one of the diagnostic tools [4]. This leads to the impairment of screening efficacy and scale-up efforts [4,5]. Thus, the introduction of artificial intelligence (AI) in medical imaging with multiple technological approaches aided in reducing those obstacles [6,7].

AI is the ability of a digital computer or machine to perform tasks commonly associated with intelligent beings [8]. The rapid development of information technology worldwide and its use in multidiscipline practice make AI a new area of interest, especially in the medical profession [9]. Recently, approaches to using innovation in the health care system to support patient care are highly sought-after comorbidities. Thus, with AI technology, medical imaging (digital x-ray) can reduce the period of tuberculosis management, and patients with tuberculosis can receive early treatment. At present, various AI methodologies for the diagnosis of tuberculosis are being developed, that is, general regression neural network, multilayer neural network, convolutional neural network (CNN), artificial immune system, fuzzy logic controller, and real-world tournament selection, all of which have yielded promising accuracy for tuberculosis detection [10]. The capability of AI to recognize tuberculosis-related abnormalities via CXR, especially in mass screening with minimal time, has substantially improved and outperformed the human interpreter, thus reducing the work burden of health professionals [11]. Several studies have evaluated the efficacy and accuracy of using AI worldwide [12], but no such study has been carried out in Malaysia.

Therefore, this study aims to evaluate the performance of Putralytica and Qure.ai software for CXR screening and PTB diagnosis among the Malaysian population.

Methods

Sampling Design

This is a retrospective case-control AI software evaluation study that will take place at 3 different health facilities: the Respiratory Medicine Institute, National Cancer Institute, and Sungai Buloh Health Clinic. The study is expected to take 1 year to complete. We will collect CXR images from all adults (≥15 years) who meet the inclusion criteria for this study (Textbox 1). A total of 1500 CXR images will be retrieved; 500 of which will be abnormal PTB cases, 500 of which will be abnormal non-PTB cases, and 500 of which will be normal cases (healthy control). In this study, these images will serve as the reference standard. Primary demographic data from the CXR reports (patient's age, gender, and race), patients' clinical investigations and medical history (symptoms, CXR interpretation, and comorbidity), and laboratory results (AFB smear, MTB culture, and GeneXpert assay) will be collected by assessing electronic or hard-copy medical records.

XSL•FO
RenderX

Textbox 1. Inclusion criteria.

Inclusion criteria for abnormal pulmonary tuberculosis (PTB) cases

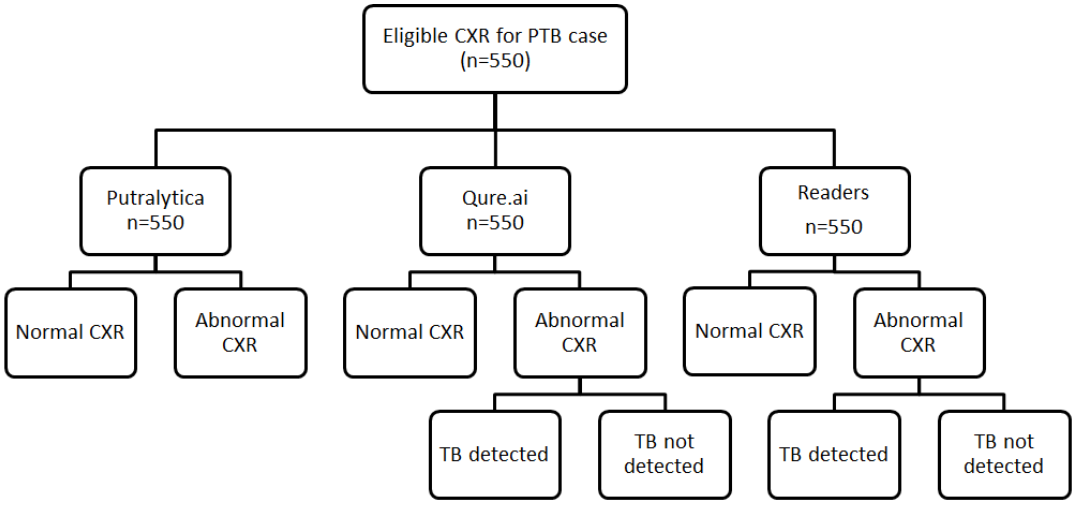
- Aged 15 years and older
- One chest x-ray (CXR) per PTB case or mix case with other lung pathology who completed treatment for tuberculosis
- One CXR per patient upon diagnosis
- Spectrum of severity is reflective of real clinical setting

Inclusion criteria for abnormal non-PTB cases

- Aged 15 years and older
- One CXR per abnormal case (non-PTB case)
- One CXR per patient upon diagnosis
- Spectrum of disease(s) is reflective of real clinical setting

Inclusion criteria for normal cases (healthy control)

- Aged 15 years and older
- One CXR per healthy control
- Latest CXR image is used



Sample Size Calculation

According to a sample size estimation when comparing sensitivities (Sn) or specificities (Sp) in a matched-groups diagnostic study in radiology research, a total of 1500 CXR images are needed in this study. It was calculated with the assumption that the probability of disagreement between both AI software is 0.131, with the highest Sp/Sn being 0.95 and the lowest Sp/Sn being 0.91, a power of 80%, and significant level of 5%:

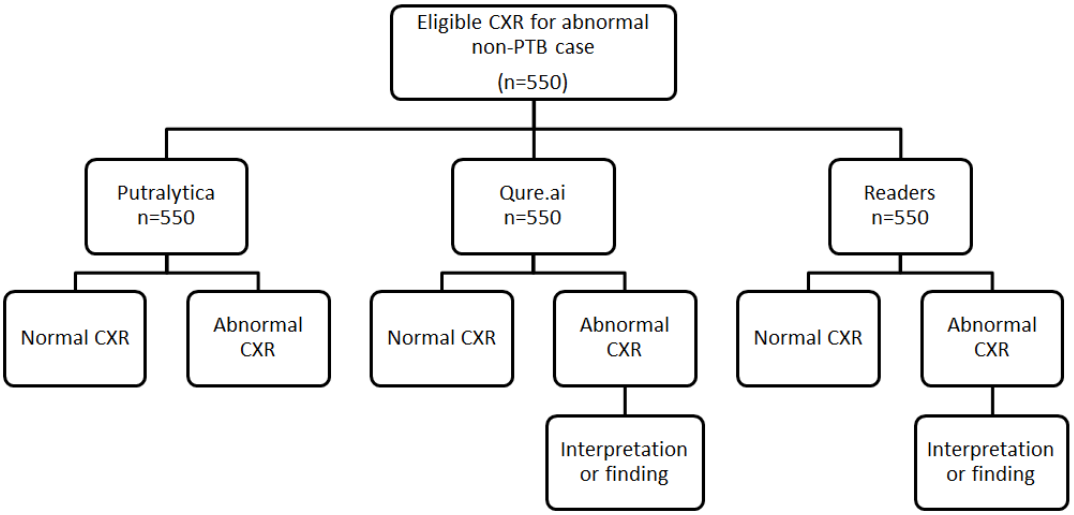
Work Flowchart

The reporting of this study will adhere to the Standard for the Reporting of Diagnostic Accuracy Studies (STARD) guidelines. The work flowchart for CXR images of each case is shown in Figures 1-3.

Figure 1. Work flowchart for chest x-ray (CXR) images of abnormal pulmonary tuberculosis (PTB) cases. TB: tuberculosis.

XSL•FO
RenderX

Figure 2. Work flowchart for chest x-ray (CXR) images of abnormal non-PTB cases. PTB: pulmonary tuberculosis.



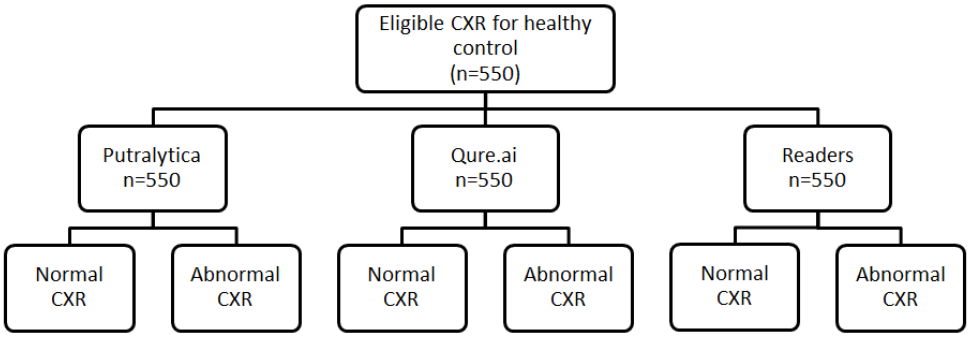


Figure 3. Work flowchart for chest x-ray (CXR) images of normal cases (healthy control).

Reference Standard

The reference standard in this study is the interpretation of the preselected CXR images according to the 3 aforementioned categories. First, an abnormal PTB case is defined as a patient with PTB who had been prescribed and completed PTB treatment based on the following criteria: formal diagnosis; symptom status; CXR interpretation; and results from laboratory investigation, including AFB smear, MTB culture, and GeneXpert assay. Second, an abnormal non-PTB case is defined as any patient with lung abnormalities that are not PTB, based on the following criteria: formal diagnosis, symptom status, and CXR interpretation. Third, a healthy control is defined as any healthy person with normal CXR, including health screening and contact with a person with PTB who completed follow-up, based on the following criteria: formal diagnosis and CXR interpretation.

Index Test

Qure.ai (India)

Qure.ai is a CXR screening tool that detects signs of pulmonary, hilar, and pleural tuberculosis. The AI algorithm underlying Qure.ai is trained to detect normal and abnormal CXR images, classical primary PTB, and atypical manifestations. The software is trained and validated using a data set of over 2.5 million CXR images worldwide. Qure.ai classifies findings from the CXR into 3 categories: active tuberculosis, nonactive tuberculosis and other lung or chest abnormalities, and normal. The final interpretation generated by this software is either PTB or not PTB, together with a conclusive radiological finding for abnormalities other than PTB. The AI algorithms produce a continuous abnormality for threshold scoring (from 0 to 1), representing the probability of the presence of tuberculosis. It claims to yield an accuracy of >90%, with the established threshold of 0.5 by the AI developer. The software can be accessed with or without an internet connection.

Putralytica (Malaysia)

Putralytica is a web-based platform that uses machine learning and automatic detection of pathology. This AI software is a type of CNN that can interpret normal and abnormal CXR only. The CNN was trained and internally validated using an open-access public CXR data set from the National Institutes of Health containing 112,120 frontal view CXR images. The software was developed using the Python 3 language with the KERAS and Tensorflow 2.0 application programming interface framework. The AI algorithms produce a continuous abnormality for threshold scoring (from 0 to 100), representing the probability of the CXR abnormality. It claims to yield an accuracy of >85%, with the established threshold of 60% by the AI developer. The software can be accessed with or without an internet connection.

Readers' Interpretation

The readers consist of 3 professionals with varying levels of experience in the radiology field: a clinical radiologist with >10 years of service, a clinical radiologist with <10 years of service,

XSL•FO
RenderX

and a medical officer who works in the radiology department. These readers will be oblivious to clinical and sociodemographic information about patients, and they will analyze the CXR images independently. They will fill out a structured form to provide their interpretation based on the given variables.

Case Definition

Clinically Diagnosed Tuberculosis

A clinically diagnosed tuberculosis case is a patient who does not fulfil the criteria for bacteriological confirmation but has been diagnosed with active tuberculosis by a clinician or other medical practitioner, who has decided to give the patient an entire course of tuberculosis treatment. This definition includes cases diagnosed with x-ray abnormalities or suggestive histology and extrapulmonary cases without laboratory confirmation. Clinically diagnosed cases subsequently found to be bacteriologically positive (before or after starting treatment) should be reclassified as bacteriologically confirmed [13].

Bacteriologically Confirmed Tuberculosis

A bacteriologically confirmed tuberculosis case is a patient from which a biological specimen is positive by smear microscopy, culture, or WHO-recommended rapid diagnostic tool such as the GeneXpert MTB/RIF assay. All such cases should be notified, regardless of whether tuberculosis treatment has started [13].

Working Definition

In this study, a PTB case is defined as an abnormal CXR (suggestive of PTB), clinical finding with a formal diagnosis suggestive of PTB, a laboratory investigation suggestive of the presence of tuberculosis, or any combination of these. An abnormal non-PTB case is defined as any abnormal CXR excluding the PTB cases, and a normal case for healthy control is defined as any normal CXR finding.

Data Collection and Data Handling

A structured form will be designed to retrieve and collate data from the existing reports of CXR examination and laboratory investigation with AI software–interpreted results and the readers' interpretation. The information will be kept in an assigned documented file where it can only be accessed by the investigators. Considering the duration of this research project and to allow the process of publishing the findings, the research data will be stored and archived for 18 months. Afterward, the research data will be destroyed by permanently deleting the file from the storage hard disk.

Ethics Approval

Ethics approval had been granted by National Medical Research Register and Medical Research and Ethics Committee. Permission to conduct the study is upon approval by the State Health Director.

Privacy and Confidentiality

For all data, privacy and confidentiality will be maintained. The result of the study will be anonymized. The information revealed will not allow the identification of any individual participants. The result will also be in an aggregated form and will not identify any individual or address. Only those involved with this study and data analysis will have access to the data.

Dissemination

The analysis results will be presented in technical or scientific meetings at the state or Ministry of Health level and published as technical reports or journal articles. Details of individuals will not be disclosed but will only be reported in an aggregated form.

Statistical Analysis

All retrieved data will be downloaded and exported to the SPSS software (IBM Corp) for analysis. Data will be grouped based on the variable, description, and data type to facilitate analysis (Table 1). The results of CXR interpretation from both software and the readers will be specified solely based on the description provided (Table 2). This is done to avoid lengthy reader responses and ensure interpretation consistency and uniformity. Descriptive analysis will be used to describe the sociodemographic and clinical characteristics of the patients. Data analysis will be performed for both AI software against the reference standard by constructing 2×2 tables to determine true positive, false positive, false negative, and true negative results. The overall diagnostic accuracy parameters and their 95% CIs will be computed: sensitivity and specificity, positive likelihood ratio, negative likelihood ratio, Youden index, and area under the curve. Cohen κ statistic will be applied to determine interrater agreement among the readers and between the readers' and the AI software's interpretations.

Results

Data collection on sites is expected to commence in August 2023, once the funding has been granted. It is anticipated that 1 year will be needed to conduct the study. Data collection will commence in phase 1 of the project (3-5 months), whereas CXR image distribution for readers' interpretation will take place in phase 2 of the project (3-6 months). All results will be collated and presented at the state and ministry levels. Reports and manuscripts will be produced throughout 2024 after obtaining approval and resolution from all parties involved.

Discussion

This study considers biases commonly overlooked by researchers, particularly in diagnostic accuracy studies. To reduce the spectrum of bias (disease and nondisease), this study will include a variety of CXR abnormalities, not only to detect the presence of PTB but also other abnormalities, with CXR images chosen based on severity level. All CXR images will be in the form of digitalized images to standardize the methodology and reduce measurement bias. Most studies only focused on software performance or the agreement between radiological interpretations of CXR image results independently. Some studies do not use MTB culture and GeneXpert assay as bacteriological evidence in their reference standard, and some do not even compare the performance of the AI with human readers. This study, indeed, will incorporate all variables and analyses into a single comprehensive assessment. The difficulty we encountered while conducting this study was the need to visit several sites to collect CXR images for use as the standard reference. We had to adjust various processes and workflow to get the patients' information without interfering with the staff's primary responsibilities at the study sites. In the future, this study will be instrumental in proving that AI is appropriate when there are various obstacles, whether in clinical settings or fieldwork. In clinical settings, AI can alleviate the burden on medical personnel, particularly in areas where imaging technology is widely used with large workloads. In fieldwork, AI is very beneficial for prevalence studies involving data collection in remote areas and studies that require interpreting numerous results quickly and accurately.

Acknowledgments

We would like to thank the Director General of Health Malaysia for allowing us to publish this study protocol. The authors have not declared any grant for this research from public, commercial or nonprofit sector funds. The manuscript submission and publication will be funded by the Ministry of Health Malaysia. The artificial intelligence developers had no role in the study design, data collection, analysis plan, or study writing. The developers only had access to the chest x-ray images and did not receive any of the participants' demographic, symptom, medical, or testing data.

Authors' Contributions

MFMH conceived the idea and study methods, was involved in data extraction, and contributed to the drafting and editing of the manuscript. NAL, ENM, and FNA aided data extraction and contributed to the drafting and editing of the manuscript. MIM and ZAB supervised the preparation of the protocol and reviewed the manuscripts. All authors have approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Generalized anxiety disorder (GAD) is a highly prevalent and severely distressing condition that can lead to functional impairments and is considered one of the most difficult anxiety disorders to treat. Following new technological developments, a highly structured cognitive behavioral therapy (CBT) approach that has already shown success in face-to-face psychotherapy can be implemented: internet-delivered CBT (iCBT). There is now evidence for the efficacy of both guided and unguided iCBT interventions for GAD regarding symptom reduction.

Objective: To establish the usefulness of such interventions, we plan to evaluate the efficacy of a web-based self-help program (Selfapy) for GAD in a relatively large sample. We aim to assess effects beyond symptom reduction, including effects on well-being, functioning, and mental health literacy, as well as the effect on health care burden, while testing the intervention in conditions comparable to routine care.

Methods: Patients (n=156) who have been diagnosed with GAD, are aged between 18 and 65 years, have internet access, and have sufficient German language skills will be recruited for this study. The intervention group (n=78) will receive access to the 12-week self-help web-based program Selfapy. The waitlist control group (n=78) will receive no intervention in the context of the study. However, both groups will be allowed to access further health care services (eg, psychotherapy, medication), reflecting current routine care in Germany. Outcome measures will be assessed at baseline (T1) and 6 weeks (T2) and 12 weeks (T3) after the start of the intervention. The primary outcome will be generalized anxiety symptoms and quality of life at T3. Additional outcomes include depression, work capacity, therapy-related expenses and burdens, health literacy, and negative effects.

Results: By May 2023, all participants had finished the trial and the report was being prepared for publication.

Conclusions: Web-based interventions may be an important addition to the German health care system to reduce barriers to treatment access. Further, they may prove cost-effective for the treatment of GAD.

Introduction

Background

Generalized anxiety disorder (GAD) is characterized by generalized and persistent excessive worry about various aspects of the past, present, or future without being confined to specific environmental conditions [1]. GAD can lead to severe distress and limitations in the daily lives of those affected [2] and is often associated with comorbid depressive disorders [3]. Subsequently, GAD poses an economic challenge to the health care system [4,5]. Lifetime prevalence is estimated at 6.2% [6].

GAD can be successfully treated by pharmacotherapy or psychotherapy [7]. Still, as individuals affected by GAD show lower response rates to therapies than other anxiety disorders, it is considered one of the most challenging anxiety disorders to treat [8]. One reason may be that individuals with GAD wait on average about a decade until they begin treatment [9]. Therefore, many cases remain undiagnosed and untreated, especially in the context of long waiting times and limited resources [9]. Following technological advancements, technology-based treatment alternatives have been increasingly developed over the past years to address the aforementioned problems [10]. Cognitive behavioral therapy (CBT) is especially suited for the transfer to web-based interventions due to its highly structured, directive, and standardized nature, as well as its emphasis on psychoeducation and homework [11]. In addition to being independent of limited resources, internet-delivered CBT (iCBT) also provides easier access for those who reject traditional forms of therapy due to stigma or other reasons [12].

Systematic reviews and meta-analyses [13] suggest that the use of iCBT programs for GAD compared to inactive control groups was significantly more effective and had moderate to large effect sizes (Hedges g=0.79) in reducing GAD symptoms. Further, iCBT programs for GAD achieved comparable effects to face-to-face CBT while the time required for each patient was 7.8 to 13 times less [14-17]. Of particular note is the benefit of iCBT to the health care system, as it may be a more cost-effective treatment alternative for GAD [18] since it can help reduce the waiting time for outpatient therapy, which averages 5 months in Germany [19] and has increased since the beginning of the COVID-19 pandemic [20].

While most of the literature focuses on guided forms of iCBT with therapeutic support, minimally guided, self-directed iCBT programs also show large effect sizes in the treatment of GAD (eg, Cohen d=2.43 [21]). Dear et al [22] found no significant differences between guided and unguided iCBT in terms of symptom reduction, completion rates, and satisfaction in the treatment of GAD. Moreover, first evidence suggests that characteristics of the guidance, such as the frequency of supportive monitoring [23], type of reminder (eg, phone, email), and the experience or training of the support person [24], do not have a significant influence on GAD symptom reduction. Nevertheless, it is important to take steps to promote adherence and minimize the typically high dropout rates of web-based, particularly self-directed, interventions [25] (eg, motivational content).

Objective

Taken together, minimally guided web-based interventions provide a low-threshold method of access to mental health care and may be particularly helpful for GAD patients who often do not seek help [9]. We aim to establish further evidence for a web-based self-help program in a setting comparable to routine care. For this purpose, a comparison is made with a wait-list control group within a randomized controlled trial framework. Further, we want to address outcomes beyond symptom reduction, such as functioning in both daily life and the workplace, as well as mental health literacy and the health care burden.

Methods

Participants

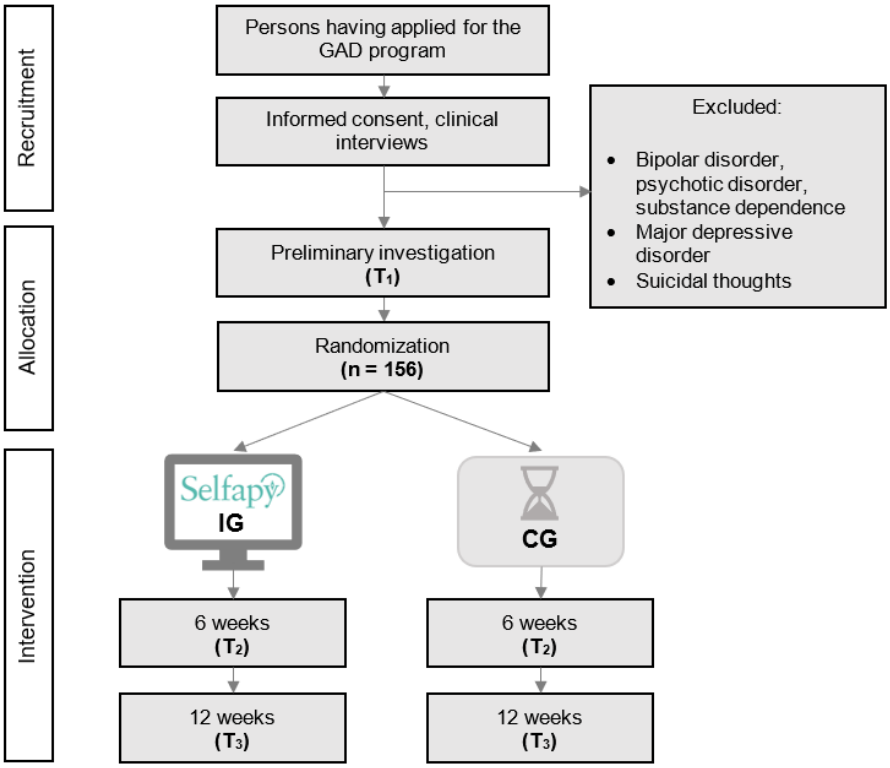
Recruitment is carried out through newsletters and social media advertising drawing attention to Selfapy. Interested individuals can register for participation on the web, and after a successful video call–based screening procedure they will be contacted by the study center to schedule a diagnostic appointment.

Video calls will be conducted with all subjects, during which eligibility will be evaluated based on a diagnostic interview, the Diagnostic Interview for Mental Disorders–Open Access (DIPS-OA) [26]. Trained interviewers with at least a master's degree (or equivalent) in psychology focusing on clinical psychology will conduct all interviews. The interviewers are trained at the Justus Liebig University in Giessen, Germany. Furthermore, there is close supervision on questions of diagnostics, as well as the inclusion and exclusion criteria, by a psychotherapist licensed in CBT.

Eligible subjects (1) are aged between 18 and 65 years, (2) have sufficient knowledge of the German language, (3) have uninterrupted internet access, (4) provide electronic informed consent to participate in the study, and (5) currently meet the diagnostic criteria according to the Diagnostic and Statistical Manual of Mental Disorders [1] for a diagnosis of GAD (International Classification of Diseases, 10th Revision code F41.1).

Subjects will be excluded if they do not fulfill any of the inclusion criteria or meet any of the following exclusion criteria: (1) past or current diagnosis of bipolar disorder, (2) past or current diagnosis of psychotic disorder, (3) current diagnosis of substance dependence, (4) current diagnosis of a severe major depressive episode, and (5) acute suicidality. A primary diagnosis of a disorder other than GAD is not an exclusion criterion, as we want to represent routine care. However, substance dependence, bipolar disorder, or psychotic illness are exclusion criteria because they conflict with the implementation of the program. Subjects who do not meet our inclusion criteria due to severity of illness are encouraged to seek professional help. Adequate language skills will be determined during the initial interview.

Study Design



A 2-arm randomized controlled trial is being conducted to test the efficacy of the minimally guided web-based program Selfapy

XSL•FO
RenderX

for GAD. The web-based course is defined as minimally guided as it is completed independently by the participant. However, as part of the patient safety concept, a psychologist monitors the participant's progress to support the patient and respond to adverse events, such as suicidality. The participants can ask a psychologist questions about the program via an integrated messaging function. Figure 1 shows the schematic study design for patients in the intervention group and control group. After a structured diagnostic interview (DIPS-OA [26]) to clarify the inclusion and exclusion criteria, eligible patients will receive the first questionnaire and subsequently will be randomly assigned to the intervention group or control group. Patients in the intervention group will be able to use Selfapy immediately after randomization, while the control group will only have access to Selfapy after a waiting period of 12 weeks. Interim and final evaluations will occur 6 weeks (T2) and 12 weeks (T3) after the entry survey.

Subjects in the intervention group will have free access to the 12-week internet-based self-help treatment. Participants are advised to spend at least 15 to 20 minutes per day on the program. If no module is finished over 4 weeks, this will be counted as a dropout for an additional sensitivity analysis. Patients in the control group will not receive any treatment or support from the researchers during the first 12 weeks after the initial survey. However, they are free to seek any other assistance they desire, including pharmacological and psychological treatments. All concurrent therapies will be repeat-measured using self-reports.

Figure 1. Flowchart of the study design for intervention and control groups. GAD: generalized anxiety disorder; CG: control group; IG: intervention group.

Measures

Table 1 provides an overview of survey instruments at each time point, and more detailed descriptions are also provided below.

XSL•FO
RenderX

Table 1. Survey instruments at each time point.

Time point	Survey instrument

Pretreatment measurement (T1)	• Video interview: Diagnostic Interview in Mental Disorders–Open Access (DIPS-OA).
	• Primary outcomes (self-assessed via web-based questionnaire)
	  • Generalized anxiety disorder symptomatology (Generalized Anxiety Disorder–7; GAD-7)
	  • Quality of life (World Health Organization–Five Well-Being Test; WHO-5)
	• Secondary outcomes (self-assessed via web-based questionnaire)
	  • Coping with difficulties in everyday life due to illness (Work and Social Adjustment Scale; WSAS)
	  • Work Capability (Institute for Medical Technology Assessment Productivity Cost Questionnaire; iPCQ)
	  • Health Literacy (Mental Health Literacy Scale; MHLS).
	  • Reduction of therapy-related expenses and burdens for patients and their relatives (Client Sociodemographic and Service Receipt Inventory; CSSRI)
	• Secondary outcomes
	  • Demographic questionnaire
	  • Anxiety symptomatology (Beck Anxiety Inventory; BAI)
	  • Depressive symptoms (Patient Health Questionnaire–9; PHQ-9)

Intermediate measurement 6 weeks after T1 (T2)	• Same as T1, except that there is no video interview
	• Further surveys
	  • Negative effects (Negative Effects Questionnaire; NEQ)
	  • Short demographic questionnaire

Posttreatment measurement 12 weeks after T1 (T3)	• Same as T2

Video Interview

The DIPS-OA [26] is used to classify mental disorders and record inclusion and exclusion criteria. The person conducting the interview is part of the evaluation team (ie, part of the Faculty of Psychology and Sport Science, Giessen University) and independent of Selfapy.

Primary Outcomes

Generalized anxiety disorder symptoms will be assessed with the Generalized Anxiety Disorder Scale–7 (GAD-7 [27]). The GAD-7 consists of 7 statements rated on a 4-point scale and has an internal consistency of α=.92.

The measurement used to assess well-being is the World Health Organization–Five Well-Being Test (WHO-5 [28]). The WHO-5 consists of 5 items rated on a 6-point Likert scale and has an internal consistency of α=.92.

Secondary Outcomes

Coping with functional impairments will be assessed with the Work and Social Adjustment Scale (WSAS [29,30]), which consists of 5 items for which the true score is given as a number between 0 and 8. The WSAS is used to assess the degree of functional impairment in various domains. The WSAS has been used in comparable studies, such as a study by Gräfe et al [31]. The internal consistency of the WSAS ranges from α=.70 to α=.94 [30].

Work ability and productivity are assessed via the Institute for Medical Technology Assessment Productivity Cost Questionnaire (iPCQ [32]). The iPCQ asks about long-term (>2 weeks) and short-term (<2 weeks) absences from work. In addition, the iPCQ includes three questions on productivity losses as a result of illness-related work efficiency limitations. The iPCQ was validated by Friedli et al [33].

The Mental Health Literacy Scale (MHLS [34]) will be used to measure mental health literacy. The MHLS consists of 20 items, of which the first 15 items are rated on a 4-point Likert scale and the remaining items are rated on a 5-point Likert scale. The internal consistency of the overall scale is α=.87. The MHLS has previously only been validated in English and was translated into German for this study with the involvement of a natively bilingual collaborator in a translation-backtranslation process.

Therapy-related expenses and burdens for patients and their relatives are captured using the Client Sociodemographic and Services Receipt Interview (CSSRI [35]). The CSSRI asks participants to report the actual service utilization (eg, contact with health care providers, number of therapy sessions, amount of contact with psychotherapists and psychiatrists).

Additional Outcomes

The Penn State Worry Questionnaire (PSWQ [36]) is used to assess worry as an accompanying syndrome of GAD; it consists of 16 items rated on a 5-point Likert scale. The PSWQ shows internal consistencies approximately in the range between α=.84 [37] and α=.86 [38] in GAD patients.

The Beck Anxiety Inventory (BAI [39]) is used to assess the severity of anxiety in adults and adolescents. It consists of 21 descriptive statements rated on a 4-point scale. The internal consistency of the BAI is α=.90 in clinical samples. The German version was validated by Margraf and Ehlers [40].

The Patient Health Questionnaire-9 (PHQ-9 [41]) is used to assess the presence and severity of depressive disorders. The PHQ-9 consists of 9 items rated on a 4-point Likert scale and has an internal consistency of α=.89.

To capture possible negative effects of the intervention, the Negative Effects Questionnaire (NEQ [42]) is used, which

XSL•FO
RenderX

consists of 32 items rated on a 4-point Likert scale. The NEQ has an internal consistency of α=.95.

The adherence of the intervention group is recorded via the log files of the web-based platform Selfapy. The number of modules that have been worked on is recorded.

Hypotheses

The main objective of this trial is to determine the efficacy of the 12-week Selfapy course for patients with GAD compared to a wait-list control group. Additional outcome data will be collected at 6 weeks. However, our confirmatory hypotheses, which will evaluate a positive health care effect, will focus on the 12-week outcomes. The following 2 hypotheses refer to our primary outcomes:

- GAD symptomatology (measured with the GAD-7 [27]) will significantly decrease with the use of the Selfapy course for GAD after 12 weeks compared to a wait-list control group.
- Perceived quality of life (measured with the WHO-5 [28]) will significantly increase after 12 weeks of the Selfapy course for GAD compared to a wait-list control group.

The following secondary outcomes will only be analyzed if the hypotheses for the primary outcomes are confirmed. They will also be tested using Bonferroni-Holm adjustment:

- Difficulties in daily life (measured with the WSAS [30]) will significantly decrease after using the Selfapy course for GAD after 12 weeks compared to a wait-list control group.
- Using the Selfapy course for GAD will lead to significantly better recovery of working ability (measured with the iPCQ [32]) after 12 weeks compared to a wait-list control group.
- Health literacy (measured with the MHLS [34]) will significantly improve with the use of the Selfapy course for GAD after 12 weeks compared to a wait-list control group.
- The extent of therapy-related efforts and burdens of patients and their relatives (measured with the CSSRI [35]) will be significantly reduced after using the Selfapy course for GAD compared to a wait-list control group after 12 weeks.

Our exploratory hypotheses do not address the target symptoms and are therefore not adjusted for α accumulation:

- Worry symptoms (measured with the PSWQ [36]) will significantly decrease with the use of the Selfapy course for GAD after 12 weeks compared to a wait-list control group.
- Self-rated anxiety symptoms (measured with the BAI [39]) will significantly decrease with the use of the Selfapy course for GAD after 12 weeks compared to a wait-list control group.
- Self-rated depressive symptoms (measured with the PHQ-9 [41]) will significantly decrease with the use of the Selfapy course for GAD after 12 weeks compared to a wait-list control group.
- The Selfapy course for GAD will not lead to any side effects compared to a wait-list control group after 12 weeks (measured with the NEQ [42]).

Intervention

Selfapy is a program for the treatment of GAD [43]. The program uses evidence-based methods and exercises based on CBT and elements of mindfulness-based therapy (see, eg, Hoyer et al [44] and Volz and Stieglitz [45]). The web-based course consists of a core course, which includes mandatory and optional exercise content, and a subsequent set of modular specialization areas that are individually selectable (Table 2). The program can be used via desktop browsers and mobile devices. The web-based course is divided into different lessons, each covering a specific topic, such as exposure, mindfulness, or problem-solving training, and consists of informative texts, videos, audio, and interactive exercises. Table 2 provides an overview of the core course with examples and possible in-depth areas and gives a brief overview of their content.

XSL•FO
RenderX

Table 2. Overview of modules with example content of the generalized anxiety disorder program.

Module	Content
Your start	In the first module, users can describe their problems and set personal goals.
First findings	This module focuses on psychoeducation. Users learn to recognize and understand the background of their problems. In addition, users begin keeping a worry log to identify triggers and patterns regarding their worries and fears.
The mental level	This module deals with the thoughts behind the users' anxiety disorder. With the help of various exercises, users learn to question their worries and replace them with more realistic thoughts.
The physical level	In this module, users learn about the fear response and the physical symptoms of generalized anxiety disorder.
The behavioral level	In this module, users learn about how avoidance and reassurance contribute to maintaining their anxiety disorder and how the 3 levels of anxiety interact.
The first exposure	In this module, users are introduced to exposure-based methods. They learn how exposure works and why it is helpful in the treatment of anxiety disorders. Users will also receive information on how to perform an in sensu exposure and consider when to do so.
The second exposure	This lesson is dedicated to in vivo exposure. Users are informed about what it looks like and what to consider when performing it.
Optional areas of specialization	
Self-efficacy	In this module, users learn about self-efficacy. Through various exercises, they are trained in self-efficacy so as to believe more in themselves and their abilities.
Mindfulness	A mindful approach to life can have a supportive effect to better deal with one's problems. With the help of formal and informal mindfulness exercises, users learn how to integrate a mindful approach to themselves into everyday life.
Social environment	This module deals with the impact of the social environment on one's own life. Through social networks and communication exercises, users can optimize their social support and strengthen their social skills.
Problem solving training	This module provides training in problem-solving skills. Users learn to perceive a concrete problem, grasp reaction possibilities, and implement an action to change the situation.
Your anti-anxiety package	In the final module, users take stock of the completed course. They summarize which content was particularly helpful and where they can still improve their anxiety disorder. At the end of the program, the user gains an antianxiety package to use when problems arise again or a relapse has already set in.

Randomization and Blinding

Subjects meeting the inclusion criteria will be randomly assigned to 1 of 2 groups and will receive either (1) immediate access to the minimally-guided Selfapy GAD course (the intervention group) or (2) access to the Selfapy GAD course after a waiting period of 12 weeks (the control group).

Randomization takes place after the participant has finished the entry questionnaire, which is conducted by a member of the psychology department who is not involved in the project, using a computer-assisted procedure. Random assignment is done only if participants fulfill the inclusion criteria for the study. Until this time, which group the person will be assigned to if included is unknown (allocation sequence concealment). Participants will be assigned to 1 of the 2 groups in a nonstratified 1:1 ratio. Subjects will be informed of the outcome of the random assignment via email. Participants are told that the waiting time will randomly vary between 0 and 12 weeks. Thus, patients in the control group will not know that the sample is divided into 2 groups. One group will start the intervention immediately while the other group will wait 12 weeks before receiving access to the therapy. The diagnostic interviewers will be blind to the group membership of the participants. After completing data collection, statistical analysis of the outcomes will also be performed in a blinded manner.

Power and Sample Size

The between-group effect size estimate is based on recent meta-analytic evidence for effect sizes in unguided web-based psychological interventions for anxiety disorders (Cohen *d*=0.45; see, for example, McCall et al [46]). Even though Selfapy is minimally guided, we chose this meta-analysis since the degree of guidance is not associated with the effect size [16,17]. This effect size will be used as the basis for sample size design. For the planned mixed model with 2 measurement time points with a general correlation structure [47], a directed hypothesis, a group allocation of 1:1, a power of 0.80, and an α level of .025 after Bonferroni-Holm correction, a total of 156 patients (n=78 per group) are needed. The number of cases was calculated using the R tool *longpower* [48]. For the secondary outcomes, this sample size yields a power of $1-\beta=.67$.

Statistical Analyses

For the psychometric outcome analyses, all patients who were randomly assigned to the 2 conditions and completed the initial survey (T1) will be included in an intention-to-treat (ITT) analysis. All available data will be used for this purpose. Missing values in the data will be replaced by multiple imputations (multivariate imputation by chained equations with n=5 imputations) based on the control arm, using the variables "age" and "gender" as predictors in addition to the measurement-repeated stress indicators. In addition,

XSL•FO
RenderX

last-observation-carried-forward, baseline-observation-carried-forward, reference-based-multiple imputation (jump-to-reference approach [49]), and completer sensitivity analyses will be performed.

The confirmatory analysis of the primary outcomes consists of calculating a mixed model with 2 measurement time points and a general correlation structure [47]. A random effect for the subjects is calculated (random intercept) and 3 fixed effects (group assignment, time, and the interaction of the 2 predictors). The 2 measurement time points are nested within subjects. The primary outcomes will be evaluated using a Bonferroni-Holm correction for α error inflation. Secondary confirmatory outcomes will only be analyzed if the results of the primary analysis confirm the hypotheses, and the same mixed model with a random intercept for the subject will be applied. Again, a Bonferroni-Holm correction will be used.

Independent 2-tailed *t* tests and chi-squared tests will be used to estimate differences between groups in pretreatment sample characteristics. In addition to the ITT sample, a "per-protocol" sample sensitivity analysis is defined for exploratory analyses, including all patients in the intervention group who completed at least 4 of the modules.

There are different approaches to calculating effect sizes for mixed modeling data in the literature [50]. Hedges [50] and Westfall et al [51] propose an effect size based on the Cohen *d*, which is also used for power analysis [47]:

To assess the magnitude of the treatment effects, the fixed interaction effect of time and group assignment is divided by the root of the summed variances of the random effects. Effect sizes can be roughly interpreted according to the Cohen *d*: effect sizes of 0.2 are considered small, 0.5 moderate, and 0.8 large [52]. Differences in response rates and additional health care service utilization rates are examined with 2-tailed *t* tests and chi-squared tests.

All data analyses are performed without knowing group membership (blinded data analysis). The evaluator does not know which expression of the group variable indicates membership in the intervention group and which indicates membership in the control group. Multimedia Appendix 1 shows example code for the R analysis of the outcomes.

Ethical Considerations

Participants are asked about suicidality at all measurement time points (T1, T2, and T3). For safety reasons, subjects will be contacted if they report suicidal thoughts and an emergency plan is drawn up with them. Nevertheless, the subject's data will not be passed on to the police or other authorities. If participants endorse suicidality, they will be excluded from further data analyses, and only the assessments up to the occurrence of suicidality will be used.

The study center at the University of Giessen is responsible for storing and analyzing patient data. Besides the initial interview, all data are collected via a web-based platform (SoSci Survey; SoSci Survey GmbH) that uses SSL encoding to protect the data and stores them on servers located in Germany. Participant data are stored pseudonymously in order to access contact data in cases of suicidality. However, after the study is finished, the data will be immediately deidentified. Written informed consent is obtained from all participants before participation, and the ethics committee of the Faculty of Behavioral and Empirical Cultural Science at the study center at Heidelberg University approved the clinical protocol (AZ Prüß 2021 1/1). The trial is registered at the German Clinical Trials Register (DRKS00023800) and follows the ethical principles of the Declaration of Helsinki. All patients receive an allowance of €30 (US $33) after completing the study.

Results

By May 2023, all participants completed the study, and a paper reporting the results is being prepared. The report will be submitted for publication in the coming months.

Discussion

This study tests the efficacy of a minimally guided web-based intervention (Selfapy) for the treatment of GAD in routine clinical care. The study has several strengths. First, the study was designed to strike a balance between a high degree of internal validity (eg, randomization, a standardized diagnostic procedure), allowing us to attribute observed group differences to the intervention with sufficient certainty and a high external validity (eg, allowing participants to use additional health care services) to evaluate the effects in an ecologically valid context. In particular, we did not prepare artificial measures to increase adherence to gain a representative impression of routine care patient adherence. Second, to the best of our knowledge, this study is one of the most highly powered studies on iCBT for GAD [13]. Third, we will investigate outcomes beyond symptom reduction, such as functioning and health care use. Limitations of this study include the lack of an active control group instead of a wait-list control group, even though this design allows only limited conclusions regarding the specificity of the effects found. We chose this design in an attempt to assess the incremental effect of Selfapy for GAD patients compared to the current situation in the German health care system. Patients who want to undergo outpatient psychotherapy in Germany have to wait for an average of 20 weeks to start treatment [19]. One of the main advantages of an internet intervention like the one investigated in this study is its availability. If implemented in routine clinical care, patients can make use of these interventions without delay and can expect results comparable to traditional face-to-face therapy [14]. One could argue that the waiting period in the control group (12 weeks) is too short, given the average waiting time in the health care system of 20 weeks. Still, we decided to restrict the waiting time in the control group to 12 weeks for several reasons. First, for ethical reasons, we wanted to limit the waiting time as much as possible. Withholding a likely helpful intervention should only be done as long as necessary. Again, we want to highlight that patients in the control group, as well as those in the intervention group, were allowed to seek additional treatment and help if they thought it necessary. No patients were asked to refrain from any

XSL•FO
RenderX

other mental health services. Second, 12 weeks is the time the intervention takes when completed on the recommended schedule. Therefore, fixing the control group to the same measurement schedule as the intervention allows us to evaluate the effects of having access to Selfapy for GAD compared to not having access to this intervention. Another limitation lies in the use of deception in telling the patients that the intervention will start some time between 0 and 12 weeks later. This is done to attenuate dissatisfaction with being in the control group. However, patients in the control group may still feel dissatisfied and unlucky when they have to wait what they think is the maximum amount of time for the intervention. Also, we do not assess the frequency of personality disorders, which may be reasonable because GAD is associated with higher rates of personality disorders [53]. Further limitations include the lack of follow-up measurement, the lack of a power calculation for the secondary outcomes, and the lack of a mindfulness measure despite the intervention including a mindfulness-based approach.

Due to current technological progress, the implementation of web-based interventions may be an important addition to the German health care system. This may reduce barriers to treatment provision and complement current clinical care. Therefore, we aim to assess a routine-care web-based intervention for its impact on symptom reduction, well-being, work capability, and other measures of disease burden.

Acknowledgments

This study was funded by a European Regional Development Fund awarded to Selfapy. The Professorship for Psychotherapy Research at the University of Giessen was asked by Selfapy to independently evaluate its product to the best of our knowledge and following the standards of good scientific practice. Selfapy made suggestions for the selection of survey instruments in the study's design but had no influence on the data collection, analysis, and interpretation or production of the resulting publication.

Data Availability

The data sets generated during the upcoming study will be available in the OSF repository [54].

Authors' Contributions

JR, JQ, LR, and CL wrote the manuscript. LP, CT, SH, SB, and DR read the manuscript and provided critical feedback. All authors were included in the planning phase of the study.

Conflicts of Interest

None declared.

Abstract

Background: The Pregnancy and Newborn Diagnostic Assessment (PANDA) system is a digital clinical decision support tool that can facilitate diagnosis and decision-making by health care personnel in antenatal care (ANC). Studies conducted in Madagascar and Burkina Faso showed that PANDA is a feasible system acceptable to various stakeholders.

Objective: This study primarily aims to evaluate the effects of the PANDA system on ANC quality at rural health facilities in Burkina Faso. The secondary objectives of this study are to test the effects of the PANDA system on women's satisfaction, women's knowledge on birth preparedness and complication readiness, maternal and child health service use, men's involvement in maternal health service utilization, and women's contraception use at 6 weeks postpartum. Further, we will identify the factors that hinder or promote such an app and contribute to cost-effectiveness analysis.

Methods: This is a randomized controlled trial implementing the PANDA system in 2 groups of health facilities (intervention and comparison groups) randomized using a matched-pair method. We included pregnant women who were <20 weeks pregnant during their first antenatal consultation in health facilities, and we followed up with them until their sixth week postpartum. Thirteen health centers were included, and 423 and 272 women were enrolled in the intervention and comparison groups, respectively. The primary outcome is a binary variable derived from the quality score, coded 1 (yes) for women with at least 75% of the total score and 0 if not. Data were collected electronically using tablets by directly interviewing the women and by extracting data from ANC registers, delivery registers, ANC cards, and health care records. The study procedures were standardized across all sites. We will compare unadjusted and adjusted primary outcome results (ANC quality scores) between the 2 study arms. We added a qualitative evaluation of the implementation of the PANDA system to identify barriers and catalysts. We also included an economic evaluation to determine whether the PANDA strategy is more cost-effective than the usual ANC strategy.

Results: The enrollment ran from July 2020 to January 2021 due to the COVID-19 pandemic. Data collection ended in September 2022. Data analyses started in January 2023, ended in June 2023, and the results are expected to be published in February 2024.

Conclusions: The PANDA system is one of the most comprehensive apps for ANC because it has many features. However, the use of computerized systems for ANC is limited. Therefore, our trial will be beneficial for evaluating the intrinsic capacity of the PANDA system to improve the quality of care. By including qualitative research and economic evaluation, our findings will be significant because electronic consultation registries are expected to be used for maternal health care in the future in Burkina Faso.

Introduction

Background

Antenatal care (ANC) is one of the strategies that contributes to reducing maternal and neonatal mortality. In the early 2000s, the concept of ANC was introduced and refocused to be more efficacious [1-3]. Essential activities such as the prevention of anemia and malaria in pregnant women, preparation for delivery and obstetric emergencies, and advice on good nutrition for women and newborns have found their place in the new vision of ANC [4]. In addition, the World Health Organization (WHO) guidelines recommend 8 antenatal visits to the clinic so that each point of contact will ensure a smooth and safe pregnancy [5]. According to the WHO, increasing the frequency of ANC visits for women and adolescents is associated with a reduced risk of stillbirths. These visits provide additional opportunities to detect and manage potential problems [5]. Additionally, regular antenatal visits to the clinic increase the chance of delivering at a health facility [6].

Despite the importance of ANC, data on the use of services by pregnant women remain scarce in sub-Saharan Africa [7-9]. Several reasons could explain this situation, including the quality of care and satisfaction of pregnant women with health services. Nikiema et al [10] showed that the different steps of ANC are not carefully adhered to, ignored, or misunderstood by health care providers in Burkina Faso. Tiembré et al [11] who evaluated the quality of ANC in Grand-Bassam (Ivory Coast) reported that the interpersonal communication skills of the health care providers with patients were poor. It is essential to systematically follow the different stages of ANC to provide quality care to pregnant women. One solution to improving the quality of ANC is the standardization of care, obliging health workers to systematically follow all the steps of ANC consultation [12-14]. Therefore, the use of mobile apps and telemedicine seems appropriate. The WHO insists on using mobile apps to provide maternal and child health care because these apps play an essential role in improving the quality of health care services [15]. In 2013, the World Health Assembly passed numerous resolutions on information and communication technologies in the health care sector. The use of apps in health care has been noted to be related to reduced health care costs, improved quality, and equitable access to health services [15]. The application of information and communication technologies in the health sector includes client education and behavior change, medical record management, electronic decision support, quality care in health services, human resource management, and supply chain management [16].

Concerning decision support and quality of care, ANC has been a particular focus of mobile app interventions. However, different studies [12-17] show contrasting results. In 2018, Chen et al [18] conducted a systematic review of 245 studies, including 51 randomized controlled trials, on the effectiveness and appropriateness of mobile apps for maternal and child health care between 2011 and 2016. Their results showed that mobile apps had no effect on the quality of health care in approximately half (43%) of the randomized controlled trials.

The Pregnancy and Newborn Diagnostic Assessment (PANDA) system [19,20] is a digital clinical decision support tool that facilitates diagnosis and decision-making by health care personnel in ANC. Feasibility and acceptability studies of the PANDA system have been conducted in Madagascar and Burkina Faso [14,21]. The study [21] conducted in the Koupéla district of Burkina Faso in 2016 with the nongovernmental organization, Enfants du Monde, Switzerland, showed that the PANDA system is a feasible tool for improving the quality of care for pregnant women and for collecting detailed information in the electronic form. The women in that study [21] expressed high satisfaction with the antenatal visits using this telemedicine system except for the average duration of ANC (women found that the average duration of ANC is high with the PANDA app), which would increase with the app use. The health care workers expressed their satisfaction with the service improvements and noted the different steps of ANC according to the recommendations of Burkina Faso. In the PANDA app, the different steps of ANC are presented in an imposed chronology to the health care provider. The completeness of the data for all fields conditions the passage from one stage to the next. Therefore, it is impossible to omit information. Following these encouraging results, the Ministry of Health of Burkina Faso expressed interest in using the PANDA telemedicine system for maternal and neonatal health care to improve the quality of care. Hence, we plan to implement a randomized controlled trial to evaluate the effectiveness of PANDA in improving the quality of ANC.

Study Objectives and Hypothesis

The objective of this study was to evaluate the effects of the PANDA system on the quality of ANC in Burkina Faso. We hypothesize that the PANDA telemedicine system improves (1) the quality of ANC provided to pregnant women, (2) women's satisfaction, (3) women's knowledge on birth preparedness and complication readiness, (4) maternal and child health service use, (5) men's involvement in maternal health service utilization, and therefore (6) postpartum contraception use.

Study Setting

This study was conducted in Burkina Faso, where the ANC rate varies according to the area of residence. The 2010 Demographic and Health Survey and Multiple Indicator Cluster Survey (Burkina Faso Enquête Démographique et de Santé et à Indicateurs Multiples [EDSBF-MICS IV]) showed that 1.5% and 5.7% of the pregnant women did not attend antenatal visits in the urban and rural areas, respectively [22]. Moreover,

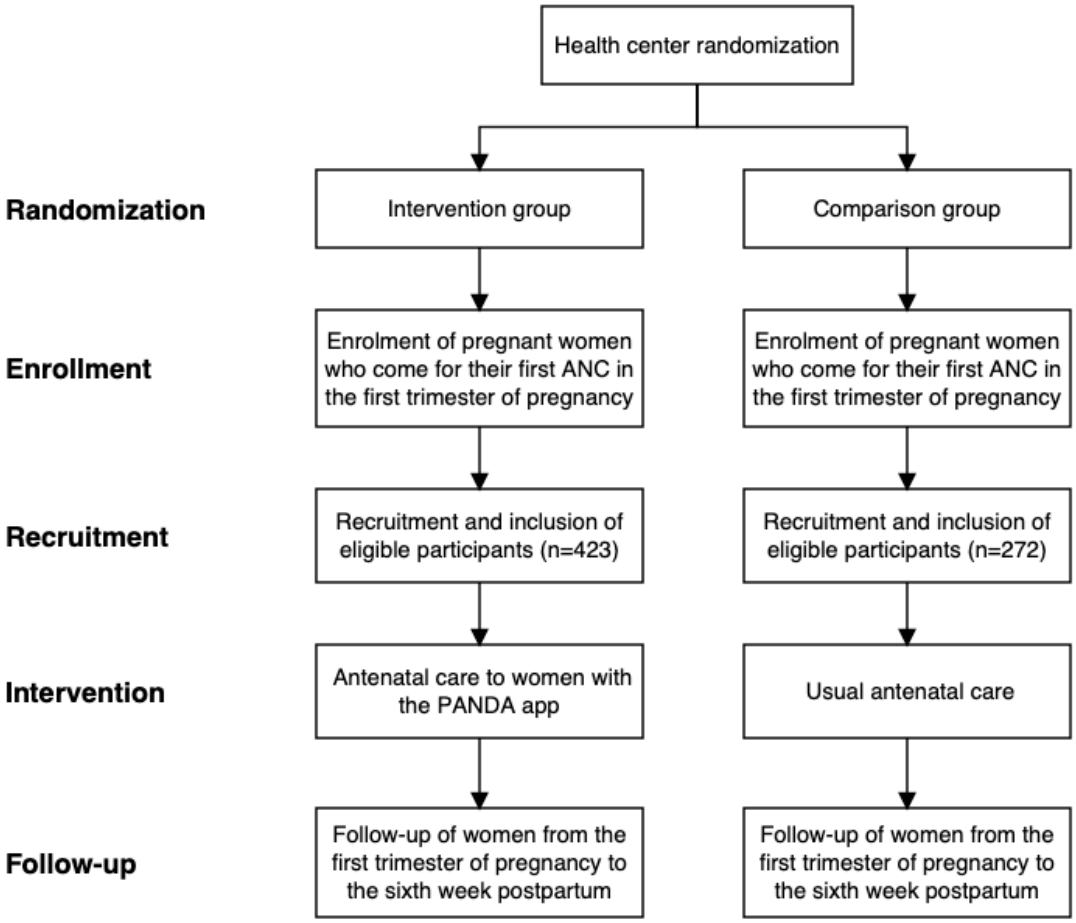
XSL•FO
RenderX

according to the EDSBF-MICS IV, only 33.7% of the pregnant women have received at least 4 ANC consultations as recommended by the WHO. Only 41.2% of the women had their first ANC visit in the first trimester of pregnancy, and the median number of months of pregnancy at the first ANC visit was 4.4 months at the national level [22]. Among the women who received ANC for the most recent birth 5 years before 2010, only slightly more than half (53%) had been informed about the signs of pregnancy complications. In ANC, it is crucial for pregnant women to know the pregnancy danger signs. The EDSBF-MICS IV also showed that almost all women (95%) received ANC from a trained provider, and the majority (61%) of these trained providers were auxiliary birth attendants. Midwives provided ANC for 17% of the women, and nurses examined almost the same proportion of women (16%). Approximately one-third of the women (34%) had at least 4 antenatal visits, which aligns with the Burkina Faso Ministry of Health's recommendations. There were significant differences between the areas of residence in Burkina Faso: in Ouagadougou (Burkina Faso's capital), 54% of the women attended the 4 recommended visits compared with 38% in other cities and only 31% in rural areas [22]. The consequences of this low access to maternal, newborn, and child health services are high maternal and infant mortality rates. One in 8 children die before 5 years, and the maternal mortality ratio was 341 deaths per 100,000 live births in 2010 [22]. We chose the health district of Koupéla (Centre-East Region of Burkina Faso) because of its proximity to Ouagadougou. At that time, there were no ongoing ANC interventions in this district. The other reason for choosing this district is that the PANDA feasibility test was conducted in this district in 2016.

Methods

Conceptual Framework of This Study

Our research project consists of implementing an intervention called the PANDA telemedicine system. This study phase, which we call the interventional phase (as it follows the design and feasibility phases of the intervention), involves 2 groups of health facilities in the same district (an intervention group and a comparison group). We compared the effects of the intervention with those of the usual ANC offered in the comparison group through a cluster randomized trial. The interventional phase also employs qualitative research and a cost-effectiveness study at the end of the trial. The qualitative research identifies the barriers and catalysts of using the PANDA system for ANC in the intervention group. The cost-effectiveness analysis provides information on the costs of implementing the PANDA system in Burkina Faso. The expected effects of the app are improvement in (1) the quality of ANC provided to pregnant women, (2) women's satisfaction, (3) women's knowledge of birth preparedness and complication readiness, (4) use of maternal and child health services, (5) men's involvement in maternal health service utilization, and (6) contraception use at 6 weeks postpartum. The long-term impact of this app is the reduction of maternal and neonatal mortality.



Cluster Randomized Controlled Trial

Study Design

In this study, the intervention is the PANDA telemedicine system. It involves 2 groups of health facilities in the same district (an intervention group and a comparison group). The intervention group offered ANC using the PANDA app installed on tablets. Each health facility in this group had at least one tablet. The health centers in the comparison group offered ANC as usual (the PANDA app was not used in these health facilities). The rationale for implementing a cluster randomized trial is that the intervention (training and use of the PANDA system) cannot be implemented at the individual (pregnant woman) level but only at the health center level. The study design is shown in Figure 1.

XSL•FO
RenderX

Figure 1. Study design. ANC: antenatal care; PANDA: Pregnancy and Newborn Diagnostic Assessment.

Participant Eligibility Criteria

The participants were pregnant women with gestational age between 14 and 20 weeks of amenorrhea, regardless of age, residence, and socioeconomic level. They were screened for eligibility for this study: first by health care workers on arrival and second by the data collectors of this study. Any pregnant woman who met the following criteria was eligible for this study: (1) <20 weeks of gestation, (2) belonging to the health facility area, (3) no plan to travel in the next 9 months (from inclusion in this study to 6 weeks postpartum), (4) not taking part in any other ongoing research, (5) volunteering to participate, (6) being in a clinical and obstetrical condition that allows delivery at the health center (no need to refer to the next level), and (7) has the intention to deliver in that health center.

Interventions

PANDA is a telemedicine system developed through a private-public partnership in Italy, with funding from the European Union, in collaboration with the WHO. The PANDA system was designed to meet the health care needs of women during pregnancy in resource-scarce settings by expanding and standardizing ANC according to the WHO guidelines. The PANDA system, designed for use by low-skilled health care workers such as community health care workers, supported remotely by skilled personnel, aims to standardize and improve the quality of ANC visits. In addition, the system can automatically generate and provide the data necessary to measure its performance. The original PANDA system, as designed for use by community health care workers, consists of 3 integrated components (see Figure 2).

1. The PANDA phone: This smartphone with an Android app allows for a standardized and quality antenatal visit by using pictograms according to the national and WHO guidelines. The health care workers enter the women's data and obstetrical and medical-surgical history into the system. The system also includes pages for medical tests to ensure that health care workers perform these tests. At the end of the visit, the PANDA phone sends the data and test results to the medical unit.
2. The PANDA point of care: A series of medical tests are performed to screen for anemia, syphilis, HIV, malaria, eclampsia, diabetes, and malnutrition. The test results are entered manually or via Bluetooth into the PANDA phone.
3. PANDA medical unit: A database system receives data from the PANDA phone, establishes diagnoses and the management of pregnant women, and maps pregnancies in the region. The PANDA medical unit in the maternity ward typically consults this database.

XSL•FO
RenderX

Figure 2. The Pregnancy and Newborn Diagnostic Assessment system. PANDA: Pregnancy and Newborn Diagnostic Assessment.

The PANDA system used in our proposed study is like the system used in the pilot feasibility and acceptability study in 2016 [21]. It has already been adapted to the Burkinabè context. The PANDA system will be integrated into the Burkinabè health system and used by the Ministry of Health's care providers in the health center under the supervision of the district management team. The PANDA app and the PANDA medical unit will be readapted to the new national norms and standards for ANC, which are currently under revision based on the new "WHO Recommendations on Antenatal Care for a Positive Pregnancy Experience" [4]. To adapt the tool to other telemedicine systems in practice in Burkina Faso, tablets have replaced smartphones. A user's manual for the PANDA app was made available to the stakeholders for the judicious use of the app. We organized several forms of training to explain better the use of the PANDA app (user training at the health center and medical unit levels).

Outcomes

The primary outcome is a binary variable derived from the quality score. It will be coded 1 (yes) for women with at least 75% of the total score and 0 if not (Table 1). The quality score considers all the components of good ANC according to the gestational age of the pregnancy. The different components are grouped into 7 main dimensions with items. These items are derived from Burkina's guidelines on ANC [23]. The categorization is that each woman has a total score for each ANC (from the first consultation to the last).

Table 1. Summary of the components of quality antenatal care.

Item (1 if yes, 0 if no)	Data source
Antenatal consultation performed	Woman's health card reports
Partner's presence at the consultation	Item asked to the woman
Possession of a verified health record	Woman's health card reports
Pregnancy test performed	Woman's health card reports
Date of last period requested	Item asked to the woman
Probable date of delivery given to the pregnant woman	Item asked to the woman
Hypertension was investigated	Item asked to the woman
Asthma was investigated	Item asked to the woman
Testing for sickle cell disease	Item asked to the woman
Diabetes was investigated	Item asked to the woman
Surgical history was obtained	Item asked to the woman
Number of pregnancies was queried	Woman's health card reports
Number of deliveries was queried	Woman's health card reports
Number of abortions or miscarriages was queried	Woman's health card reports
Number of caesarean deliveries was queried	Woman's health card reports
Number of living children was queried	Woman's health card reports
Alcohol consumption queried	Woman's health card reports
Tobacco use queried	Woman's health card reports
Sugar and albumin levels in the urine measured	Woman's health card reports
Syphilis test performed	Woman's health card reports
An HIV test was offered to the woman	Woman's health card reports
HIV test was performed	Woman's health card reports
Blood pressure measurement	Woman's health card reports
Fetal heart sounds recorded	Woman's health card reports
Search for edema of the feet and face	Woman's health card reports
Weight gain	Woman's health card reports
Temperature checks	Item asked to the woman
Physical examination: uterine height measured	Woman's health card reports
Physical examination: vaginal touch performed	Woman's health card reports
Physical examination: decision on obstetrical prognosis (normal pelvis, borderline pelvis, etc)	Woman's health card reports
Tetanus vaccination verified and performed	Woman's health card reports
Hepatitis B vaccination verified and performed	Woman's health card reports
Antianemia prophylaxis (iron–folic acid) prescribed	Woman's health card reports
Antianemia prophylaxis: woman explains dosage correctly	Item asked to the woman
Prescribed antimalarial prophylaxis	Woman's health card reports
Malarial prophylaxis: woman explains dosage correctly	Item asked to the woman
Danger signs of pregnancy explained to the woman	Item asked to the woman
Place of delivery discussed	Item asked to the woman
Importance of exclusive breastfeeding explained	Item asked to the woman
Early breastfeeding of the baby has been advised	Item asked to the woman
Maternal nutrition: good feeding practices discussed	Item asked to the woman

XSL•FO
RenderX

Item (1 if yes, 0 if no)	Data source
Postpartum contraception was discussed	Item asked to the woman
Use of an impregnated net was explained	Item asked to the woman
Newborn care was explained	Item asked to the woman
The childbirth preparation plan was discussed	Item asked to the woman
The woman was asked to raise concerns where appropriate	Item asked to the woman
The next meeting was negotiated	Item asked to the woman
Summary of the antenatal care written in the woman's health record	Woman's health card reports

The secondary outcomes to measure include the satisfaction of pregnant women (measured at each ANC), women's knowledge on birth preparedness and complication readiness (measured in the first trimester and just before delivery), use of maternal health services, men's involvement in health service use (defined as the proportion of men who accompany their wives to the health centers for ANC sessions and delivery and the proportion of men who attended an ANC session or delivery), and finally, the women's use of postpartum family planning (measured at the sixth week postpartum).

Other Variables

We collected women's sociodemographic characteristics such as women's age, education, marital status, residence, and occupation. We also collected data on women's autonomy (Multimedia Appendix 1). We asked the women, in some situations, regarding who makes the final decision: herself, her husband, mother-in-law, father-in-law, or any other person. She could name more than one person if the decision was made collectively. These autonomous situations or items could be small household expenses, major household expenses, women's expenses, women's job, buying children's clothes, where to go for advice if her child is ill, where to go to see a doctor if she is ill, buying medicines, visiting her parents (when or where), number of children in her household, and using the family planning method. The woman's autonomy variable will be derived from these variables (composite index) and will have 3 modalities (low autonomy, moderate autonomy, and high autonomy).

Sample Size

In addition to the desired statistical power and percentage of potential lost to follow-up, the calculation of the required size considered several statistical features inherent to the design of the study, such as the number of participants per cluster, the intraclass correlation coefficient (ICC), and the inflation factor [24-27]:

1. Number of participants: To be practical and comfortable with data collection, we considered 40 women per health center, excluding those lost to follow-up.
2. ICC: This measures the extent of the cluster effect and assesses the degree of similarity between the individuals within a cluster. It is based on the relationship between the intercluster variance and the intracluster variance. For this reason, the sample sizes must be increased to account for the clustering effect. In particular, the value of ICC depends on the unit of randomization and the type of outcome. In our case, we have women likely to come from the rural areas of several health zones. Given the composition of health care workers in rural health centers (midwives and birth attendants), it is reasonable to assume that there will be slight variations between women moving from one health center to another. For this, we propose an ICC of 0.015.
3. Inflation factor: The increase required to account for the cluster effect is influenced by ICC and cluster size. The standard sample size was increased by an inflation factor equal to $[1 + (n – 1) \rho]$, where n is the average cluster size and ρ is the estimated ICC. By numerical application, inflation factor = 1.585.
4. The desired statistical power was 80%.
5. The margin of error was 5%.
6. The estimated proportion of those lost to follow-up was set to 10%.

Using Stata 15.1 software [28], health centers needed to detect a difference of at least 15% (80% in the intervention group vs 65% in the control group) in the proportion of women with an excellent ANC quality score in 6 health centers in each group. Considering the loss to follow-up proportion at 10%, the minimum final size required is 264 women in each group with 12 health centers, except the urban health facility. The hypothetical proportion of 65% in the comparison group was derived from a study conducted in Ghana in 2019 by Baafi et al [29].

Participant Recruitment

The health care providers recruited the participants during the ANC sessions after history taking and physical examination. After screening a potentially eligible woman, her consent (free and informed decision) to participate in this study was obtained after she received all the necessary information from the data collector.

Randomization

Facilities were randomized using a matched-pair method. Health centers were selected by identifying 6 pairs of comparable health centers. The matching criteria were (1) number of total ANC visits in the year before the trial, (2) number of total deliveries in the year before the trial, (3) number of total postnatal care visits in the year before the trial, (4) number of women of childbearing age in the health center area, (5) total number of health care workers in the health center as well as the distribution by profile (midwives, nurses, and auxiliary birth attendants), and (6) size of the population served. These matching variables allow us to obtain facilities within each pair

XSL•FO
RenderX

that are similar to each other regarding these matching factors. Within each pair, the center that received the PANDA app was chosen randomly using the draw of 1 health center from each pair; the names of the health centers were previously arranged in individual envelopes and sealed. The drawer was different from the one who prepared the envelopes and did not attend the sealing. The draw, therefore, was carried out 6 times. All consecutive and eligible participants were included in the clusters.

To assess women in the semiurban environment (city of Koupéla), we included the health center in Koupéla, which unfortunately could not be matched to another city, given its size and characteristics. To minimize the likelihood of cross-group contamination, facilities are chosen to ensure they are far enough apart. Moreover, women generally did not move from one center to another due to the distance between the health centers. They usually visit the same health center for ANC during their pregnancy. We included only the women who were sure they would realize all their ANC visits in the health center where they were included in this study. Lastly, no staff move was noted during the study between the 2 arms. The health centers selected as the study sites are shown in Table 2.

Table 2. Study sites.

	Health center
Pair 1	Baskouré and Kalwêga
Pair 2	Boangtenga and Zaogo
Pair 3	Dialgaye and Yargo
Pair 4	Baadtenga and Sampongho
Pair 5	Gounghin and Ligdi-Malguem
Pair 6	Kabéga and Zéguédéga
One semiurban center	Koupéla health center

Implementation

After the health care workers were trained in the intervention group's health centers, supervisions were organized throughout the data collection period to verify the implementation of the intervention.

Blinding

Given our intervention's nature, blinding the participants and the research team was impossible.

Data Collection Methods

Data collectors were trained before the inclusion of participants on all the procedures of inclusion, follow-up, and how data must be collected (data sources). They were not health care workers. Therefore, the study procedures were standardized across all sites. Data were collected from women on the day of inclusion and at each successive ANC, up to the sixth week after delivery. One data collector was assigned to 2 neighboring health centers for the duration of the study (1 intervention group health center and 1 comparison group health center). The questionnaires were administered to the participants immediately after the antenatal visit, after the delivery, and after each postpartum visit. The interviewer visited the health center according to the ANC schedule. A field coordinator was recruited and responsible for checking all the data collection steps, including the recruitment of participants.

The participant's knowledge was measured at the study inclusion and at the end of pregnancy. This knowledge covered topics such as the danger signs of pregnancy, signs of labor starting, danger signs after childbirth for the woman, and newborn's danger signs. All these signs are normally discussed with the woman at each ANC visit to improve her knowledge to stimulate early consultation if any one of the following signs occur:

1. Danger signs of pregnancy: vaginal bleeding, fever, intense intractable headache, difficulty breathing, convulsions and loss of consciousness, intense abdominal pain, non–bloody vaginal discharge, lack of fetal movement, and feet and hands edema.
2. Signs of the onset of labor: loss of water, painful and regular contractions, and discharge of red and viscous mucus.
3. Newborn danger signs: fever, hypothermia, convulsions, inability to breastfeed, vomiting, pus or bleeding from the cord, purulent discharge from the eyes, jaundice, hypotonia, unexplained crying, abdominal pain, bloating, diarrhea, and difficulty breathing.
4. Danger signs after childbirth for the woman: convulsions, heavy vaginal bleeding, intense abdominal pain, intense headaches, dizziness, rapid or difficult breathing, fever, bad odor discharge from the vulva, and paleness of the mucous membranes.

For each group of signs, there was a proportion of women who knew no signs and a proportion of women who knew at least 3 signs. Furthermore, we measured women's birth preparedness by asking the woman if she had identified a health facility for her delivery or in case of emergency, if she had identified a companion of choice for labor and childbirth, or in case of emergency, if she had planned the financing of the main expenses related to her delivery and if she had identified one means of transport to reach the health facility for the delivery. Those who took precautions for each of the 4 questions scored 1 for each question and 0 if the woman took no precautions. The use of maternal and child health services was measured by the number of ANC visits attended by the woman, place of delivery, postnatal consultation on days 6-10, and postnatal consultation in 6-8 weeks. The different variables with their measurement periods are presented in Figure 3.

Use of postpartum family planning										✓

For this study, data were collected using a closed questionnaire by directly interviewing the women and extracting data from ANC registers, delivery registers, ANC cards, and health care records. To understand the satisfaction of pregnant women, we use a satisfaction scale consisting of very satisfied, satisfied, neutral, not very satisfied, and not at all satisfied, which will be rated as 4, 3, 2, 1, and 0, respectively. The data collector explained to the woman that she is free to give the number of green stars corresponding to her satisfaction level for each subitem listed in Textbox 1 below. The image is shown and explained to the woman in order to rate her satisfaction. The number of green stars chosen correspond to her level of satisfaction with that subitem. The maximum score for each subitem is 4 and the minimum is 0. This satisfaction was measured at each antenatal visit for each woman enrolled in the research. It should be recalled that the data collectors were women without health care training who were recruited and assigned to each health center. Data collectors did not interfere in the care relationship with the women.

Textbox 1. Items and subitems for measuring the satisfaction of pregnant women.

Women's satisfaction with interpersonal relations with staff (5 subitems)

- Welcoming
- Respecting the confidentiality of consultation with the health care provider
- Respecting privacy during consultation
- Respect and courtesy of the health care providers during antenatal care
- Goodbye from staff

Quality of service (9 subitems)

- Waiting time
- Overall time spent in the health center
- Other times to wait for test results
- Health care provider skills
- Explanation of iron–folic acid dosing
- Explanation of malarial prophylaxis
- Explanation of preventive measures against malaria
- Explanation of women's diet
- Explanation of different complementary examinations

Data Management

Data collection was performed electronically by using tablets. Only the identifying information of the participants was collected on paper to maintain the anonymity of the women in the different databases. In both groups, registers, health records, ANC cards, and women's self-report were used for data collection. We developed a data quality assurance plan for the duration of the trial. Implementation was under the supervision of the research team. Confidentiality of the data was ensured by protecting devices with passwords kept in a secure location. A data entry program was developed using the CSEntry Android app of Census and Survey Processing System software [30]. The data manager exported the data to Stata 15.1 for correction and use. We implemented the following measures to ensure effective data management:

1. The information collected during the various contacts with women was verified several times at different levels. Data collectors were responsible for ensuring that all data collected were accurate. They reviewed all the completed forms before uploading them to the server to guarantee completeness and resolve inconsistencies.
2. All data were stored on a server compatible with good clinical practice, and data transmission will be encrypted to ensure data integrity and patient confidentiality. The access to data management was password protected, and only authorized users had access.

Statistical Methods

Quantitative data were extracted and transferred to Stata 15.1 for analysis. We will perform an intention-to-treat and per-protocol analysis of the cluster randomized trial. The unit of analysis will be women. The analysis will compare the intervention and comparison groups' unadjusted and adjusted primary outcomes results. Unbalanced factors between the 2 study groups will be used to adjust the intervention effects on the study outcomes. These factors will be women's sociodemographic factors and women's autonomy. The means and proportion comparison tests for independent samples will be used at the 5% threshold. In case of nonnormality of a quantitative variable (satisfaction scores, knowledge scores, etc), robust or Poisson regression will be used.

Data Monitoring

Since the participants were not given an experimental drug, we did not conduct an interim analysis to determine whether to stop. The team was supervised every month. The management focused on aspects such as the quality of the collected data, careful adherence to every step of the protocol and validated methods, and using the PANDA app. In addition, monthly meetings were held online with all technical and financial partners to resolve difficulties. The supervision and meeting reports were produced and archived systematically.

Ethics Approval

This trial was retrospectively registered with the Pan-African Clinical Trials Registry under PACTR202009861550402 on September 21, 2020. The Burkina Faso Health Research ethics committee approved the research protocol for this trial under approval 2020-3-051. This study does not introduce any new drug treatments. The PANDA system was designed by the standards and protocols in force in Burkina Faso. Any problems identified will be managed according to the procedures and practices in the health system. Adult participants (at least 18 years old) were included after obtaining their informed consent. Minor participants were included by obtaining their assent and parental consent. In the case of minor participants, informed consent of the parent or the respective legal guardian was obtained in conjunction with informed permission of the underage participant (younger than 18 years). The interviewers assigned to the various health centers were responsible for obtaining consent. This process was carefully checked during the field supervision of the research team. All questionnaires in the database did not contain any information that could be used to identify a woman formally. The participants' phone numbers and identities were recorded in a physical document, allowing the interviewer to locate the woman, if necessary, to administer a questionnaire.

Qualitative Analysis of Factors Hindering or Facilitating Implementation

We conducted a qualitative evaluation of the implementation of the PANDA system to identify the interactions (positive or negative) between the intervention and the implementation environment. The target population comprised the intervention group and the resource personnel. The intervention group included women who had recently given birth, providers of the health centers where the PANDA system was used, and resource persons. With women, we measured mainly their perceptions of the quality of care and interactions with health providers. The health care providers were interviewed to give their opinion about the PANDA system's technical aspects, interactions with women, and perceptions of the quality of the medical procedures provided. Given their positions in this research, the resource persons were the key informants. They were the district management team, managers of the medical unit, Directorate of Health Information Systems, Directorate of Family Health, and members of 2 nongovernmental organizations, namely, Enfants du Monde, Switzerland, and the Private and Community Initiative for Health and the Response to HIV/AIDS in Burkina Faso.

Following the reasoned approach, we performed 4 focus groups with women who had recently given birth (1 focus group per center in 4 health centers), 22 in-depth individual interviews, and again with women who had recently given birth in the 7 health centers (3 interviews per center); 18 in-depth individual interviews were conducted with the health workers of the 7 health centers (2 per center, including the medical unit). However, given the size of the CSPS Urbain (the only semiurban center), the number of health workers interviewed was 4. We also conducted 4 in-depth individual interviews with the technical and financial partners. In total, 44 individual interviews and 4 focus groups were performed.

The qualitative component used the semistructured interview [31]. The women were recruited in a reasoned manner from among those included in the study—mainly the last women enrolled in this study to give birth to guarantee the freshness of memory. In addition to the primary data, secondary data were

XSL•FO
RenderX

collected through activity reports (training missions since the beginning, supervision missions conducted by the research team, etc), budgets allocated to program activities, national health policy documents, PANDA app user guide, etc. The explored themes were as follows: the satisfaction of the participants in the intervention group, the acceptability of the intervention to health care workers, and the barriers and catalysts for an efficient and effective implementation of the PANDA system.

Content analysis [32] was used as the data processing and analysis technique. The digitally collected data were transcribed into French and entered into Microsoft Word. The transcribed data were analyzed thematically using a manual approach with the help of analysis tables. The analysis model used was the strengths-weaknesses-opportunities-threats model. It enabled us to identify the interactions (positive or negative) between the intervention on the one hand and the implementation environment on the other. These diversions will allow us to consider the necessary readjustments for greater efficiency and effectiveness of the intervention.

Economic Evaluation

An economic evaluation was added to this research to determine whether the PANDA strategy is more cost-effective than the usual ANC strategy in Burkina Faso's context. The economic assessment collected data from pregnant women (expenses related to antenatal visits), health agents, and financial partners (costs of designing the app, training costs, acquiring equipment, etc). The direct prices included drugs and consumables for health centers. For women, the costs included direct costs such as transport costs for the health center visit and indirect costs, especially the monetary value of the time spent visiting the antenatal service. As ANC is currently free for women, no expenses of ANC-related care are paid by women in principle.

The economic evaluation data were analyzed using Stata software (version 17.1; StataCorp LLC) for the descriptive analyses and R software (version 4.0.2; R Foundation for Statistical Computing) for the Monte Carlo simulations. We also adapted the WHO CostIt tool [33] to calculate the costs according to the ingredients approach [34] for each cost category. Incremental cost-effectiveness was examined based on comparisons of costs and effects between the study groups. We conducted a probabilistic sensitivity analysis by testing the effect of simultaneous variations in several parameters by using Monte Carlo simulations to generate plausible values from the baseline parameter distributions. A total of 10,000 iterations were generated by R programming. A cost-effectiveness acceptability curve was developed based on the willingness to pay to gain a percentage of ANC quality and compared to the gross domestic product per capita of Burkina Faso in 2020.

Results

Participant recruitment in this study was influenced by the COVID-19 pandemic. Although recruitment was planned to start in May 2020, the inclusion finally began only on July 12, 2020, and was done progressively in different health centers included in this study. Participant selection continued until the end of January 2021. The inclusion period extended more than expected because only women at <20 weeks of gestational age were included. There were only few such cases in the study health centers because women usually start their antenatal visits late in Burkina Faso. As women were to be followed up until 6 weeks postpartum, the last data collection interview ended in September 2022. Data analysis was completed in June 2023, and the results are expected to be published in February 2024.

Discussion

Study Overview

With the rise of information and communication technologies and the WHO's recommendations for the use of mobile technology in antenatal health care, several clinical trials using mobile health apps have been conducted with varied results. Most of these clinical trials [12-17] used a mobile text messaging system for sending awareness and information messages to pregnant women. Those studies proposed to measure pregnant women's knowledge and the quality of ANC. Apart from mobile apps, some computerized clinical decision support systems have been implemented. Haddad et al [35] conducted a systematic review of these computerized systems in 2019 and found 9 systems that met their eligibility criteria, including the PANDA system. The PANDA system was found to be one of the most comprehensive apps with several features. However, those authors concluded that the use of these systems for ANC was limited [35]. Adepoju et al [36] conducted a systematic review of clinical decision support systems in sub-Saharan Africa in 2017 and reached the same conclusion. However, they noted that clinical decision support systems could improve patient-provider relationships by building trust in the provision of health services. They also noted that although health care workers are generally enthusiastic about using these types of systems, there are concerns about the effects of increased workload, workflow changes, and technical challenges. These different barriers to implementing health apps were also found by Zakane et al [37] in Burkina Faso. Thus, the added value of these systems remains to be proven. Although studies on the PANDA system have shown that it can provide standardized ANC as per the WHO's guidelines [14], it is still essential to evaluate its intrinsic capacity to improve the quality of care by conducting a high-level evidence study. In this sense, the randomized trial that will be conducted in our research will be of crucial importance because it will help to demonstrate whether, in addition to offering standardized care, the PANDA system allows for an improvement in the quality of care provided to pregnant women, their satisfaction, and their knowledge on birth preparedness and complication readiness. Moreover, considering that Burkina Faso is a country with limited resources, such health policies could be cost-effective; hence, the economic evaluation carried out throughout the implementation is pertinent and essential. In addition, the results of this trial will be significant because computerized clinical decision support systems are anticipated to be implemented in Burkina Faso in the future in several fields, including reproductive health (through the electronic consultation register for maternal care) and child health (through the electronic consultation register for the management of child diseases).

Strengths and Limitations of This Study

The limitations and challenges of this complex intervention include difficulties in coordinating with study sites and challenges related to the COVID-19 pandemic in implementing the intervention, maintaining its fidelity, and keeping the trial on schedule. Although we have designed a cluster randomized controlled trial, neither the study sites nor the participants are blinded to the study conditions because of the nature of the intervention. Moreover, the participating sites are limited to 1 rural district of Burkina Faso; thus, the results may not be generalizable at the national level (no urban facilities are included in this study). However, our results could guide countrywide policies for improving maternal and newborn health, highlighting the benefits of such an electronic decision support system for similar rural African areas where maternal and newborn morbidity and mortality rates are high.

Conclusion

This study will help to determine the proportion of women who receive quality ANC as recommended in clinical standards and protocols and whether electronic registries can help improve ANC in a context of low-quality human resources, like in Burkina Faso. This study's qualitative research and economic evaluation will identify the barriers and facilitators of such an app in resource-limited countries such as Burkina Faso and contribute to the cost-effectiveness analysis of 2 strategies (PANDA vs usual care). In a randomized study design, the results will likely provide a high level of evidence compared to the results already available in the literature, which are from pilot or feasibility studies with smaller sample sizes.

Acknowledgments

We would like to thank the Ministry of Health of Burkina Faso (William ND Ouango, Programmer Analyst, Information Technology Services and Telehealth Department) and the nongovernmental organizations Enfants du Monde (Mouna Al Amine, Program Officer, Switzerland; Cecilia Capello, Health Specialist and Philip Gampfer, Head of Information Technology) and the Private and Community Initiative for Health and the Response to HIV/AIDS in Burkina Faso (specially Ouedraogo Noaga Pascal, Health Advisor, Maieutic Sciences and Reproductive Health Option, and Zeïnab Kaboré Ouédraogo). This study would not have been possible without their support. We also thank Sogo Armel, the data manager of this study; Soulama Arnaud, medical doctor and field coordinator; and all the data collectors involved in this study. Lastly, we also thank this research's funder, Enfants du Monde, Switzerland; the research funder had no role in the study design, data collection, data analysis, data interpretation, or in writing this paper.

Data Availability

The data sets generated and analyzed during this study will be available from the corresponding author upon reasonable request following the completion of the trial and publication of the primary outcome paper.

Authors' Contributions

AC wrote the first draft with important contributions from SK. AC and SK are members of the research team. SK is the principal investigator and AC is the coinvestigator. The authors agree to be accountable for all aspects of this work.

Abstract

Background: Peers are an important determinant of health and well-being during late adolescence; however, there is limited quantitative research examining peer influence. Previous peer network research with adolescents faced methodological limitations and difficulties recruiting young people.

Objective: This study aims to determine whether a web-based peer network survey is effective at recruiting adolescent peer networks by comparing 2 strategies for reimbursement.

Methods: This study will use a 2-group randomized trial design to test the effectiveness of reimbursements for peer referral in a web-based cross-sectional peer network survey. Young people aged 16-18 years recruited through Instagram, Snapchat, and a survey panel will be randomized to receive either scaled group reimbursement (the experimental group) or fixed individual reimbursement (the control group). All participants will receive a reimbursement of Aus $5 (US $3.70) for their own survey completion. In the experimental group (scaled group reimbursement), all participants within a peer network will receive an additional Aus $5 (US $3.70) voucher for each referred participant who completes the study, up to a maximum total value of Aus $30 (US $22.20) per participant. In the control group (fixed individual reimbursement), participants will only be reimbursed for their own survey completion. Participants' peer networks are assessed during the survey by asking about their close friends. A unique survey link will be generated to share with the participant's nominated friends for the recruitment of secondary participants. Outcomes are the proportion of a participant's peer network and the number of referred peers who complete the survey. The required sample size is 306 primary participants. Using a multilevel logistic regression model, we will assess the effect of the reimbursement intervention on the proportion of primary participants' close friends who complete the survey. The secondary aim is to determine participant characteristics that are associated with successfully recruiting close friends. Young people aged 16-18 years were involved in the development of the study design through focus groups and interviews (n=26).

Results: Participant recruitment commenced in 2022.

Conclusions: A longitudinal web-based social network study could provide important data on how social networks and their influence change over time. This trial aims to determine whether scaled group reimbursement can increase the number of peers

XSL•FO
RenderX

referred. The outcomes of this trial will improve the recruitment of young people to web-based network studies of sensitive health issues.

Introduction

Background

Late adolescence is an important time in health and social development when many potentially modifiable health risks arise. This period often includes the exploration and initiation of behaviors including sexual activity, alcohol and other drug use, and the emergence of mental health problems [1]. Peer relationships are one of many interrelated determinants of health during adolescence [1]. For instance, adolescents with peers who engage in tobacco, alcohol, and cannabis use are more likely to initiate these behaviors themselves [2,3]. Despite the acceptance of peers as an important determinant of health, there is little recent quantitative research examining the influence of adolescents' peer networks compared to research focused on the individual. Furthermore, the social environment that adolescents live in is constantly evolving, with more interactions taking place on the internet than in previous generations [4]. There is therefore a need for updated research about the influence of peers in the current context that leverages these new interactions and social connections.

Social network theory is an approach used to understand the influence of adolescents' peers, among other things [5]. In the context of adolescent health behaviors, social network research involves the collection and analysis of information about relationships between individuals and their health behaviors [6]. Research seeks to understand the influence of a peer network and the mechanisms of this influence (eg, social pressure, communication of attitudes and norms, and social support) [6]. Understanding peer influence and its mechanisms can be used to design health interventions that leverage the strengths of adolescents' social networks [7]. The majority of prior social network studies on adolescents have recruited participants from schools, with the "network" cast as entire classes or schools [3]. This recruitment setting produces high response rates and high ascertainment of contacts and links. It also has the potential for demographic diversity within the sample (particularly if several different schools were selected for the study). However, many longitudinal studies of this type were designed with relatively short follow-up periods (eg, 1-2 years) due to students changing classes and leaving school [8-10]. Studying a whole network (eg, an entire school or class) also limits the generalizability of findings to the wider adolescent population. As the network boundary is restricted, respondents are commonly limited to nominating friends from a directory within their class or their school year [11,12]. Alternative recruitment settings in social network research are community or health organizations. These settings were used by studies that sought specific subgroups (eg, youth experiencing homelessness or those with a specific health condition) and where recruitment staff had pre-established relationships with the participants [13,14]. However, studies recruiting from these settings reported difficulties reaching the desired sample sizes at sufficient speed [15,16]. Moreover, analyses of peer influence and sociometry in these studies were limited to egocentric data, meaning that primary participants report on the characteristics and behaviors of their friends, which limits the accuracy and reliability of behavioral reports [14].

Conducting social network research on peer groups using web-based techniques could overcome some of these disadvantages and has the potential to be used in longitudinal studies for the ongoing collection of information about people's social networks beyond school. More broadly, web-based mechanisms are increasingly being used to recruit young people, as researchers have found web-based studies can effectively reach many young people, including those in more marginalized groups such as young people who identify as lesbian, gay, bisexual, transgender, queer, asexual, or other (LGBTQA+) [17,18]. Web-based questionnaires also provide greater privacy during completion than in person- or school-administered questionnaires, which is particularly important for sensitive topics such as sexual health and substance use [19]. To our knowledge, there are no social network studies with adolescents conducted entirely on the internet, but web-based cross-sectional, individual-level surveys have used social media recruitment, specifically Facebook, to recruit young people [17,20,21]. Social media platforms rapidly emerge, update, and outdate, resulting in frequent changes to their popularity and hence their usefulness as recruitment sites.

Web-based respondent-driven sampling (webRDS) offers a model for how we could recruit adolescents' peer networks. Like traditional respondent-driven sampling (RDS), webRDS involves primary participants who are incentivized to recruit a specific number of peers into the study by offering a monetary reimbursement per recruited peer [22]. Studies using webRDS have either recruited the primary participants in person through study administrators [22,23] or used targeted Facebook advertising and phone screening to enroll primary participants [24]. Referral of secondary participants has been facilitated using emails [22,24] or private messages primarily via Facebook [23,24]. Reported benefits of using webRDS were that it was

XSL•FO
RenderX

quicker, cheaper, and overcame barriers related to participants distributing physical coupons compared to RDS [23]. Potential limitations and considerations of webRDS include differences in participant demographics and risk profiles between recruitment using RDS and webRDS [23]. Fraudulent or duplicate cases were identified as a problem due to some participants trying to increase their reimbursement by creating false email addresses to artificially increase their number of referrals [24]. The reimbursements offered for survey completion and friend referral varied between each study, and the impact of the reimbursement was not tested. Therefore, the extent to which a reimbursement affects the recruitment of peers remains an important practical question that impacts the cost and feasibility of conducting a web-based social network study.

Rationale

Our study will address gaps identified in previous research by determining whether a web-based approach is effective in recruiting adolescent peer networks. We will also address how different reimbursement models impact recruitment. In group 1 (experimental group: scaled group reimbursement), all participants within a peer network will receive an additional Aus $5 (US $3.70) voucher for each referred participant who completes the study, up to a maximum total value of Aus $30 (US $22.20) per participant. In group 2 (control group: fixed individual reimbursement), participants will only be reimbursed for their own survey completion.

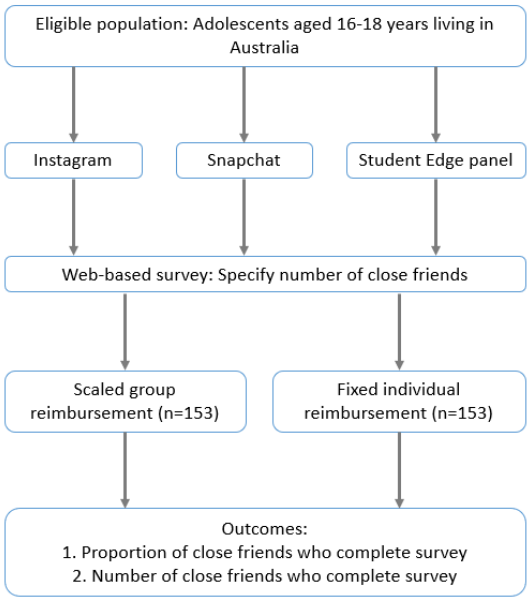
If a web-based social network study proves feasible, this method has the potential to overcome barriers related to conducting longitudinal network research and use this web-based approach to better examine how social networks and their influence change over time. Identifying the characteristics associated with successful peer network recruitment would enable us to determine whether adolescents with certain key demographics or at-risk groups are more or less likely to refer their peers. By identifying these groups, we can gather further feedback and tailor the study methods in the future so that these social networks may be better captured.

Aims and Research Questions

The primary aim of this study is to compare the effectiveness of 2 different financial reimbursement strategies for recruiting young people into a web-based peer network study. This will be explored through the following research questions:

1. Does a scaled group financial reimbursement for peer referral increase the proportion of an individual's close friend network that completes the survey compared to having no peer referral reimbursement?
2. Does a scaled group financial reimbursement for peer referral increase the number of close friends per participant who complete the survey compared to having no peer referral reimbursement?

We hypothesize that a scaled group financial reimbursement for peer referral will result in a significantly higher proportion of participants' close friend networks and a significantly higher number of close friends per participant who complete the survey, compared to a fixed reimbursement rate for individuals.



The secondary aim is to determine what demographic and behavioral factors are associated with successfully recruiting close friends.

Methods

Study Design

This study uses a 2-group randomized trial design to test the effectiveness of reimbursements for peer referral in a web-based cross-sectional peer network survey. Participants will either be randomized to scaled group reimbursement (the experimental group) or fixed individual reimbursement groups (the control group). The trial will be of 60 days duration. Figure 1 illustrates the study design.

Figure 1. Study design.

XSL•FO
RenderX

Participants and Eligibility

This trial involves both primary participants and secondary participants. Primary participants are defined as individuals recruited through the recruitment platforms (Instagram, Snapchat, and the Student Edge panel) and are able to refer their close friends. Secondary participants are individuals nominated by a close friend and referred to the study by a primary participant.

Primary participants will be eligible if they are aged between16 and 18 years and are currently living in Australia. Secondary participants will be eligible if they are aged 16 years or older and currently living in Australia.

Intervention

All primary and secondary participants will receive Aus $5 (US $3.70) as reimbursement for their own survey completion. Primary participants will be randomized to either (1) scaled group reimbursement (experimental) or (2) fixed individual reimbursement (control). In the scaled group reimbursement, all participants within a peer network (ie, the primary participant and all secondary participants) will receive an additional Aus $5 (US $3.70) voucher for each added secondary participant that the primary participant recruits to the study, up to a maximum total value of Aus $30 (US $22.20) per participant. The reimbursement per participant stops increasing at 6 per peer group, but up to 11 people in a peer group can be referred and reimbursed up to Aus $30 (US $22.20) each (1 primary and 10 secondary). In the fixed individual reimbursement, all participants will only be reimbursed Aus $5 (US $3.70) for their own survey completion. Table 1 describes the reimbursement amounts for participants in each group depending on the number of secondary participants who complete the survey within their friendship group.

Table 1. Reimbursements for each intervention group.

Number of participants in friend group who complete survey	Reimbursement value per participant	
	Scaled group reimbursement (experimental)	Fixed individual reimbursement (control)
1 primary; 0 secondary	Aus $5 (US $3.70)	Aus $5 (US $3.70)
1 primary; 1 secondary	Aus $10 (US $7.40)	Aus $5 (US $3.70)
1 primary; 2 secondary	Aus $15 (US $11.10)	Aus $5 (US $3.70)
1 primary; 3 secondary	Aus $20 (US $14.80)	Aus $5 (US $3.70)
1 primary; 4 secondary	Aus $25 (US $18.50)	Aus $5 (US $3.70)
1 primary; 5-10 secondary	Aus $30 (US $22.20)	Aus $5 (US $3.70)

Reimbursements are in the form of a gift voucher sent by SMS to participants' mobile numbers using a third-party service provider at the end of the trial period. However, due to the procedures of Student Edge, primary participants recruited through this setting will receive the initial Aus $5 (US $3.70) reimbursement on survey completion through Student Edge and further reimbursements via SMS at the end of the study, if applicable.

Outcomes

The primary outcome is defined as the proportion of primary participants' close friends who complete the survey. Survey completion is recorded if the secondary participant clicks the final survey submission button. This outcome measure indicates the level of complete data about each primary participant's close friend network.

The secondary outcome is the number of close friends who complete the survey per primary participant. This outcome measure assesses whether the reimbursement model results in an overall higher number of participants.

Sample Size

We calculated the required sample size to test the difference in proportion of an individual's close friend network that completes the survey between the intervention and control groups. Based on previous literature, we estimated that the average number of close friends listed in the survey (nominations) is expected to be 3 [9,11,25], and that approximately half of the primary participants in the scaled reimbursement group would successfully recruit at least one friend into the study [22,23]. Based on these data and assuming that the probability of recruiting each friend is binomial, with the probability of recruiting no friends being $(1–p)^n$, where n is the total number of friends and p is the probability of each friend being recruited, we estimated that the probability of any one nomination being recruited would be 0.2. We assessed the sample size required for 80% power to detect a 2-fold difference in proportion between the scaled group reimbursement and fixed individual reimbursement groups. We assumed some variation between friendship groups and considered each friendship group as a cluster, with an assumed intracluster correlation (ICC) of 0.5 and a mean cluster size of 3, with a coefficient of variation for cluster size of 0.83. Based on these assumptions, 153 primary participants must be randomized to each group, and a total sample of 306 primary participants is required. Based on this sample size, we will also be able to detect a difference in the number of close friends per participant who complete the survey of 1.4 and 80% power. In total, across both groups, we estimate that at least 92 secondary participants will be recruited based on conservative assumptions.

Since we plan to recruit through 3 primary participant recruitment settings, we intend to recruit 102 primary participants from each setting (Instagram, Snapchat, and the Student Edge panel). Recruitment in each setting will continue until 102 primary participants are reached, or 6 weeks have passed. If fewer than 102 participants are recruited from any

XSL•FO
RenderX

setting, further recruitment will be conducted from successful settings.

Recruitment

Primary participants will be recruited from 3 web-based platforms: Instagram advertising, Snapchat advertising, and the Student Edge panel. Specific details about each recruitment platform and how participants will be recruited are outlined below:

- Instagram is a free-to-use photo and video sharing social network service predominantly used through smart phone apps. Instagram allows users to engage with a range of advertisements outside of their immediate social network. Instagram is currently owned by Meta, which administers Instagram's advertising manager function. Using the advertising manager, businesses and users can manage paid advertisements on Instagram. The study will use the advertising manager to select target ages 16-18 years and limit the geographic area to Australia. The advertisement will feature images relating to the survey topics and text outlining the study. Tapping or swiping on the Instagram advertisement will direct prospective participants to the study information page.
- Snapchat is an instant messaging app that allows users to share pictures and videos (called "snaps"). Messages are usually only available to recipients for a short period before they can no longer be viewed. The study will use Snapchat's paid advertising feature to select the target audience of people aged 16-18 years, within the geographic area of Australia. Paid advertisements in the form of a short video appear between viewing friends' snaps, and people can swipe up to interact with the ad. The advertisement will feature a short, animated video with text outlining the study. By tapping on the advertisement, prospective participants will be redirected to the study information page.
- Student Edge [26] is a web-based organization targeted toward people in high school, technical and further education (TAFE), and university in Australia. The website provides students with study tips, news, promotions, competitions, job listings, and surveys. People can voluntarily sign up for the Student Edge Surveys panel to earn rewards. Student Edge will send an email invitation to prospective participants aged 16-18 years, who have signed up for their panel. Participants then click on the link in the email and are redirected to the study survey page.

Secondary participants are recruited by primary participants. When primary participants reach the end of the survey, a default message and URL unique to them and their friendship group will be generated. The primary participant is asked to discuss the project with their friends and share the message and URL. Secondary participants can click on the link to take them to the study information page and then proceed to the survey. One reminder email is sent to the primary participant 72 hours after they complete the survey. Secondary participants are not given the option to refer additional friends (ie, there is only 1 wave of secondary recruitment).

All participants will be required to provide their email address and mobile phone number. To prevent multiple responses from the same individual, repeat email addresses and mobile phone numbers will be detected by Research Electronic Data Capture (REDCap; Vanderbilt University), which is used to collect data (see below), and these participants will not be able to proceed with the survey.

Allocation of Intervention

Primary participants are randomized upon opening the study webpage. Randomization is managed through a REDCap survey form to enable automatic allocation independent of the researchers. The timestamp when a participant opens the webpage determines their allocated group, with those opening at an even number of seconds assigned to the scaled group (intervention) and at an odd number of seconds to the fixed group (control). Primary participants are informed about their intervention group after they answer how many close friends they have. Secondary participants are assigned to the same intervention group as the primary participant who recruited them. Researchers will not be blinded to the intervention group as they have no direct contact with the participants.

Data Collection

Participants will complete a web-based survey using the REDCap data collection tool [27]. The survey will capture information about peer networks, mental health, alcohol and other drug use, COVID-19 vaccination, sexual health, social media, and media related to sexual health, including pornography, sexting, and dating apps. The survey begins with a study information webpage containing a brief video accompanied by written information explaining the purpose of the research, what is involved, and how to participate. After the study information, participants proceed to a sign-up or consent page. Participants provide their contact details (email and mobile number) and will be asked to complete a checkbox list indicating their informed consent to confirm they understand and agree to provide their information and the use of that information for the purpose of the study. Participants complete a 2-step authentication by entering a code sent to their nominated mobile number. Participants will then be directed to complete the survey. If the individual is a primary participant, a unique URL will be generated at the end of the survey to share with their friends.

The target peer networks for recruitment are assessed by asking primary participants about their close friends. Participants are asked how many people they consider to be their close friends and to give their initials or a codename for each. Participants proceed to answer questions about each friend's age, gender, and perceived closeness. If participants have more than 10 close friends, they are asked to answer the questions for their 10 closest friends. Therefore, the possible range of nominated close friends who may be referred to as secondary participants is 0 to 10. A network size of up to 10 was deemed sufficient, as in other studies, most young people nominate only 2-3 close friends [9,27]. A limit was necessary to minimize the burden on participants to answer too many questions and manage the study's budget for participant reimbursements.

Potential factors associated with close friends completing the survey are collected through the web-based survey. Primary

XSL•FO
RenderX

participant-level factors include primary participant demographic characteristics, recruitment settings (Instagram, Snapchat, and the Student Edge panel), and health outcomes and behaviors. Health domains include mental health and well-being, sexual health, social media use, technology use related to sex, alcohol, tobacco smoking, other drugs, and COVID-19 vaccination. Friend-level predictors include network size and close friends' gender, age, perceived closeness, and frequency of discussing various health-related topics.

Data Management

Survey data for participants within the same peer network group will be linked using the unique auto-generated survey URL. Secondary participants' survey data will be linked to the primary participants' reported data using codenames and initials.

Statistical Analysis

All analysis will be conducted in Stata (version 15; StataCorp). We will first compare the 2 baseline groups to determine whether they are comparable on key demographic factors. If not, further analysis will be adjusted for any differences.

Our primary analysis will assess the effect of the reimbursement intervention on the proportion of primary participants' close friends who complete the survey using a multilevel logistic regression model. In this model, close friend nominees are the lowest level of data and are grouped by primary participant. Each close friend nominee can either be successfully recruited or not recruited (a binary outcome).

For aim 2, to determine the effect of the intervention on the number of close friends per primary participant who complete the survey, we will use a regression model with a count distribution appropriate for the data.

In secondary analysis, we will identify factors associated with successfully recruiting each close friend by including friend-, relationship-, and primary participant–level variables. We will use a logistic regression model where the outcome is whether a primary participant successfully recruited at least one friend or recruited zero friends, and the potential predictors include recruitment setting, demographics, health variables, and network size.

Data Monitoring

This study is the first time we have tested this referral approach. The number of reimbursements needed depends on the number of secondary participants. Therefore, we plan to monitor the secondary participant referral rate during data collection to ensure we do not exceed the budget for reimbursements (Aus $20,000; US $14,800). If the referral rate indicates we will exceed this budget, we will stop advertising the project and close the survey early to new primary participants. We will monitor the secondary participant referral rate at recruitment of 50, 100, 150, and 200 primary participants.

Community Engagement

Young people were involved in the development of the study design through previous focus groups and interviews [28]. Twenty-six participants aged between 16 and 18 years living in Victoria were recruited through paid advertisements on Facebook and Instagram. In these interviews, young people were asked about their perspectives on acceptable and engaging ways to conduct peer network research. Young people identified recruitment settings and strategies to communicate the study to participants. For the recruitment of social networks, young people endorsed having the autonomy to ask their friends if they would like to participate and using a referral link. Young people recommended using reimbursements to overcome barriers to participation and to show them that the researchers value their participation and experience. Young people suggested including video, more information about the researchers conducting the project, and a visually appealing design for research materials to improve how research participation is communicated to them, build trust with the research organization and increase their engagement in the research project. The researchers developed the research questions and outcomes for this study. Young people then gave their feedback on the acceptability of the survey topics and suggestions to improve their comfort with answering sensitive questions. This study is informed by this previous work and will test the strategies identified by young people. Young people who participated in formative development will not be involved in the conduct of this trial.

Ethics Approval

This study has been approved by the Monash University Human Research Ethics Committee (23132). Our study involves primary participants aged 16-17 years, and some secondary participants will also be aged 16-17 years. Individuals aged 16-17 years can have the competence and capacity to give informed consent without parental knowledge or permission [29]. As this study takes place on the internet and aims to ask participants about sensitive topics such as pornography and sexual health, it would be inappropriate and uncomfortable to require parental consent for participation in the study. If participants wish, they are encouraged to discuss the study with their parents or guardians. Despite being a randomized controlled trial, the study was not registered, as the primary outcome (recruitment of friends) was not a direct health or medical outcome.

Some primary participants may be concerned about their friends' privacy, as they are sharing information about their friends. We will only collect the minimal required information about friends to enable linking data within peer networks. We are not collecting identifiable information from primary participants about their friends (such as friends' email addresses or mobile numbers). Friends choose to voluntarily participate and provide their own contact information directly.

To further protect friends' right to freely choose to participate, primary participants will not be informed about whether their friend has signed up for the study. A reminder email contains a generic message and disclaimer to ignore it if they have already discussed the project with their friend.

We will disseminate our findings through peer-reviewed publications, conference presentations, and a PhD thesis. A summary of results will be sent to participants and posted on the research organization's website.

XSL•FO
RenderX

Results

Participant recruitment commenced in March 2022 and was completed in May 2023. Data analysis has not yet commenced.

Discussion

Principal Findings

This new social network research study about young people's peer networks uses web-based methods (ie, recruitment, peer referral, and survey). If feasible and effective, our study design could be used to overcome previous barriers to conducting longitudinal social network research with young people and take advantage of the benefits of using web-based methods (eg, reach marginalized groups and improve privacy). The randomized controlled trial design will enable us to determine the effect of 2 different reimbursement models on the recruitment of young people's peer networks. The limitations of this study are convenience sampling and cross-sectional design, which limit the extent to which the findings would apply to a longitudinal study.

Acknowledgments

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors. MR is supported by a Monash University Research Training Program scholarship. Abstract

Background: Prolonged bouts of sedentary time, independent from the time spent in engaging in physical activity, significantly increases cardiometabolic risk. Nonetheless, the modern workforce spends large, uninterrupted portions of the day seated at a desk. Previous research suggests—via improved cardiometabolic biomarkers—that this risk might be attenuated by simply disrupting sedentary time with brief breaks of standing or moving. However, this evidence is derived from acute, highly controlled laboratory experiments and thus has low external validity.

Objective: This study aims to investigate if similar or prolonged cardiometabolic changes are observed after a prolonged (2-week) practice of increased brief standing and moving behaviors in real-world office settings.

Methods: This randomized crossover trial, called the WorkWell Study, will compare the efficacy of two 2-week pilot intervention conditions designed to interrupt sitting time in sedentary office workers (N=15) to a control condition. The intervention conditions use a novel smartphone app to deliver real-time prompts to increase standing (STAND) or moving (MOVE) by an additional 6 minutes each hour during work. Our primary aim is to assess intervention-associated improvements to daily postprandial glucose using continuous glucose monitors. Our secondary aim is to determine whether the interventions successfully evoke substantive positional changes and light-intensity physical activity (LPA). Other outcomes include the feasibility and acceptability of the intervention conditions, fasting blood glucose concentration, femoral artery flow-mediated dilation (f-FMD), and systolic and diastolic blood pressure.

Results: The trial is ongoing at the time of submission.

Conclusions: This study is a novel, randomized crossover trial designed to extend a laboratory-based controlled study design into the free-living environment. By using digital health technologies to monitor and prompt participants in real time, we will be able to rigorously test the effects of breaking up sedentary behavior over a longer period of time than is seen in traditional laboratory-based studies. Our innovative approach will leverage the strengths of highly controlled laboratory and free-living experiments to achieve maximal internal and external validity. The research team's multidisciplinary expertise allows for a broad range of biological measures to be sampled, providing robust results that will extend knowledge of both the acute and chronic real-life effects of increased standing and LPA in sedentary office workers. The WorkWell Study uses a rigorous transdisciplinary protocol that will contribute to a more comprehensive picture of the beneficial effects of breaking up sitting behavior.

Introduction

Society is rapidly evolving to embrace the technological advances in communication, entertainment, and transportation that have benefited nearly every sector of daily life. These advances have also contributed to the accumulation of time spent engaging in sedentary behaviors, with approximately 60% of waking hours spent sedentary [1]. Sedentary behavior (defined by the Sedentary Behavior Research Network as <1.5 metabolic equivalents in a seated posture) [2] is a growing public health concern due to its well-established links to cardiometabolic disease development and premature mortality, independently from time spent in moderate to vigorous physical activity (MVPA) [3-7]. Meeting the recommended 150 minutes per week of MVPA is associated with beneficial cardiometabolic health outcomes [8-11]. However, MVPA alone does not offset the numerous negative health outcomes associated with prolonged bouts of inactivity. Research suggests that for each additional hour spent sedentary, the likelihood of developing metabolic syndrome and type 2 diabetes increases by 39% and 22%, respectively [12]. Therefore, reducing time spent in prolonged bouts of inactivity may lead to favorable long-term health outcomes [13].

Breaking up prolonged bouts of sitting attenuates the negative health outcomes associated with sedentary behavior [14-20], likely due to postural change and contraction of large skeletal muscle groups [13]. These actions result in increased vascular blood flow and shear stress via gravitational pull and the skeletal muscle pump, thus increasing venous return, decreasing blood pooling in the lower limbs, and activating contraction- and insulin-mediated glucose uptake pathways [21]. Taking a break to stand, walk, or exercise—in some cases, for as little as 2 minutes for every 20 minutes spent sitting [14,17]—improves glycemic control [14-19,22], insulin sensitivity [16,17], vascular response [14,23], and cardiometabolic health outcomes [16,19].

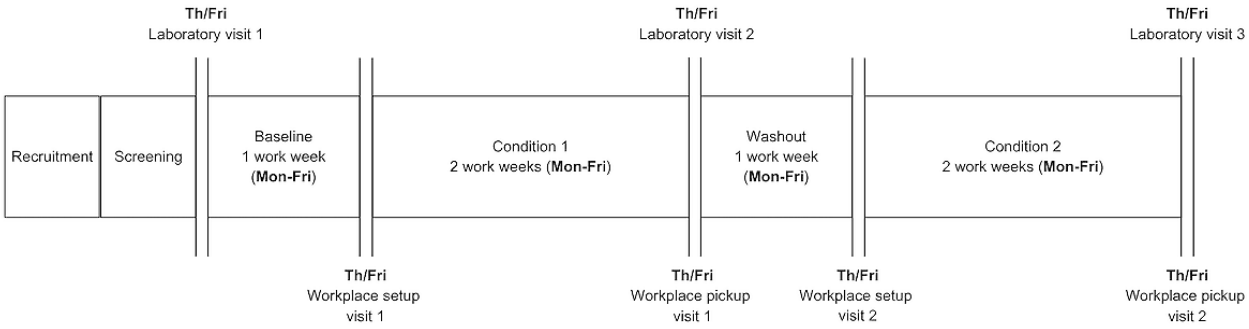
Adults spend 7.7 to 11.5 hours per day engaging in sedentary time [4,24,25], with modern office-based employees spending more than 89% of their workday seated [20]. This sedentary time, however, might be reduced through various intervention techniques. A meta-analysis reported that environmental (eg, sit-stand workstation at work) and multicomponent (eg, sit-stand workstation, education, and mobile app) intervention approaches resulted in sedentary time reductions of 40.6 and 35.5 minutes per day, whereas behavioral interventions (eg, education) resulted in a modest reduction of 23.87 minutes of sedentary time [26]. Studies using isotemporal modeling indicate that replacing sitting bouts of 30-60 minutes with either light-intensity physical activity (LPA) or MVPA is associated with reduced risk for all-cause and cardiovascular mortality, and improved cardiometabolic risk biomarkers, particularly in adults who are less active [27,28]. These findings support the feasibility and efficacy of interventions targeting sedentary time reduction and resulting health benefits [26-31].

Intervention-based research aimed at reducing sitting time and improving health outcomes has typically been conducted in tightly controlled laboratory environments, and the few studies conducted in real-world settings lack the intensive clinical and behavioral measures of a laboratory-based study. Thus, workplace-based efficacy and feasibility studies incorporating rigorous procedures with high internal validity are needed to better evaluate interventions aimed at reducing sitting time. The protocol described is a workplace study using evidence-based intervention components along with mobile and wearable technologies. A randomized crossover design will be used to explore cardiometabolic outcomes resulting from the addition of brief periods of standing or LPA during work hours while also assessing the efficacy and feasibility of the intervention in the real-world office setting.

Methods

Study Aims

The primary aim of this study is to examine the impact of 2 different intervention conditions (STAND and MOVE) on 3-hour postlunch postprandial glucose compared to the baseline control condition. Interventions entail adding 6 minutes per hour to baseline standing and LPA minutes during the workday. We hypothesize that both intervention conditions will improve postprandial glucose regulation. The secondary aim is to assess intervention adherence and changes in standing and LPA. Exploratory aims include (1) assessing participant acceptability and satisfaction during the intervention; and assessing intervention-induced changes in (2) sleep, (3) anthropometrics and body composition, (4) endothelial function, (5) central and peripheral blood pressure, (6) fasting blood glucose concentration, (7) fasting insulin concentration, (8) fasting high-density lipoprotein (HDL) concentration, (9) low-density lipoprotein (LDL) oxidation, (10) fasting triglycerides, (11) total antioxidant capacity (TAC), (12) hemoglobin A_{1c} (HbA_{1c}), (13) microbial diversity of the gut, (14) metabolomics from stool and plasma, and (15) DNA variants that may explain differences in response to the intervention.



Study Design

The WorkWell Study is a pilot 6-week randomized crossover design with 2 balanced arms. Across 2 intervention periods, all participants (N=15) will experience both workplace interventions following a baseline control condition: (1) MOVE,

XSL•FO
RenderX

an intervention targeting 6-minute increase in baseline LPA each work hour and (2) STAND, an intervention targeting 6-minute increase in baseline standing each work hour via a sit-stand workstation. Participants will wear a Bluetooth accelerometer and will be prompted with a mobile app during each intervention period. The intervention sequence is randomized and a washout period of at least 1 week will occur between interventions to reduce any potential carryover effect. Clinic-based assessments will occur at baseline and after each intervention period is completed (Figure 1).

Figure 1. WorkWell Study timeline.

Study Eligibility

Potential participants will go through a biphasic screening process to determine eligibility, see full eligibility criteria in Textbox 1. Participants will complete the web-based screening questionnaire, which will be reviewed by staff to determine initial eligibility; individuals who are conditionally eligible will be asked to consent to continue the screening process and to complete a medical history review. Next, an in-laboratory visit will confirm BMI eligibility. Those with qualifying BMIs are considered eligible to participate in the WorkWell Study and will have the opportunity to undergo full informed consent.

Textbox 1. Eligibility criteria

Inclusion criteria

- Age of ≥18 years
- Primary work activities performed seated
- Ability to use sit-stand workstation
- Works ≥4 days per week (in-office or remote)
- BMI of ≥25 (≥23 for Asian descent)

Exclusion criteria

- Taking certain medications and supplements, which includes glucose control, blood pressure, and blood thinner medications; hormone replacement therapy; corticosteroids; high-dose statins; second-generation antipsychotics; and prebiotics, probiotics, or antibiotics (in previous 3 months)
- Inability to stand or move for prolonged periods due to lower limb injury, disability, preexisting medical condition, or doctor's orders
- Serious medical conditions including, neuromuscular, cardiovascular, and respiratory disorders, as well as inflammatory bowel or intestinal malabsorption conditions, or food allergies
- Actively using a sit-stand workstation
- Work travel of ≥3 days per week
- Smoking

Procedures

Study Recruitment

Participants will be recruited on a rolling basis from the Arizona State University community via email listserves, slack channels, e-newsletters, staff website advertisements, and word-of-mouth. Preexisting partner businesses and organizations throughout the Phoenix Metropolitan area will be contacted by email. Employee-facing flyers containing study information and a link to the screening questionnaire will be disseminated electronically through the aforementioned channels.

Baseline Period

Once enrolled and initial baseline measures taken, participants will go through a 1-week baseline period in which they are outfitted with multiple devices that they will wear during each intervention period: a continuous glucose monitor (FreeStyle Libre, Abbott Diabetes Care), activPAL micro (PAL Technologies), and GENEActiv accelerometer (ActivInsights). These devices will be worn continuously (ie, 24 hours per day) for 7 consecutive days to assess baseline glycemic response, activities (including sitting, standing, and lying behaviors), and sleep, respectively. Participants will engage in their normal behaviors during the week-long baseline period.

XSL•FO
RenderX

Lunch will be delivered on workdays during the baseline period and both intervention periods. Participants will select options from a standardized menu (approximately 33% of daily caloric needs is equal to 660 kcals, with macronutrient composition of 55% carbohydrate is equal to approximately 90.75 g, 30% fat carbohydrate is equal to approximately 22 g, 15% protein [±10%] is equal to 24.75 g) created from a list of local vendors. The standardized meal choices will be consistently repeated each week during the trial, with the same meals provided Monday to Friday during baseline and both intervention periods. Participants will be asked to avoid eating or drinking (with the exception of water and black coffee or tea) 3 hours before and post lunchtime. Food logs will be used to report when they started and finished eating their lunch, how much food they ate, and the exact food consumed during the trial.

Randomization

After completion of the baseline period, each participant will be randomized to an intervention sequence (MOVE-STAND or STAND-MOVE). Randomization is completed using the REDCap (Research Electronic Data Capture; Vanderbilt University) randomization tool and a preloaded table with treatment sequences [32,33].

Interventions

The MOVE and STAND interventions will be delivered across 2 work weeks (approximately 10 days). Both use the WorkWell mobile app and Bluetooth Activator micro (PAL Technologies) device as intervention tools in conjunction with the equipment worn during the baseline period (Figure 2). The primary behavioral target of the MOVE intervention will be to increase baseline LPA time by an additional 6 minutes per hour during work. Similarly, the primary behavioral target of the STAND intervention will be to increase baseline standing time by an additional 6 minutes per hour during work. This target of adding 6 minutes per working hour of standing and LPA was selected as an achievable goal with evidence for cardiometabolic health improvements [14-19,22].

After the baseline period is completed, the self-reported work hours and corresponding activPAL micro data will be used to identify the average minutes of standing and moving for each hour of the participant's workday. The intervention goals will be identified for each participant by adding 6 minutes to these hourly averages. For example, if a participant stands for an average of 10 minutes per work hour during the baseline period, their STAND intervention goal will be 16 minutes of standing per work hour. The same approach will be used to identify MOVE intervention goals. The WorkWell app will use live feedback from the Bluetooth Activator micro to prompt participants in the STAND intervention to meet their hourly standing goals using a sit-stand workstation, while the MOVE intervention will prompt participants to engage in light-intensity movements (eg, walking) to meet their hourly goals.

Prior to the start of the intervention, staff will meet with participants to provide the devices, equipment, and logs needed during the intervention period. Participants will undergo an introductory tour before each intervention and are reminded of their intervention goal for that period. During the intervention, participants will wear the Bluetooth Activator micro device on the mid-thigh and use the WorkWell mobile app during their workday in conjunction with the continuously-worn continuous glucose monitoring (CGM), activPAL, and GENEActiv. When the workday begins, participants will wear the Bluetooth Activator micro and log their work start time in the app, signaling the "start" of the intervention for that day. The Activator micro device will send real time accelerometer data to the WorkWell app via a Bluetooth signal, providing live participant-facing feedback on hourly goal progress as well as day-level summary information. Summary data will also be sent to a secure server, allowing study staff to monitor participant compliance and to facilitate support when needed. Participants will additionally receive a variety of prompts, including hourly reminders to work toward their hourly goal, encouraging messages, or messages that acknowledge that they achieved their hourly goal. Participants will be instructed to log the end of their workday in the app before removing the Bluetooth Activator micro, thus signaling the "end" of that day's intervention.

XSL•FO
RenderX

Figure 2. WorkWell intervention tools—WorkWell mobile app and Activator micro device.

Measures

All measurements will be completed at the baseline visit and after each intervention period, for a total of 3 laboratory visits. Table 1 shows the measures collected and the associated measurement period. Demographic and health history information will be assessed at baseline. During the baseline period, as well as during each intervention period, participants will complete 3 paper-form daily logs for sleep, work, and food recall. All other study data and questionnaires will be collected and managed using REDCap hosted at Arizona State University [32,33]. REDCap is a secure, web-based software platform designed to support data capture for research studies, providing (1) an intuitive interface for validated data capture, (2) audit trails for tracking data manipulation and export procedures, (3) automated export procedures for seamless data download to common statistical packages, and (4) procedures for data integration and interoperability with external sources.

[d]Measured continuously (device-based).

[e]N/A: not applicable.

Primary Outcomes

Our primary outcome, the change in 3-hour postlunch postprandial glucose excursion, will be assessed using a CGM device. This small, single-use sensor is placed on the back of the arm and samples glucose levels approximately once every 15 minutes for up to 14 days [34]. This device provides a valid and reliable measure of glucose using flash glucose monitoring [35,36]. Research staff will facilitate the insertion of the CGM for baseline and both intervention periods. If the device falls off or is accidentally removed, staff will replace the device as needed. Participants will be provided a macronutrient-controlled meal (approximately 33% of daily caloric needs, with macronutrient composition of 55% carbohydrate, 30% fat, 15%

XSL•FO
RenderX

protein [±10%]) delivered daily for lunch during the work week to control for dietary variability. The 3-hour postlunch postprandial incremental area under the curve (iAUC) and mean blood glucose concentration in response to the lunchtime meal will be calculated from these data.

Secondary Outcomes

The secondary outcomes of the interventions will assess intervention adherence and changes in sitting, standing, and LPA during work hours. Intervention adherence is defined as meeting the hourly intervention goal of ≥80% of the workday (eg, meeting the hourly goal for ≥8 hours during a 10-hour workday). The Activator micro device will be taped midthigh during work hours and will communicate with the WorkWell smartphone app via Bluetooth technology. The app's user-friendly interface will provide real time feedback, allowing participants to monitor their progress as 8 bubbles gradually turn green to signify the hourly goals that were met. The WorkWell app will sync to a secure server, providing real time stand-and-move data for study staff to monitor adherence to intervention protocols; data will be stored for broader analysis upon trial conclusion.

The activPAL micro will also assess sitting, standing, and moving behaviors. Work logs will be used to differentiate between work and nonwork hours. Device attachment procedures are based on several large-scale intervention studies [5,6,37]. Devices will be waterproofed using a medical grade adhesive covering and placed on the midline of the thigh with breathable, hypoallergenic tape, to allow for 24 hours per day of continuous wear during measurement periods without removing for bathing or other water-based activities. Data will be processed into bouts of sitting or lying, standing, stepping, or time in bed (ie, primary lying bout) and expressed as minutes per day, assessing posture and intensity using activPAL software version 8.10. Waking time assessed as lying or seated will be categorized as sedentary behavior. Stepping time will be split into periods of LPA (<100 steps per minute) and MVPA (≥100 steps per minute) [38]. Total physical activity will be a cumulative daily value of LPA and MVPA. The following periods of wear will be excluded: (1) continuous sitting or standing behavior >6 hours (considered nonwear), (2) days with ≤10 hours of valid wear time during the wake period, and (3) participants with only 1 valid day of activPAL wear.

Exploratory Outcomes

Additional exploratory outcomes will include sleep, intervention acceptability and satisfaction, body anthropometrics, femoral artery flow-mediated dilation (f-FMD), central aortic blood pressure, fasting glucose, fasting insulin, HDL, LDL, LDL oxidation, triglycerides, TAC, gut microbial diversity, HbA_{1c}, metabolomics of the blood and stool, and genetic variants assessed during 1 or more measurement periods.

Sleep will be assessed using the wrist-worn GENEActiv accelerometer (ActivInsights) (initialized to collect at 40 Hz); participants will wear the device 24 hours per day during the measurement periods while also completing a validated sleep diary each night to identify sleep from wake periods. The GENEActiv device has been validated for sleep [39-42] and will be used in conjunction with a sleep log that differentiates sleep or wake periods in data [43]. An open-source and validated algorithm (GGIR package, R-software) [42] will be used to process device-based sleep measures, including sleep duration, sleep efficiency, sleep onset latency, and wakefulness after sleep onset [44-47]. Sleep will be considered the total sleep time accumulated within the sleep window; wake time, daytime sleep, and the time of sleep onset will not be counted. GGIR signal processing includes autocalibration using local gravity as a reference [45], detection of prolonged abnormal high values, nonwear detection and average magnitude of dynamic acceleration calculation, corrected for average gravity over 5-second epochs and reported in milligravitational units (mg). Data files will be excluded if a postcalibration error of >0.01 g (10 mg), <3 days of valid wear (defined as >16 hours per day [44,48]), or wear data are not present for each 15 minutes period of the 24-hour cycle. Nonwear detection is described elsewhere [44]. The default nonwear setting will be used, which includes invalid data that will be imputed by the average at similar time points on different days during the assessment week. Sleep duration will be calculated using automated sleep detection (HDCZA sleep detection algorithm) [47]. The average of all valid days will be used.

Intervention acceptability and satisfaction will be assessed using the Treatment Evaluation Questionnaire (TEQ) to measure the adherence and feasibility outcomes of the study. Prior to starting each intervention, participants will be provided an introductory tour to explain the intervention and describe how to use the WorkWell app and device. Research staff will actively discuss strategies to assist participants in engaging with the intervention. After this session and prior to the start of the intervention, participants will be sent a pre-study survey with the TEQ; once each intervention is completed, a postsurvey is sent also containing the TEQ.

Body anthropometrics, including height, weight, body fat percentage, and waist circumference, will be measured at each laboratory visit. Height and weight will be measured using the Seca scale and stadiometer (Seca 286 EMR Ready Ultrasonic Measuring Station). Waist circumference (taken at the level of the iliac crest) will be measured twice using a Gulick tape measure. Body fat percentage will be measured twice using the Tanita TBF-400 digital scale device (Tanita), which calculates percent body fat using bioimpedance. If there is a difference of ≥0.2% for body fat, an additional measurement will be taken. Values will be averaged to arrive at a final measure.

f-FMD will be used to measure the endothelium-dependent, flow-mediated dilation of the superficial femoral artery using B-mode ultrasound (Terason uSmart 3300+TM) via guidelines set forth by the Brachial Artery Reactivity Task Force [49]. Participants will be asked to lie quietly for 15 minutes on the ultrasound table before baseline images are obtained from their left upper thigh. Simultaneous ultrasound images (B-mode) and Doppler waveforms will be recorded for 30 seconds. An appropriately sized cuff will be selected based on manufacturer guidelines (Hokanson Instruments) and subsequently wrapped around the participant's upper thigh, 3-4 cm below the bifurcation of the common femoral artery. After baseline images of the superficial femoral artery are acquired, the blood pressure

XSL•FO
RenderX

cuff on the participant's upper thigh will be inflated using a rapid-cuff inflator (Hokanson instruments) to a suprasystolic pressure of 250 mm Hg for 5 minutes. The recording of the image will begin 30 seconds prior to the cuff release. At 5 minutes following cuff inflation, the cuff will be rapidly deflated and arterial images are recorded for 6 minutes. Images obtained will be analyzed by a trained, blinded researcher using previously validated edge-detection software [50]. In our laboratory, intraclass correlation coefficients for baseline and peak diameter are 0.994 and 0.995, respectively (Cronbach α=.976).

Central aortic blood pressure that includes both central and peripheral blood pressure, and aortic stiffness (via applanation tonometry) will be measured using the SphygmoCor XCEL (CvMS; ATCOR Medical). This device has been found to reflect measures of central pressures and stiffness reliably and accurately [51,52]. All measurements will be taken after the participant rests in a supine position for approximately 15 minutes, prior to f-FMD initiation, to ensure hemodynamic stability. Triplicate measures will be collected, and the 2 closest values averaged and reported.

Fasting blood samples will be collected at each laboratory visit via venipuncture. The 15-mL samples will be immediately processed and aliquoted for storage at –80 °C for subsequent analysis. Fasting blood glucose will be examined in multiple batches, pairing samples from the same participant's previously aliquoted plasma. Plasma glucose concentration will be analyzed using the AU480 Chemistry Analyzer (Beckman Coulter, Inc) in accordance with manufacturer's instructions. Exploratory cardiometabolic disease risk analysis will be performed on plasma and serum glucose, insulin, triglycerides, total cholesterol, HDL cholesterol, LDL cholesterol, LDL oxidation, and TAC. Exploratory, targeted metabolomics analyses will also be performed with plasma samples using mass spectrometry (MS).

Participants will be provided with a stool sample collection kit and instructions at each laboratory visit. All participants will be given the option to schedule sample pick-up at their home or workplace; alternatively, samples can be dropped off at the Translational Research Center. Participants will be instructed to collect this sample within 4 days of each laboratory visit for a total of 3 collections. Once collected, samples will be frozen at –80 °C within 24 hours of the sample leaving the body. Participants will be instructed to contact staff to retrieve the sample when ready. The stool samples will later be thawed at 4 °C and microbial DNA extracted for microbiome sequencing and characterization of intervention-specific bacterial community differences. Microbial DNA sequencing will be carried out in batches of paired samples from the same participant. Bacterial DNA will be extracted from the stool samples using DNeasy PowerSoil Pro DNA Isolation Kit (47014, Qiagen) as per manufacturer recommendations. DNA quality and concentration will be quantified (QIAxpert System Qiagen) before being sent out for sequencing (Illumina MiSeq instrument, Illumina, Inc.) at ASU's DNASU Genomics Core Facility. Raw Illumina microbial data will be cleaned and analyzed using the Quantitative Insights into Microbial Ecology 2 software, as previously described [53]. Exploratory, targeted metabolomics analyses will be performed with the stool samples using MS. Short-chain fatty acids, bile acids, pathway-specific targeted liquid chromatography tandem MS, liquid chromatography–MS, gas chromatography–MS aqueous metabolite profiling, and liquid chromatography–MS global lipidomic profiling will be carried out.

HbA_{1c} will be collected at baseline only using the DCA Vantage analyzer (Siemens Munich) with 1 µL of blood obtained using a finger stick. After collection, the results are obtained within 6 minutes and data will be used for descriptive purposes.

Saliva samples will be collected at baseline using Oragene Discover collection kits (OGR-600 Ottawa), and will be archived for future exploration of genetic variants.

Data Analysis

Statistical Analysis Plan

Participant characteristics will be reported as frequencies or means with SDs. Outcome variables with nonnormal distributions will be log-transformed to assume normal distribution. All data processing and statistical analyses will be performed in SAS (version 9.4; SAS Institute) with an α criterion of .05. To address our specific aims and hypotheses, we will use linear mixed model analyses [54,55] for intervention (ie, MOVE and STAND), sequence (ie, MS and SM), and time period (ie, 1 or 2) as fixed factors and an unstructured covariance structure for the 3 repeated measurements per person. The primary outcome will be postprandial glucose iAUC, and secondary outcome will be change in posture and LPA. All data from randomized participants will be included in the analyses in accordance with intent-to-treat principles.

Sample Size Calculation

To determine the sample size needed, we based our effect size estimates on previous studies [17,56] that have similarly evaluated the impact of interrupting prolonged sitting on glucose iAUC. These studies reported a 20%-30% decrease in iAUC level for the intervention groups. Therefore, for the WorkWell Study, we used a conservative estimate of 15% difference between baseline and the 2 intervention measurements (with a 1% population estimate of SD). Using G*Power software (version 3.1.9.2) [57], we estimated that we will have to recruit 15 individuals (allowing for 80% retention) to obtain a final sample size of 12 participants (α=.05, power=80%).

Ethics Approval

This study has been reviewed and approved by the institutional review board at Arizona State University (STUDY00010172) as well as registered on ClinicalTrials.gov (NCT04269070). Screening consent will be obtained prior to in-person screening visit and subsequent full-informed consent will be obtained from all qualifying participants prior to enrollment. All participant information and data will be deidentified and assigned an identification number in which all subsequent data, samples, and surveys will be labeled to ensure confidentiality. As a part of the study intervention, participants will be provided lunchtime meals during the work week as well as up to US $65 in a web-based gift card of their choice for completion of the study.

Results

Recruitment is ongoing as of January 2023. To date, 10 participants have been enrolled, with 2 withdrawing from the study for personal reasons. Enrollment was completed in March 2023.

Discussion

Comparison to Prior Work

While low levels of physical activity have been a public health concern, there is evidence that sedentary behavior duration may also confer health risks [13]. Observational studies suggest that breaking up sedentary time is associated with improved cardiometabolic health [58]. These free-living, mainly observational studies have demonstrated the theoretical feasibility of workplace interventions, yet cannot control for potentially confounding factors, obscuring the meaningful analysis of the relationship. Laboratory studies, however, suggest a causal relationship between decreased sedentary time and cardiometabolic health [59]. While these studies are tightly controlled in both the environment and intervention, they lack important context regarding the translation of these findings into real-world settings.

The WorkWell Study is a novel randomized controlled crossover trial that has been designed to extend laboratory-based, controlled study designs into the natural environment of the workplace. To accomplish this, we have used digital health technologies to monitor and prompt participants in real time while maintaining rigorous adherence to increased standing and moving regimes. This innovation will allow us to test the effects of breaking up sitting with standing and LPA over a longer period of intervention than has been used in traditional laboratory-based studies. Additionally, we have included a broad set of concomitant biological measures, including dynamic changes in postprandial and 24-hour glucose, as well as outcomes in the emerging areas of metabolome and gut microbiome composition. We will use two 2-week interventions targeting behavior change to decrease sitting time in the workplace as well as to improve cardiometabolic health and to assess behavior change. This study was carefully designed to extend laboratory-based studies—both in duration, as well as translation into more ecological settings—thus providing more evidence on the causal role of interrupted sitting time (with standing and moving) on cardiometabolic health. As a result, we will be able to address (1) statistical association via baseline and washout weeks that allow participants to serve as their own controls, (2) temporality via continuous accelerometer tracking and prescheduled laboratory visits, and (3) nonspuriousness via randomized assignment and controlled treatment dosage.

Strengths and Limitations

Our project attempts to achieve levels of internal validity previously found only in laboratory-based studies while simultaneously maximizing external validity. While others have demonstrated the benefit of breaking up sedentary behavior in either highly controlled laboratory environments or ecological environments, we will use emerging technologies (ie, wearable sensors and smartphone apps) to deliver a rigorous clinical trial within an employee's real-life workspace. Despite this important strength, some potential challenges warrant discussion. Recruitment and retention of participants in longitudinal research is challenging. We hope to overcome this challenge by allowing participants to engage in the study in their typical work setting, rather than having participants carry out the intervention in a laboratory setting. If successful, this approach will add important information to our current understanding of how best to intervene and engage participants in reducing sedentary time in workplace settings. Participants may also feel uneasy about collecting fecal samples. To ensure this is not a barrier for successful completion of the trial, the study team will provide participants with a discrete collection kit that can be used mostly anywhere that is comfortable for the participant. Delivery of samples to the research facility can then be initiated by the participant or the study staff can retrieve the sample at a place of convenience for the participant. This method has been used by our investigative team in previous studies and has proven beneficial for ensuring receipt of quality samples within the required time frame.

With a wide range of expertise represented on our research team, we are able to consider outcomes in the behavioral, physiological, and microbial realms and are able to examine our outcomes in an integrated and transdisciplinary fashion. While previous research has broadly examined some of these factors, our design and transdisciplinary approach will allow for a more global viewpoint of the influence of breaking up sedentary time during the workday on cardiometabolic health. Currently, the biological and metabolic underpinnings of sedentary behavior-linked disease are grossly understudied. Previous observational work has highlighted potential microbial and metabolic derangements [60-63], but these findings have not been extended to longitudinal interventions, leaving the previous work highly correlational. Our team is well-positioned to advance this area of study toward better mechanistic understandings of sedentary behavior and how intervention in real-world settings can improve health.

Conclusions

The WorkWell Study is a randomized controlled crossover trial examining the feasibility and impact of breaking up sedentary behavior on cardiometabolic health using the scientific rigor of a laboratory-based study with the context and translatability of a free-living setting. We will explore the effects that standing or moving 6 additional minutes per hour has on postprandial glucose and other physiological measures in the real-world workplace and assess intervention feasibility. Using a rigorous transdisciplinary approach, we seek to fill gaps in previous research and contribute to a more comprehensive picture of the beneficial effects of breaking up sitting behavior.

Abstract

Background: University life typically occurs during a period of life transition, where the incidence of mental health and substance use problems and disorders peaks. However, relatively few students obtain effective treatment and support. e-Interventions have proven effective in improving the psychological outcomes of university students and have the potential to provide scalable services that can easily integrate into existing models of care. *Minder* is a mobile app codeveloped with university students that offers users a collection of evidence-based interventions tailored to help university students maintain their mental health and well-being and manage their substance use.

Objective: This paper describes the protocol for a randomized controlled trial (RCT) that aims to assess the effectiveness of the *Minder* app in improving the mental health and substance use outcomes of university students.

Methods: This study is a 2-arm, parallel assignment, single-blinded, 30-day RCT with 1 intervention group and 1 waitlist control group. Overall, 1496 (748 per trial arm) university students from the University of British Columbia Vancouver Campus (N=54,000) who are aged ≥17 years, have a smartphone with Wi-Fi or cellular data, and speak English will be recruited via a variety of web-based and offline strategies. Participants will be randomized into the intervention or control group after completing a baseline survey. Those randomized into the intervention group will gain immediate access to the *Minder* app and will be assessed at 2 weeks and 30 days. Those randomized into the control group will be given access to the app content after their follow-up assessment at 30 days. The primary outcomes are measured from baseline to follow-up at 30 days and include changes in general anxiety symptomology, depressive symptomology, and alcohol consumption risk measured by the General Anxiety Disorder 7-Item scale, Patient Health Questionnaire 9-Item scale, and US Alcohol Use Disorders Identification Test-Consumption Scale, respectively. Secondary outcomes include measures related to changes in the frequency of substance use, mental well-being, self-efficacy in managing mental health and substance use, readiness to change, and self-reported use of mental health services and supports (including referral) from baseline to follow-up at 30 days.

Results: Trial recruitment and data collection began in September 2022, and the completion of data collection for the trial is anticipated by June 2023. As of May 10, 2023, a total of 1425 participants have been enrolled.

Conclusions: The RCT described in this protocol paper will assess whether the *Minder* app is effective in improving the mental health and substance use outcomes of a general population of Canadian university students. Additional secondary outcome research

XSL•FO
RenderX

aims to explore additional outcomes of interest for further research and better understand how to support students' general mental well-being.

Introduction

Background

University represents a period of transition where many students move away from home for the first time, requiring them to navigate the newfound independence and overcome unanticipated challenges when trying to make new friends and preserve existing relationships [1-3]. Students may find themselves suddenly dealing with new stressors without their previously relied upon support systems [4]. These stressors related to university life are combined with a period of development where the onset of many mental health and substance use disorders peaks [5,6]. Certain individuals may also be more likely to experience mental health problems in university based on various factors such as age, sexual orientation, ethnicity, and adverse childhood experiences [7]. Overall, this results in a population with a relatively high prevalence of mental health and substance use disorders [8,9]. For example, a study of college students across multiple countries found the 12-month prevalence of major depressive disorder, generalized anxiety disorder, and alcohol use disorder to be 18.5%, 16.7%, and 6.3%, respectively [9]. Despite the high prevalence of emerging mental health and substance use concerns, many university students do not seek help for these issues [10,11].

e-Interventions that promote self-management and link students to in-person services represent a promising means of addressing needs related to substance use and mental health issues. The potential of digital mental health interventions (eg, web-based programs and mobile apps) has been widely promoted, as they are often easily scalable and as beneficial as in-person therapies in promoting university students' mental health [12-14]. Considering the high co-occurrence between mental health and substance use concerns [15], e-interventions are well positioned to offer low-barrier access to content supporting transdiagnostic approaches to interventions that acknowledge not only each individual concern but also their intersectionality. Existing digital interventions also address a range of challenges, including depression and anxiety [16], substance use [17], safety and risk management [18,19], and levels of severity (eg, subclinical mild to moderate symptom management and treatment for clinical conditions), and can be easily integrated into existing systems of care as a form of low-intensity, self-directed support [20].

Objective

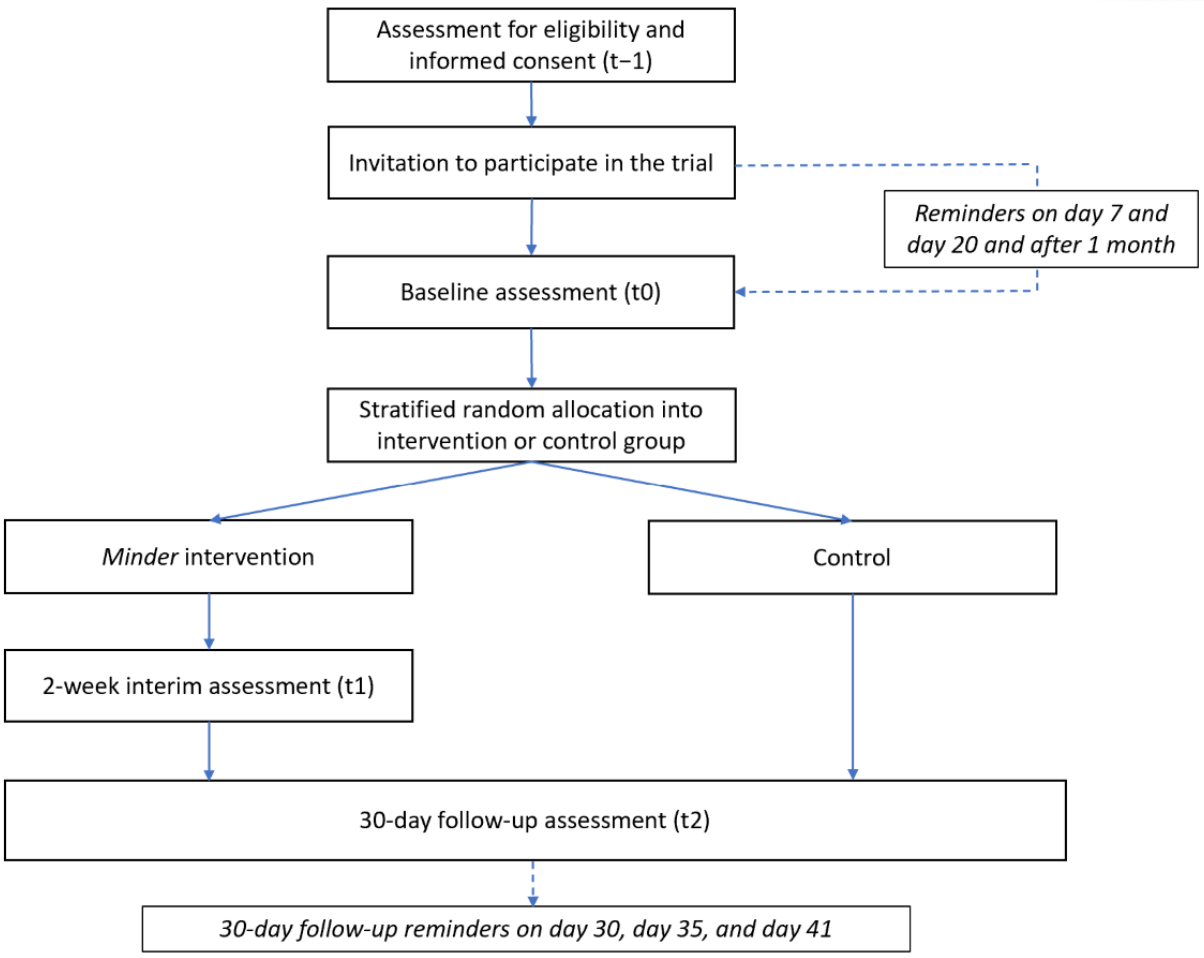
To address these needs, a mental health and substance use mobile app called *Minder* was codeveloped with and for Canadian university students. This codevelopment process involved significant input from students through the creation of a Student Advisory Committee (SAC), usability testing via a virtual bootcamp (ie, individual user testing combined with a web-based survey), focus groups, and a pilot feasibility study [14]. By combining the prevention and early intervention components, the *Minder* app has been designed to target the general population of university students. This paper describes the protocol for a pragmatic 2-arm randomized controlled trial (RCT) to assess the effectiveness of the *Minder* mobile app in improving university students' mental health and substance use outcomes.

Methods

Study Objectives and Hypotheses

Our primary objective is to test whether the *Minder* intervention improves mental health and substance use outcomes in a general population of university students. Our null hypothesis is that there is no difference between the intervention group, who are given access to a full version of the *Minder* mobile app, and the control group, who are given access to a restricted version of the app that sends reminder notifications about baseline and follow-up surveys but prevents access to all intervention components. We hypothesize that assignment to the intervention group will result in greater effects on the primary mental health and substance use outcomes. As such, we expect that participants assigned to the intervention group will be more likely to experience improvements in their mental health and substance use outcomes than those in the control condition.

Study Design and Setting



The study is a single-blinded, 2-arm parallel assignment RCT with 1 intervention group and 1 control group (Figure 1). In the pretrial period (t−1), all students are screened for eligibility and invited to enroll in the study; enrolled participants then complete the baseline assessment survey (t0). After randomization, all participants enter into the trial (with full access or restricted access to the *Minder* app, depending on group assignment), concluding with a follow-up assessment survey at 30 days (t2; see Table 1 for participant flow through the study). In addition to the baseline and follow-up surveys, the intervention group will also complete an assessment at 2 weeks. The baseline and follow-up assessments contain all primary and secondary outcomes, whereas the 2-week survey contains only 2 primary outcome measures (Patient Health Questionnaire 9-Item [PHQ-9] and General Anxiety Disorder 7-Item [GAD-7]). All assessments are delivered through the app and typically require approximately 15 minutes to complete but may be completed at the participant's own pace. The 30-day follow-up assessment

XSL•FO
RenderX

may be completed for up to 14 days after the 30-day study period end point.

Upon the completion of the randomized controlled trial, participants in the control group will be offered access to the intervention for ethical reasons and will be followed (with those already in the intervention group) for up to 6 additional months as part of a separate period of natural observation not included in the formal RCT analyses. This trial was registered with ClinicalTrials.gov (NCT05606601) on November 4, 2022. The study will be conducted at the University of British Columbia (UBC), Vancouver Campus. All data will be collected in Canada.

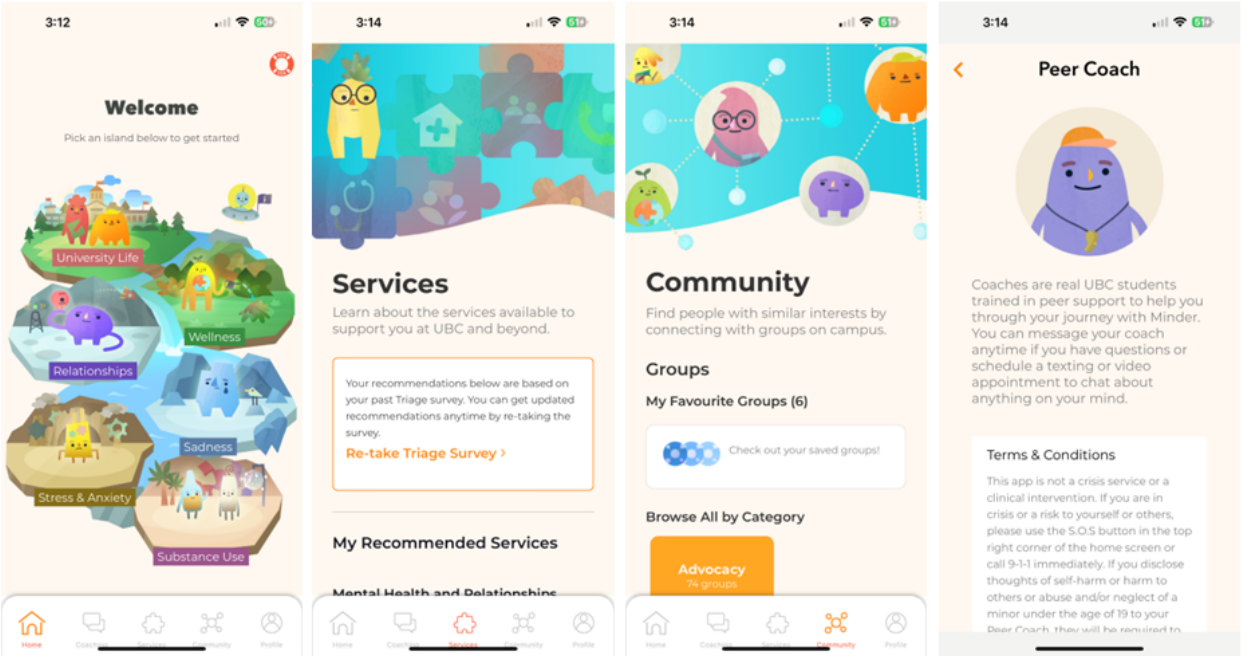
[e]SWEMWS: Short Warwick-Edinburgh Mental Wellbeing Scale.

Eligibility Criteria and Assessment

Participant eligibility will be determined through an eligibility screener delivered on Qualtrics, a web-based survey platform, before registering for the study.

Participants must meet all the following inclusion criteria: student currently enrolled at the UBC Vancouver campus, aged ≥17 years, have access to and be able to use a smartphone with Wi-Fi or cellular data, and speak English. Students will be excluded based on an eligibility screening item assessing suicidality risk (“We want to make sure that this app is appropriate for you at this time. Do you have a current suicidal plan [i.e., a plan to end your life]?”). Anyone endorsing a current suicidal plan (ie, answering “yes”) will not proceed with the registration form and will instead be provided with a list of crisis resources.

Intervention



Minder was codeveloped with input from 225 university students, including 44 student project team members. Codevelopment occurred through engaging students and volunteers on the project team, a SAC, and quantitative and qualitative studies (web-based survey, pilot feasibility RCT, and focus groups). Feedback was used to guide the app revisions following each of these processes, resulting in a final app that differed considerably from the initial prototype. Details of each component of these adaptation processes can be found in the study by Vereschagin et al [14].

Minder delivers a suite of evidence-based interventions that have been tailored to help university students improve their well-being and manage their substance use through 4 main components: Chatbot Activities, Services, Community, and Peer Coaching (Figure 2). The Chatbot Activities consist of an automated preprogrammed chatbot text and videos that draw

XSL•FO
RenderX

primarily from cognitive behavioral therapy (CBT), given its demonstrated transdiagnostic efficacy in web-based intervention programs [21-24]. The Chatbot Activities also incorporate evidence-based content derived from metacognitive therapy, dialectical behavioral therapy, and motivational interviewing. These activities have been developed through collaboration with mental health professionals and university students so that the information can be presented in a way that is consistent with evidence-based practices and appropriate for this demographic. The Chatbot Activities were designed to support students on a range of topics and include content to manage mild to moderate distress and emotions and to help navigate general student life (eg, relationships, time management, and sleep hygiene). In addition, the content of the Chatbot Activities relates to the use of alcohol, cannabis, opioids, and stimulants, including general psychoeducation and motivational interviewing. These topics encapsulate many general skills included in CBT for managing emotions (eg, recognizing automatic thoughts) as well as additional topics highlighted by students through our codevelopment process as being more relevant to student well-being, such as transitioning to university. To increase the accessibility of the app, all activities that include video content have been closed-captioned in both English and French. Users have access to this entire range of content in the app and can choose to engage with any activities, regardless of their current mental health or substance use status. The Services component of *Minder* includes a validated psychosocial screening tool that provides users with tailored recommendations and resources based on their current needs and preferences [25]. It consists of a short survey with several categories (mental health, safety, substance use, abuse, housing, education, and sexual wellness) and an individually tailored list of relevant services that can be filtered by factors such as cost, availability, and delivery method. The Community component of *Minder* contains a searchable inventory of student groups or clubs at the university, which can be filtered according to the student's interest. Finally, to support the use of the app, Peer Coaches (university student volunteers that have been trained by the research team's clinicians) are available to help users navigate through different app components and provide nonclinical peer support. Once a Peer Coach is assigned, users can communicate with their coach through secure in-app texting or video calls in a synchronous or asynchronous manner. In this study, users in the intervention group will be offered Peer Coaches who will reach out to their assigned users twice during the study period (ie, at the beginning of the trial upon assignment and around the midpoint of the trial). Additional information on the development of *Minder* and its components can be found in the study by Vereschagin et al [14].

Figure 2. Minder main app components. The Minder app home page has 6 islands (University life, Relationships, Stress and Anxiety, Wellness, Sadness, and Substance Use) that deliver a variety of activities through an interactive chatbot. The Services component includes a short survey that assesses needs and preferences and matches users with resources. The Community component provides users with a directory of student groups and clubs they can filter through by interest. The Peer Coaching component matches users with a trained peer that provides psychosocial and app support.

Outcomes

Primary Outcomes

The primary outcomes are changes in general anxiety symptomology, depressive symptomology, and alcohol consumption risk from baseline to follow-up at 30 days.

Anxiety Symptoms

The GAD-7 scale is a commonly used self-report scale to assess symptoms of generalized anxiety. Questions on the scale draw from the Diagnostic and Statistical Manual of Mental Disorders, 4th edition [26], criteria for anxiety disorders and were formally validated against diagnostic psychiatric interviews [27]. Each question is scored from 0 (not at all) to 3 (nearly every day),

XSL•FO
RenderX

with total scores ranging from 0 to 21 and higher scores indicating a worse outcome (ie, greater frequency of anxiety symptoms). In this study, changes in anxiety symptomology from baseline to follow-up at 30 days will be based on the GAD-7 total scores in both the intervention and control groups.

Depression Symptoms

The PHQ-9 scale is a self-report scale used to assess symptoms of depression and has been validated against diagnostic interviews administered by mental health professionals [28]. The 9 questions are based on the Diagnostic and Statistical Manual of Mental Disorders, 4th edition [26], diagnostic criteria for depressive disorders and scored on a scale of 0 (not at all) to 3 (nearly every day). The total scores range from 0 to 29, with higher scores indicating a worse outcome (ie, greater frequency of depression symptoms). In this study, changes in depressive symptomology from baseline to follow-up at 30 days will be based on the PHQ-9 total scores in both the intervention and control groups.

Alcohol Consumption Risk

The US Alcohol Use Disorders Identification Test-Consumption Scale (USAUDIT-C) is a 3-item self-report scale adapted from the consumption questions in the widely used Alcohol Use Disorders Identification Test (AUDIT). Compared with the AUDIT, the USAUDIT-C includes expanded response options for the first 3 AUDIT questions—from 5 to 7 categories—to allow for more precise measurements in accounting for differences in standard drink sizes and cut-off limits [29]. Although the USAUDIT-C was primarily adapted for US contexts, we believe the expanded response options will also allow for a more precise assessment of adherence to guidelines in drinking frequency (question 1), drinking quantity (question 2), and binge drinking (question 3) within Canadian contexts. For questions 1 and 3, scoring ranges from 0 to 6, where 0 represents “Never” and 6 represents “Daily” frequency. For question 2, scoring ranges from 0 to 6, where 0 represents “1 drink” and 6 represents “10 or more drinks” on a typical day when drinking. The total scores summed from all 3 questions range from 0 to 18, with higher scores indicating a worse outcome (ie, higher-risk level of excessive or harmful alcohol consumption). In this study, changes in alcohol consumption risk from baseline to follow-up at 30 days will be based on the USAUDIT-C total scores in both the intervention and control groups.

Secondary Outcomes

Overview

To provide further information on the underlying mechanisms and areas in which *Minder* is affecting participants’ overall well-being, a variety of secondary outcomes will be examined. Secondary outcomes include measures related to changes from baseline to follow-up at 30 days in the frequency of substance use (cannabis consumption, binge drinking, alcohol use, opioid use, and nonmedical stimulant use), mental well-being, self-efficacy managing mental health and substance use, readiness to change, and self-reported use (including referral) of mental health services and supports. An example of the questions used to assess secondary outcomes is provided in Multimedia Appendix 1.

Substance Use: Opioid Use Frequency

Changes will be based on the self-reported frequency of *both medical and nonmedical* opioid use in both the intervention and control groups.

Substance Use: Stimulant Use Frequency

Changes from baseline to follow-up at 30 days will be based on the self-reported frequency of nonmedical stimulant use in both the intervention and control groups.

Substance Use: Cannabis Use Frequency

Changes from baseline to follow-up at 30 days will be based on the self-reported frequency of cannabis consumption in both the intervention and control groups.

Substance Use: Alcohol Binge Frequency

Changes from baseline to follow-up at 30 days will be based on the responses to question 3 of the USAUDIT-C in both the intervention and control groups.

Substance Use: Alcohol Use Frequency

Changes from baseline to follow-up at 30 days will be based on the responses to questions 1 and 2 of the USAUDIT-C in both the intervention and control groups.

Mental Well-Being

Changes from baseline to follow-up at 30 days will be based on the total scores from the Short Warwick-Edinburgh Mental Wellbeing Scale in both the intervention and control groups. The Short Warwick-Edinburgh Mental Wellbeing Scale is a 7-item scale that has been widely validated, has strict unidimensionality, and is free from item bias [30]. The total scores range from 7 to 35, with higher scores indicating better outcome (ie, higher positive mental well-being).

Readiness to Change

Changes from baseline to follow-up at 30 days for the use of individual substances (alcohol, cannabis, opioids, and stimulants) will be based on self-reported readiness to change ladder assessments in both the intervention and control groups. The ladder assessments consist of a single item for each substance that asks participants to rate their readiness to change their use on a Likert-type response scale ranging from 0 (no thought of changing) to 10 (taking action to change). The response range parallels stages in the behavior change process from precontemplative to action stages, with higher scores indicating higher readiness to change and, therefore, a higher likelihood of changing their current substance use behavior. These questions were adapted from a readiness to change measure used by Merrill et al [31] to assess anticipated changes in alcohol use (adapted from The Contemplation Ladder, originally validated by Biener and Abrams [32]).

Self-Efficacy

Changes in mental health self-efficacy from baseline to 30-day follow-up are based on 5 survey questions in the intervention and control groups. Each question is scored separately using a Likert-type response ranging from 1 (not at all confident or

XSL•FO
RenderX

likely) to 5 (totally confident or likely), with higher scores indicating a better outcome (ie, greater self-efficacy). Similarly, in both the intervention and control groups, changes in substance use self-efficacy from baseline to follow-up at 30 days will be based on 4 self-report survey questions assessing different aspects of self-efficacy related to substance use management. Each question is scored separately using a response ranging from 1 (not at all confident) to 5 (totally confident), with higher scores indicating a better outcome (ie, greater self-efficacy). Both the mental health and substance use self-efficacy survey questions were developed by the research team based on the theory of self-efficacy by Bandura [33].

Connection to Services and Supports

Changes in the use of mental health services and supports in both groups will be assessed by comparing responses to 2 yes-or-no survey questions from baseline to 30-day follow-up. The questions ask if participants have been diagnosed or treated by a professional for a list of mental health conditions and whether they have used any mental health treatments (medication, psychotherapy, mindfulness, and web-based tools) in the past 30 days or currently. Two additional survey questions are only asked at the 30-day follow-up: accessing types of support services and joining any university clubs or participating in any club-related events.

Supplementary Feedback on User Experience

In addition to questions on the primary and secondary outcomes associated with the randomized controlled trial, participants in the intervention group will be asked a set of 12 additional questions on their experience using the *Minder* app at the end of the 30-day follow-up assessment. These questions will be used to inform the ongoing development of the app and use a combination of Likert-type and open text box responses to collect information on experiences using specific app components, reasons for using (or not using) features such as the Peer Coach, and any suggestions for improving key features such as the *Minder* chatbot.

Sample Size and Power

The sample size calculation for a small effect assessed by the PHQ-9, GAD-7, and USAUDIT-C was calculated using an effect size defined by Cohen $d=\Delta/\sigma$, where Δ is the group mean difference at the completion of the study and σ is the (pooled) within-group SD. For a small effect size (Cohen $d=0.2$), the sample size required to have 80% power at the level of significance $P=.02$ (0.05/3 primary outcomes) is 524 in each group. Assuming a 30% attrition rate, we require 748 participants in each group. To account for a conservative estimate of a small effect size and a 30% attrition rate, we estimate that a minimum of 748 randomized participants will be needed for each study group, totaling at least 1496 participants.

Sample Recruitment

Sample recruitment will use a widespread, multifaceted approach that includes web-based and offline interactions with students as well as university faculty and administrators.

Web-based recruitment will occur through social media engagement via Facebook, Instagram, Twitter, and Reddit research laboratory or project pages or through recruitment material reposted by organizations represented on the SAC or UBC-affiliated groups (eg, student clubs and student government representatives). Web-based recruitment will also occur through the linked Student e-Mental Health survey, a version of the World Mental Health International College Student survey adapted for Canadian contexts and administered at UBC (approved by the UBC Behavioral Research Ethics Board under ethics ID #H19-02538 [34]). At the end of the linked survey, prospective participants will receive a message offering an opportunity to test a mental health and substance use app, and interested students will be redirected to a registration form for this study where they can consent and register to participate if qualified.

Offline recruitment will include in-person booths of student team members in frequented communal areas with high student traffic (eg, student union and main campus lawn or pathway) around the UBC Vancouver campus; placing recruitment posters in public places on campus; and distributing mini posters with QR codes to classes, students, and student groups on campus.

Student engagement will also occur through collaboration with select UBC faculty members and administrators. Specifically, members of the research team will attend in-person and web-based courses at the university to provide students with a short presentation about the study and will request that recruitment materials be included on course web pages and emails. In addition, student groups at the university will be contacted to share recruitment information with their members through emails and newsletters or to coordinate with study team members attending group meetings or events to directly share information about the study. Invitations to participate in this study will also be sent to students who have previously expressed interest in participating in research studies and asked to be contacted if study opportunities with the research laboratory became available.

Widespread signage will also be implemented through posters at on-campus bus stops and digital screens in on-campus buildings, as well as printed posters within buses designated for routes with direct connections to the university.

Randomization and Study Arms

A study participant is defined as an individual who has completed the baseline survey and has been randomly assigned into either the control or intervention group. Participants are randomized using a stratified block randomization function built into the app. The randomization list for the built-in function was created using the web-based stratified block randomization list creator in the clinical trial software Sealed Envelope (Clerkenwell Workshop) [35]. To ensure that each arm of the randomized trial contains an equal number of participants endorsing a history of substance use, participants will be assigned to either group A (substance use: any medical opioid use, nonmedical opioid use, or nonmedical stimulant use) or group B (nonsubstance use), based on their answers to the opioid and stimulant use questions in the baseline survey. After being stratified into group A or group B, individuals are then

XSL•FO
RenderX

automatically randomly assigned (via the randomization list embedded into the app) to either the control or intervention arm of the trial using a 1:1 ratio in blocks of 10.

Those randomized into the control group will receive a message saying that they will be asked to complete an additional survey at 30 days and will only receive full access to the app after that. During the 30-day study period, the control group participants will receive a restricted version of the app that only permits access to the following: an introduction video with several students providing a broad overview of the different aspects of the app and its potential value, several onboarding slides with a short summary of the main app components, and baseline and follow-up assessment surveys plus reminder notifications to complete those surveys. Participants randomized into the intervention group will receive immediate access to the full *Minder* app.

Strategies to Improve Adherence to Intervention Protocols

All participants will receive both email reminders and in-app push notifications to complete the assessment surveys. More specifically, after the initial email to prospective participants with instructions to download the app and complete the baseline survey (to be randomized), an email reminder to complete the baseline survey will be sent on day 7 and again on day 20 to those who have not yet completed it. Participants who have not completed the baseline after 1 month may receive an additional email reminder. Participants assigned to the intervention group will then receive an email and push notification to complete the 2-week survey. Participants in both the intervention and control groups will receive an email and push notification 30 days after baseline completion and a group assignment to notify them to complete the follow-up survey, along with a reminder email 5 days and 11 days later if the survey has still not been completed.

Participants in the intervention group will also receive general in-app push notifications on days 4, 18, and 24 to highlight the different features of the app. The intervention group also receives a push notification when they have a new in-app message from their assigned Peer Coach, either a scheduled message (at assignment and around the study midpoint) or a reply to an ongoing text conversation with the participant.

Data Management and Withdrawal

All data are collected in the app and stored on secure servers located in Canada. The research team will download all study data regularly (business days excluding statutory holidays) and monitor for any issues with data collection. Access to the data will be limited to the members of the research team. To ensure that participant information and privacy are protected, the *Minder* app backend will abide by the UBC Research Ethics Board guidelines and British Columbia's Freedom of Information and Protection of Privacy Act. Participant data are collected using a unique study ID value within the system to ensure that survey response data and app use data remain separate from identifying information contained in the participant registration and remuneration documentation. The only exception will be if a participant elects to withdraw from the study and indicates their decision to have their data deleted; in this case, the data manager will use the unique study ID value to link their registration information with their survey response data and app use data and delete all their data from the system and all saved files.

Data Analysis Plan

Statistical Analysis

The primary analysis will be intention to treat (ITT) to estimate the causal effects of the assignment to treatment on the trial outcomes for all participants. A participant within the study is defined as an individual who has completed the baseline assessment survey and has been randomized into either the control or intervention group. The analysis will consider the following 2 features of the trial design: 3 primary end points and the method of randomization. The effects of some of these design features (ie, randomized blocks) are expected to be small and statistically nonsignificant. Nonetheless, we will use multilevel regression and SAS (version 9.4; SAS Institute Inc) and R (version 4.3.1; R Foundation for Statistical Computing) software in our analyses to control for these effects.

Before any testing, we will compare the baseline differences between the randomization groups on demographic (eg, sex, gender, and ethnicity), socioeconomic (eg, year of study), and personal risk variables (eg, mental health diagnoses and use of mental health treatments). Any baseline prognostic variable with a standardized difference between the groups of Cohen $d>.05$ will be considered a candidate variable to control for in the analysis. The selection of Cohen $d>.05$ is arbitrary: there is no accepted threshold to determine a meaningful difference between the 2 groups. However, this is a very small effect and indicates approximately a 4% nonoverlap between the 2 populations.

For the 3 primary end points (PHQ-9, GAD-7, and USAUDIT-C), a global test with the null hypothesis of no treatment difference in all primary end points between the control and treatment groups will be conducted using a marginal multivariate regression model for correlated data on PHQ-9, GAD-7, and USAUDIT-C. Compared with testing each outcome separately, the advantages of the global test from joint modeling include more parsimonious hypothesis tests and mitigated concern of multiple testing issues [36-38] as well as pooling of the information over the correlated outcomes to increase study power, especially with missing outcomes [39]. When the global test rejects the null hypothesis and we conclude that there is an intervention effect on at least 1 of the 3 end points, we will then analyze each end point separately to identify which of the 3 study end points are affected by the intervention. We will use the sequential Hochberg correction method [40] to control the overall family-wise error rate at $\alpha=.05$ when testing the hypothesis for each individual primary end point.

The general approach for analyzing all the types of study outcomes separately (including the 3 primary end points and the secondary end points) will be the generalized linear mixed-effect models (GLMMs) for clustered measures, with the randomization block as the clustering variable. These models can handle a wide range of outcome types, including continuous, binary, ordinal, and count, and can account for the correlations

XSL•FO
RenderX

among observations within the same cluster. Specifically, we will analyze each primary end point using a linear mixed-effect model, a special case of the GLMM. For secondary outcomes, we will use linear mixed-effect models to analyze mental well-being measures and readiness to change measures, mixed logit models to analyze the connection to services and support-related measures (binary: yes or no), mixed-effects quasi-Poisson regression models with the log link (a special case of GLMMs) for substance use frequency measures, and mixed-effects proportional odds ordinal logistic regression (another special case of GLMMs) for self-efficacy measures. The treatment effect on an outcome at 30 days will be assessed using a GLMM with the treatment allocation as the main explanatory variable and with adjustment for baseline outcome assessment value and other baseline prognostic factors as fixed effects and the randomization block as a random effect. By properly specifying the GLMM, a wide range of scientific hypotheses can be tested, including the primary ones regarding treatment effect estimation. The quality of statistical inferences will be substantiated through rigorous model checking and validation techniques. When statistical models assume that residuals at certain levels follow normal distributions, this assumption will be checked using a normal probability plot, in which the ranked residuals are plotted against corresponding points on a normal distribution curve. When substantial departures from the normal residual assumption are found, robust empirical SE estimates that are valid with nonnormal residuals will be used for statistical inference. We will use SAS software (version 9.4; SAS Institute Inc) and R (version 4.3.1; R Foundation for Statistical Computing) for the statistical analyses of our primary and secondary outcomes. Subgroup analysis will be performed using the GLMM on the subsets of data formed by the subgroup.

Missing data will take two forms: (1) missed questions or items and (2) unit nonresponse or attrition (withdrawals and lost to follow-up). We anticipate that most missing data are owing to attrition, which leads to unit nonresponse at the 30-day assessment. To reduce bias and avoid the loss of statistical power in our analysis of primary and secondary outcomes, we will use likelihood-based direct estimation, which is equivalent to performing multiple imputations under the model to predict values for missing data. One advantage of using the abovementioned multilevel GLMMs for analyzing primary and secondary outcomes is that it uses all the available data by including those study units with missing outcome values and it produces valid inference under the assumption of missing at random, which is a more relaxed assumption of missing data mechanism than missing completely at random. The missing values will be regarded as missing at random when the nonresponse behavior is believed to be a function of observed data, particularly common when assessing mental health and substance use behaviors and using a digital self-report format. The potential bias of these inferences will be quantified if these missing data were suspected to be nonrandom even after conditioning on the observed data, using the methods [41,42] developed by our team member and implemented in R package *isni* [43]. In summary, state-of-the-art statistical methods will be used to address these missing data issues.

In addition to the primary analysis using ITT, we will conduct a secondary analysis to evaluate the Complier Average Causal Effect (CACE) of the intervention. The primary analysis using ITT estimates the causal effects of treatment assignment on the trial outcomes for all participants, regardless of whether those assigned to the intervention actually use the *Minder* app (ie, complying with the treatment assignment). The results from the ITT analysis will be useful to policy makers and inform the effects of applying the treatment program to the population. Although ITT analysis is informative and valid, one limitation of the ITT analysis is that it estimates the program effectiveness rather than method efficacy. The program effectiveness depends on the proportion of compliers, which can change (eg, students change their willingness to use the intervention after they learn that the intervention works). Thus, to complement this approach, we will also conduct a CACE analysis that will focus on the intervention efficacy of those who actually use the e-intervention. The CACE analysis in conjunction with the abovementioned ITT analysis will provide a more complete picture of the intervention effect. By identifying who uses and benefits from the intervention, the trial can yield findings of direct interest to the scientific community and individual students. To overcome the challenge that the study participants' compliance and app use behaviors are self-selected in nature and not randomized, we will use the principal stratification approach to estimate the CACE effects on multiple end points in RCTs with treatment noncompliance [36] and the dose-response relationship between the extent of app use (eg, completed Chatbot Activities and number of contacts with Peer Coach) and intervention effect [44]. Given the diverse nature of the target population combined with the self-guided use of intervention components, we also plan to examine heterogeneity in treatment effects using a series of exploratory analyses that use sociodemographic (eg, gender and year of study) and assessment data (eg, symptom level on PHQ-9 and GAD-7) collected at baseline to examine the impact of the *Minder* app on key subgroups.

Masking

The study will use a single-blinded approach where only the investigators (including the statistician) will be blinded to the treatment group assignment when examining the primary hypotheses.

Continued Monitoring

There will be no stopping rules in this study—the anticipated benefits and unanticipated adverse effects are not life threatening and too small to merit such an approach. In addition, there will be no sequential analyses of the data: the analyses will commence at the end of the trial when the data manager provides the statistician with a blinded database for the analyses. Of note, data from the 2-week assessment completed by the intervention group will be removed from the data set used for the primary outcome analysis to maintain the blinding of the statistician.

Ethics Approval

This study was approved by the UBC Behavioral Research Ethics Board on January 6, 2022 (ethics ID: H21-03248). Any

XSL•FO
RenderX

changes to the protocol will be submitted for approval to the UBC Research Ethics Board.

Consent

Consent will be obtained using a web-based UBC Qualtrics form before the email validation process (ensuring current student enrollment and only 1 study registration per student), which provides access to the app and baseline assessment survey.

Results

The trial was registered on ClinicalTrials.gov (NCT05606601) on November 4, 2022. Recruitment and data collection began in September 2022. As of May 10, 2022, a total of 1425 participants have been enrolled. The results of the study will be available at the end of 2023 and will be published in international and national journals and presented at conferences.

Discussion

Expected Findings

Postsecondary students have been found to have high rates of mental health and substance use problems but many of these students do not access mental health or other professional supports [10]. e-Interventions have been shown to be effective among university students and may help address barriers to seeking support by providing tools that are easily accessible and can be scaled up for university campuses [16]. This manuscript describes the study protocol for a RCT to assess whether the *Minder* app is effective in improving mental health and substance use outcomes in a general population of Canadian university students. We hypothesize that individuals assigned to the intervention group will be more likely to experience improvements in mental health and substance use outcomes compared with individuals in the control condition. Additional secondary outcomes and analyses seek to inform potential mechanisms through which future studies can be conducted to better understand how to support the mental well-being of students and support the ongoing improvement of the *Minder* app as an effective digital mental health tool.

Limitations

Although many similar e-interventions have experienced large loss to follow-up and poor participant engagement, the incorporation of Peer Coaches for each participant in addition to well-spaced reminders to return to the app and complete baseline and follow-up surveys are expected to improve app engagement and reduce loss to follow-up. It is also important to note that this intervention was designed for use in the general population with mild symptomology so recruitment may be challenging as these students may be less interested than a clinical population in participating in a mental health study. We have addressed this challenge by using a comprehensive set of recruitment methods to engage potential participants in the broader university population. The intervention also includes components relevant to all students, including content addressing general well-being and more clinically relevant content. Students who choose to participate in this study may also be more motivated than the general population to seek help or to improve their mental health or substance use concerns. This may impact their willingness to participate and responses to self-report surveys, which may lead to reporting bias; however, we believe that these biases will not differ across the surveys or between intervention and control groups. Moreover, mental health and substance use concerns are high among university populations, with a large fraction experiencing psychological distress; therefore, a study sample reporting a range—including elevated levels—of mental health or substance use concerns is representative of students' functioning, which supports the generalizability of the results to the broader student population. In addition, participants in the intervention group will be unblinded, which could lead to biased self-reports of mental health symptomology related to placebo effects and social desirability. Although our use of standardized assessments completed via nonidentifiable web-based surveys should help mitigate some of these risks, it will be important to address this limitation in future studies on the *Minder* app by incorporating a sham or placebo control in future trials and examining the cognitive mechanisms associated with targeted outcomes.

Conclusions

Despite these limitations, the findings from this trial will inform the ongoing refinement of the *Minder* app. One key aspect of the *Minder* app that separates it from other similar tools is its extensive codevelopment process with students, especially in the development of content that is presented in a chatbot manner that is more interactive than other modular, web-based CBT interventions. It is designed to support a general population of students across many potential topics, whereas many existing tools target specific issues (eg, depression or anxiety). Thus, by designing a tool that can be used by all students, we hope to provide a suite of interventions (eg, from time management to managing emotions) that builds resilience across a range of conditions and improves the well-being of students as they face the many challenges associated with postsecondary education and young adulthood. This includes the tailoring and ongoing improvement of content using focus groups and continued engagement with specific groups of university students who may have more unique university experiences, including international students; lesbian, gay, bisexual, transgender, queer, 2-spirit, intersex, asexual, and similar minority (LGBTQ2IA+) students; and Indigenous and other racialized students. Through further analyses of app use data and subgroup analyses, we hope to identify areas of particular interest and need to help us better understand how to improve and scale up the delivery of the app to other student populations.

Abstract

Background: Reducing sedentary behavior and increasing physical activity in people with type 2 diabetes (T2D) are associated with various positive health benefits. Just-in-time adaptive interventions offer the potential to target both of these behaviors through more contextually aware, tailored, and personalized support. We have developed a just-in-time adaptive intervention to promote sitting less and moving more in people with T2D.

Objective: This paper presents the study protocol for a microrandomized trial to investigate whether motivational messages are effective in reducing time spent sitting in people with T2D and to determine what behavior change techniques are effective and in which context (eg, location, etc).

Methods: We will use a 6-week microrandomized trial design. A total of 22 adults with T2D will be recruited. The intervention aims to reduce sitting time and increase time spent standing and walking and comprises a mobile app (iMove), a bespoke activity sensor called Sedentary Behavior Detector (SORD), a messaging system, and a secured database. Depending on the randomization sequence, participants will potentially receive motivational messages 5 times a day.

Results: Recruitment was initiated in October 2022. As of now, 6 participants (2 female and 4 male) have consented and enrolled in the study. Their baseline measurements have been completed, and they have started using iMove. The mean age of 6 participants is 56.8 years, and they were diagnosed with T2D for 9.4 years on average.

Conclusions: This study will inform the optimization of digital behavior change interventions to support people with T2D Sit Less and Move More to increase daily physical activity. This study will generate new evidence about the immediate effectiveness of sedentary behavior interventions, their active ingredients, and associated factors.

Introduction

Overview

People with type 2 diabetes (T2D) have higher levels of sedentary behavior (SB) and lower levels of moderate to vigorous intensity physical activity (PA) compared with those without T2D [1]. Device-based measurement of SB has shown that people with T2D spend >64% of their daily waking time sedentary [1], which has subsequently sparked calls for targeted behavior change programs to reduce SB in this population, in addition to the promotion of regular PA [2].

SB has become a distinct target for individuals who are susceptible to or have been diagnosed with T2D [3]. It is suggested that people with T2D break up their sitting time by light PA, which can serve as a means for gradually adopting a more active lifestyle [4]. Reducing sitting time by either standing or light ambulation has been shown to improve glucose homeostasis among people at risk of or diagnosed with T2D [3].

Ubiquitous mobile health (mHealth) technologies such as smartphones and wearable sensors offer considerable potential to improve access to and delivery of behavior change support for reducing SB and promoting PA [5,6]. Progress in mHealth technology has enabled the design of just-in-time adaptive interventions (JITAIs), which aim to deliver behavior change support in real or near time, matched to when users need or want the support [7,8]. JITAIs harness information captured through mHealth technologies (smartphone sensors, GPS, and internet access) to determine which behavior change support component should be delivered and tailor it to an individual's changing context (where) or status (when) [9]. The delivery of more contextually aware intervention support at more salient times to end users is hypothesized to enhance behavior change compared with other delivery approaches (eg, face-to-face and websites) [9].

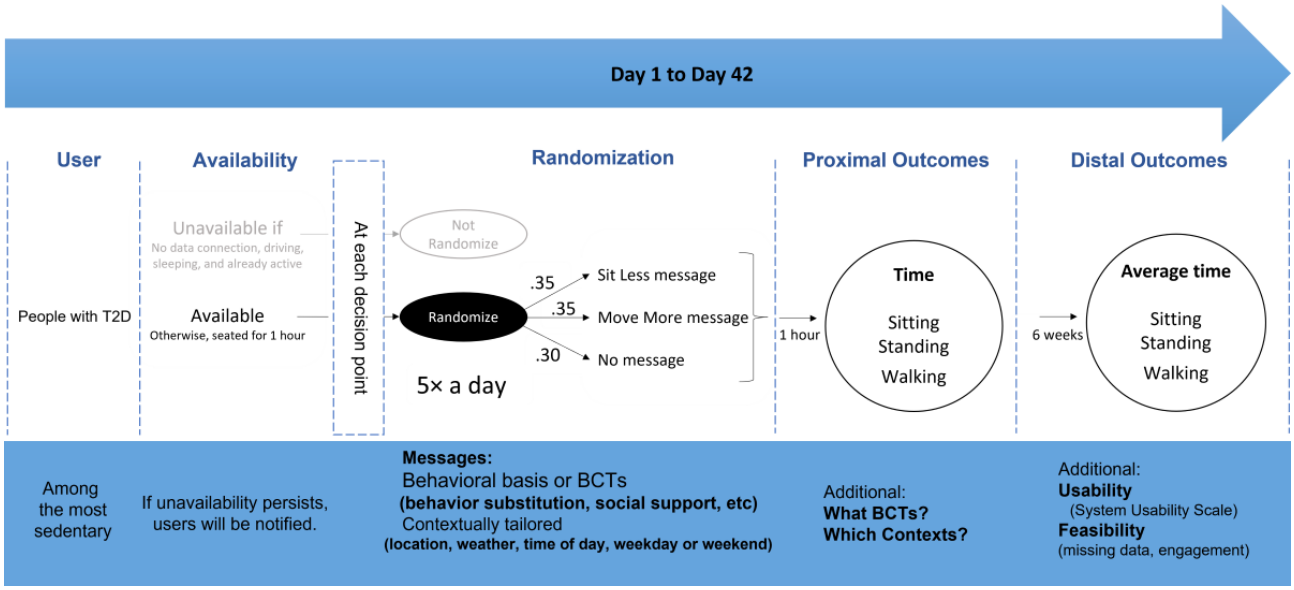
It has been argued that conventional experimental designs are not sufficient to support the development of JITAIs because they do not enable researchers to determine empirically when a particular intervention component should be delivered and whether a JITAI that was delivered exerted the intended effect [10]. Traditional randomized controlled trial designs evaluate the overall effect of an intervention on a specific behavior or health outcome, not specific components of that intervention. Moreover, randomized controlled trials do not provide information on the particular time when the intervention had an effect and the moderators that affected the behavior change [11].

Other study designs, such as factorial designs, enable researchers to determine the effects of each intervention component, the interactions between components, and the dosing of the intervention. However, they are unable to delineate the time when the intervention was most receptive and what moderators influenced the intervention [11]. To address these limitations, Klasnja et al [11] proposed the microrandomized trial (MRT), which, they argued, could supplement the use of behavioral theory to guide the development of JITAIs. The MRT design provides data on the effects of specific intervention components, changes in effects over time, and potential moderators, including contextual and psychological factors [11]. Due to the dynamic nature of SB and PA that change throughout the day and in various contexts, adaptive designs such as MRT align well with interventions targeting SB and PA behavior change [12]. The MRT design has been suggested as necessary to leverage the potential of smartphones as a tool to improve PA and reduce SB [13]. MRT enables assessing the immediate effects of antisedentary and walking interventions [14] and therefore contributes to the optimization of SB and PA interventions.

Microrandomization refers to randomly allocating an intervention option at relevant times when a person would be most responsive to an intervention (based on theory, the person's past behavior, and the current context), thereby enhancing the effectiveness of the intervention [11]. MRTs explain the causal relationship between each randomized intervention component (eg, Sit Less or Move More notifications) and the proximal effects (ie, what happens in a limited time window, eg, within 1 hour, following the randomized intervention component) [11]. The distal outcome results from an aggregation of proximal effects obtained through repeated exposure to intervention components over time [11]. For example, a distal outcome would be people achieving recommended levels of PA and longer-term clinical outcomes such as improved glycemic control or improved fasting or postprandial glucose [15].

Aims

The primary aim of this study is to assess the effectiveness of theory-based motivational messages for reducing proximal sitting time and increasing proximal standing or walking time (ie, nonsitting time). The secondary aims involve (1) assessing what type of behavioral components (ie, behavior change techniques) are most effective in reducing sitting time and increasing standing and walking time, measured proximally, and (2) determining relevant contextual moderators for reducing sitting time and increasing standing and walking time.



Methods

Design

A 6-week MRT will be conducted (see Figure 1). Using this design, participants will be randomly assigned an intervention option (Sit Less message, Move More message, or no intervention) at each relevant decision point.

XSL•FO
RenderX

Figure 1. A summary of the microrandomized trial (MRT) design. Target group, availability conditions, study duration and arms, randomization probability, and outcomes are presented. BCT: behavior change technique; T2D: type 2 diabetes.

Participants and Recruitment

Overview

Participants will be recruited digitally through social media advertisements (eg, Facebook and Instagram). Moreover, posters will be placed on noticeboards of general practitioner and specialist clinics, and emails will be sent to potential participants who have indicated their willingness to participate in research studies. The plain "language statement and consent form" will be sent to eligible participants who express their interest in participating before any data collection.

Sample Size

A total of 22 participants are estimated to detect a small proximal treatment effect size of 0.13 for increasing nonsitting time with 80% power at the level of 5% statistical significance. This was based on the assumptions of 5 decision points per day, a constant randomization probability of 0.7, and an expected participant availability of 70% [16].

Eligibility Criteria

Eligible participants will be adults with T2D, aged between 35 and 65 years, who own an Android smartphone (version 7.0 or higher) and currently interact or engage with apps, have no limitations (including physical problems and medical complications) to engage in low- and moderate-intensity PA, are able to communicate in English, and can provide informed consent.

Volunteers who use other activity trackers and mobile apps that target PA, highly active people, those diagnosed with T2D less than 3 months ago, and people with psychiatric problems, attention, or memory issues will be excluded. We assume highly active people as those who meet World Health Organization (WHO) recommendation of 10,000 steps per day or 150 minutes of moderate to vigorous PA per week. The International Physical Activity Questionnaire—Short Form will be used to assess activity levels [17]. A 1-week run-in period will assess nonadherence with the activity tracker. Individuals with more than 50% incomplete data will be excluded.

Intervention Platform

The intervention comprises a bespoke mobile app (iMove app) [18] and a Bluetooth-enabled wearable sensor (SORD) developed and validated by our research group [19]. iMove is a JITAI that aims to support people to decrease sedentary time (Sit Less) and increase PA (Move More) [20]. It consists of a home tab that illustrates sitting, standing, and walking activities, an activity tab to select activities manually in situations where technical issues exist with the app, a goal setting tab to set sitting and walking goals, a notification history tab to compile previous notification messages, and a profile tab (see Figures 2 and 3). SORD is a bespoke thigh-worn device that connects to the iMove app and measures sitting, standing, lying, and PA (eg, walking) [19].

XSL•FO
RenderX

Figure 2. iMove app images.

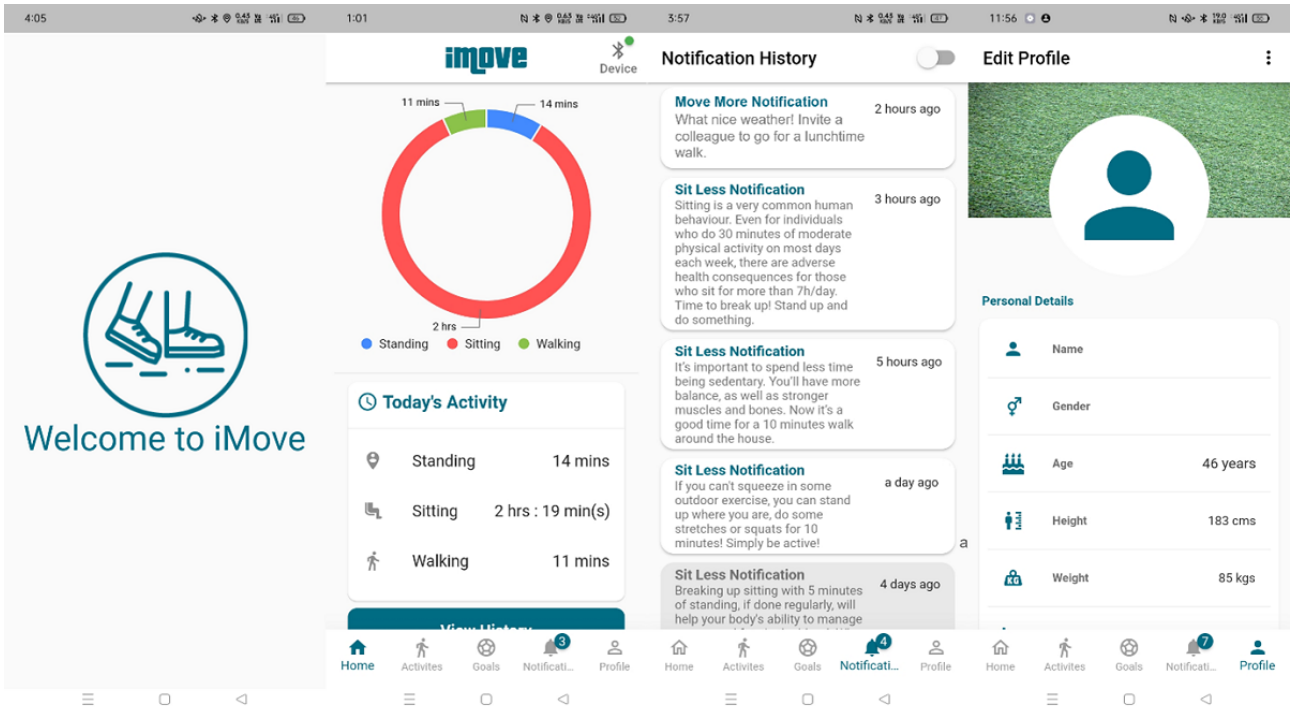


Figure 3. Sedentary Behavior Detector (SORD) device.

Intervention

Overview

Through the iMove app, participants will receive a series of Sit Less and Move More intervention messages (notifications) to serve as cues to action [21] and increase readiness to engage in activity. A pop-up message will appear on the phone screen with a sound effect when a notification is received. There will be 2 intervention options, which include Sit Less (sedentary interruption and transition to standing) and Move More (walking) for 1.5-3 minutes, approximately equivalent to 500-1000 steps, and a control option (no messages). Participants can switch off the push notification for a certain amount of time on any given day.

A list of messages is provided in Multimedia Appendix 1.

Notifications are adapted to 4 different context dimensions, including time of day, day of the week (weekend vs weekdays), location (home vs workplace), and weather conditions (good or suitable for PA, rainy and cold or not suitable for PA). Notifications are delivered on 5 occasions (decision points) throughout the day and include morning, lunchtime, afternoon 1, afternoon 2, and evening (details are presented in the "Decision Points" section below).

At each decision point, participants are randomized only if they are available (ie, they are not driving, not sleeping, not active already, and are connected to the internet). The following probabilities are used for randomization: 70% in the intervention (35% SB, 35% PA) and 30% as active control at each particular decision point. GPS will assist with the recognition of driving if the user is on the move. A preset time (9 PM to 8 AM) will be considered for rest and sleeping. In addition, both driving and sleeping can be manually modified by users.

Decision Points

A total of 5 decision points, from 8 AM to 8:30 PM, will be selected as shown in Table 1.

XSL•FO
RenderX

Table 1. Occasions (decision points) when notifications are delivered.

Decision point	Time
Morning	8 AM to 10:30 AM
Lunchtime	10:30 AM to 1 PM
Afternoon 1	1 PM to 3:30 PM
Afternoon 2	3:30 PM to 6 PM
Evening	6 PM to 8:30 PM

Intervention Messages

Notifications were developed by the research team and incorporate effective behavior change techniques to Sit Less and Move More. Behavior change techniques including behavior substitution [22], social support [23], problem-solving or barrier identification [23], instruction on how to perform the behavior [22,24], providing information on the consequences of PA specific to the individual [23], prompts or cues [24], prompting generalization of a target behavior [23], goal setting [23], self-monitoring [22], and feedback on behavior [22] were used to create messages. Table 2 presents examples of intervention messages and their associated behavior change techniques.

XSL•FO
RenderX

Table 2. Examples of Sit Less and Move More messages and their respective behavior change techniques.

Message type and behavior change technique	Example message
Sit Less	
Behavior substitution	You have been sitting for about 1 hour this morning. Why not stand up and do some stretches for 2-3 minutes.
Social support	Ask your partner to do some house chores with you (e.g., sweeping, mopping, vacuuming, etc.). It is more fun when you do this together while talking as well!
Problem-solving or barrier identification	You might not notice your long periods of sitting time, but it adds up to a lot of hours (e.g. we may sit during meals, travelling to/from work, in front of the computer, watching TV,…). Now it's the right time to take a break and stand up and do some stretches or warm-up exercise.
Instructions on how to perform the behavior	Time to stand up: you may want to grab a drink of water, talk on the phone while walking around or go and talk to your colleagues instead of emailing them.
Providing information on the consequences of physical activity (PA) specific to the individual	It's important to spend less time being sedentary. You'll have more balance, as well as stronger muscles and bones. Now it's a good time for a 10 minutes walk around the house.
Prompts or cues	Why not go take one of your favorite books and enjoy reading! This way you break up your sitting.
Prompting generalization of a target behavior	It looks like you are doing well reducing your sitting time during the mornings. Try to break your sitting time in the evenings as well. It's the time!
Goal setting	Your daily sedentary behaviour goal is *[<VALUE hours]*. While working, you can stand up and do some stretches. This helps you achieve your daily goal.
Self-monitoring	Check how much time you spent in sedentary (sitting) state yesterday.
Feedback on behavior	Congratulations! You achieved your daily sedentary behaviour goal *[<VALUE hours]* today. Keep it up!
Move More	
Behavior substitution	It's a beautiful day today, instead of sitting why not grab your lunch, go out and find a place to enjoy your food.
Social support	Invite a colleague to join you for lunch today! You can find a nice place outside to sit and enjoy!
Problem-solving or barrier identification	If most of your colleagues are inactive people and you think you have no company, you can encourage them or make new friends who are usually active. Invite someone to an afternoon walk now.
Instructions on how to perform the behavior	Getting out to walk in the rain is still a great way to connect and enjoy the outdoors. It's time to take an umbrella and go out!
Providing information on the consequences of PA specific to the individual	If you have an active lifestyle it helps you manage your blood sugar. It's time to do some outdoor light exercises in your neighbourhood.
Prompts or cues	Try now if you like: Walk around your building for a break during lunchtime.
Prompting generalization of a target behavior	Can you try to increase your activity time (while you do at work) also when you are at home? It's the right time to be active now!
Goal setting	You can achieve your daily physical activity goal (*[>=VALUE minutes]*) by engaging in short walks in your backyard or nearby park, etc. Try it now!
Self-monitoring	Check how much time you spent in physical activities yesterday.
Feedback on behavior	Congratulations! You achieved your daily physical activity goal *[>=VALUE minutes]* today. Keep up the good work!

Overview of Procedures

Eligible participants who provide their consent will be provided with the iMove app installer and invited to a web-based individual orientation session through the Zoom videoconferencing platform. During the web-based meeting, participants will be assisted in installing the app and informed about how to use the iMove app and SORD device. Weight, height, and other demographic measures (age, gender, marital status, job status, and education level) will be assessed at baseline as well as after intervention.

Data Collection and Storage

Activity sensor data (sitting, standing, and walking time) and other mobile data (location, weather, and calendar information) will be collected automatically through SORD and iMove and sent to a Deakin University secured server. Participant questionnaire data, including demographics questionnaire and system usability, will be captured digitally using Deakin secured Qualtrics surveys.

XSL•FO
RenderX

Proximal Outcome

Time spent sitting (T_{sit}), standing (T_s), and walking (T_w) within 1 hour after sending the push notification are the proximal outcomes.

Distal Outcome

The distal outcomes of interest are the "average weekly time spent sanding and walking altogether, that is, nonsitting time" and the "average time spent being in the sitting state." Moreover, we will also assess total sitting, standing, walking, and exercising time.

Contextual Measures

Contextual factors, including weather and location, will be assessed using embedded smartphone sensors (GPS) and weather application programming interfaces (APIs; eg, OpenWeatherMap).

Other Outcome Measures

Other outcome measures include feasibility and acceptability. Feasibility will be assessed with descriptive statistics, including the proportion of missing data and engagement with the app (the average time the app was opened every day). Usability is assessed using the System Usability Scale through a web-based survey at the end of the intervention [25,26].

Noncompliance with the intervention platform (ie, SORD and iMove) will be evaluated by sending reminders and phone calls. In case no data have been gathered at one decision point, an automated text message reminder will be sent to the user. This reminder will be triggered once a day. If the data remain uncollected for the second day, the system will notify the research team, and a human investigator will contact the user to encourage them to use the platform and offer assistance in resolving any problems. Each user will be expected to continue the study until they provide data for the corresponding number of days × decision times (42 days × 5 = 210).

Data Analysis

Primary Analysis

Data from the 22 participants who generated 42 days of expected data, totaling 4620 decision points, will be analyzed. The study days will be continued until we reach the required number of days of data for each individual. Moreover, to deal with missing data at various decision points that could result from Bluetooth issues with the transfer of data or any other reasons (eg, activity states not being recorded), we will impute 0 for all missing minutes of sitting, standing, and walking.

MRT data will be analyzed using the weighted and centered least-squares estimator as previously described [27]. Using this analytical method, time-varying covariates can be handled, and the causal effect can be consistently estimated. Statistical analyses will be performed using R software (R Foundation for Statistical Computing) using the geepack R package.

Primary outcome measures include decision point, day, availability, interventions, and proximal change in activity states (ie, within 1 hour after the intervention is delivered). Overall effects of delivering a suggestion compared with not providing a suggestion on the subsequent 1-hour sitting, standing, and walking behaviors will be assessed. Moreover, linear treatment effects for Sit Less and Move More suggestions will evaluate the interaction between suggestion effects (ie, Sit Less or Move More) and decision points.

Statistics including β estimate, 95% CI, and *P* values will be reported for the average proximal effect as well as the multivariate effect (main effect). Sit less, Move More, and no suggestion (ie, control) conditions will be compared.

Secondary Analysis

Applying control systems principles [28], matchable-observable linear identification algorithms will be used to estimate linear time-invariant models from iMove intervention data [28]. Behavioral changes, including standing and walking time, will be assessed as a function of the onset, and offset of individual intervention components (ie, messages) and time-variant determinants (eg, contextual factors). Changes to the input variable (eg, behavior change technique) enable estimation and validation of computational models, therefore allowing exploration of personalized models. An individualized mathematical model of standing and walking time (outputs) will be created for Sit Less and Move More messages considering different contextual factors in different models. Also, further analysis will reveal unique intervention messages that generate the most effective behavior change (ie, either increasing standing or walking time) across various contexts.

Ethics Approval

The study received ethical approval from the Deakin University Human Research Ethics Committee (2021-258).

Results

The iMove app and integration with SORD were finalized in August 2022. Recruitment was initiated in October 2022. So far, 6 participants (2 female and 4 male) have provided their consent and enrolled in the study. They have completed baseline measurements and started using iMove. The mean age of 6 participants is 56.8 years, and they were diagnosed with T2D for 9.4 years on average.

Discussion

Overview

We present an MRT to evaluate the development of a Sit Less and Move More JITAI intervention in people with T2D [20]. The proximal and distal main effects of the sedentary and PA interventions on reducing sitting time and increasing standing or walking time (ie, nonsitting time), along with their univariate effects, will be evaluated. Moreover, the most effective behavior change technique will be recognized. Furthermore, the most critical contexts (eg, location: home or workplace) in which users are most responsive to interventions will be identified.

Too much sitting is a distinct behavior consideration from too little exercise for increasing the risk of cardiovascular disease [20]. Practical and integrated approaches involving both Sit Less and Move More have been introduced for risk reduction

XSL•FO
RenderX

[20]. It is expected that interventions delivering a combination of Sit Less and Move More would add to the overall daily activity of an individual rather than focusing on at least 150 minutes of weekly exercise [20].

To our knowledge, there are no previous MRT studies targeting SB and PA among people with T2D. Other studies have focused on the general public including healthy sedentary adults [14] and university students [29]. The study by Klasnja et al [14] showed that the 6-week MRT intervention (antisedentary or walking vs no suggestion) among healthy sedentary adults (n=44) was effective to increase the average 30-minute step counts (ie, within 30 minutes after the intervention) by 14%. The study by Figueroa et al [29] conducted a 6-week MRT with university students (n=99) to improve their PA level. They showed that receiving the intervention (motivational messages and feedback on step counts vs no suggestion) increased daily steps by 729 steps, but this effect was diminished over time to –33 steps a day. They recommend that future studies need to take into account both user context and preferences [29].

These theory-based MRT studies were mainly focused on walking [14] rather than standing. Incorporating standing into the intervention package could make the Sit Less and Move More concept more practical. Replacing sitting time with standing could be considered a medium in which the most sedentary populations (eg, T2D) may make the initial transition from an inactive lifestyle to a more active lifestyle [30].

Limitations and Strengths

Due to the data-intensive nature of this study and the reliance on mobile apps for data transfer, heavy data loads may complicate data transfer to the backend server and generate missing instances. Even though multiple troubleshooting steps have been taken to develop iMove, such issues could still occur on certain smartphones with restricted manufacturers' system mandates. A key strength of this study is the incorporation of standing as a measured outcome. Because the focus of this MRT is on supporting people with T2D transition from sedentary to more overall physical activities, assessing transitional states, that is, standing, seems relevant. Assessing standing time, distinct from sitting and moving time, is expected to provide more robust evidence on how such Sit Less and Move More MRT performs.

Conclusions

Overall, the results of this study will inform the optimization of digital behavior change interventions to reduce SB and increase PA among people with T2D. Moreover, the findings will provide practical implications to clinicians concerned about recommending high-intensity exercise to older people with T2D. Finally, policy makers will be informed about simple smartphone-based interventions to reduce the burden of sedentariness among people with chronic diseases (eg, diabetes).

Conflicts of Interest

None declared.

Abstract

Background: Children with neurodevelopmental disorders have a high risk of sleep disturbances, with insomnia being the most common sleep disorder (ie, chronic and frequent difficulties with going and staying asleep). Insomnia adversely affects the well-being of these children and their caregivers. Pediatric sleep experts recommend behavioral interventions as the first-line treatment option for children. Better Nights, Better Days for Children with Neurodevelopmental Disorders (BNBD-NDD) is a 5-session eHealth behavioral intervention delivered to parents to improve outcomes (eg, Pediatric Quality of Life Inventory [PedsQL]) for their children (ages 4-12 years) with insomnia and who have a diagnosis of mild to moderate attention-deficit/hyperactivity disorder, autism spectrum disorder, cerebral palsy, or fetal alcohol spectrum disorder. If cost-effective, BNBD-NDD can be a scalable intervention that provides value to an underserved population.

Objective: This protocol outlines an economic evaluation conducted alongside the BNBD-NDD randomized controlled trial (RCT) that aims to assess its costs, efficacy, and cost-effectiveness compared to usual care.

Methods: The BNBD-NDD RCT evaluates the impacts of the intervention on children's sleep and quality of life, as well as parents' daytime functioning and psychosocial health. Parent participants were randomized to the BNBD-NDD treatment or to

XSL•FO
RenderX

usual care. The economic evaluation assesses outcomes at baseline and 8 months later, which include the PedsQL as the primary measure. Quality of life outcomes facilitate the comparison of competing interventions across different populations and medical conditions. Cost items include the BNBD-NDD intervention and parent-reported usage of private and publicly funded resources for their children's insomnia. The economic evaluation involves a reference case cost-effectiveness analysis to examine the incremental cost of BNBD-NDD per units gained in the PedsQL from the family payer perspective and a cost-consequence analysis from a societal perspective. These analyses will be conducted over an 8-month time horizon.

Results: Research funding was obtained from the Kids Brain Health Network in 2015. Ethics were approved by the IWK Health Research Ethics Board and the University of Calgary Conjoint Health Research Ethics Board in January 2019 and June 2022, respectively. The BNBD-NDD RCT data collection commenced in June 2019 and ended in April 2022. The RCT data are currently being analyzed, and data relevant to the economic analysis will be analyzed concurrently.

Conclusions: To our knowledge, this will be the first economic evaluation of an eHealth intervention for insomnia in children with neurodevelopmental disorders. This evaluation's findings can inform users and stakeholders regarding the costs and benefits of BNBD-NDD.

Introduction

Background

Neurodevelopmental disorders (NDDs), estimated to affect 5%-9% of children [1,2], are a heterogeneous group of chronic conditions that affect the central nervous system. Children with NDDs are a vulnerable population that experiences significant health disparities compared to typically developing (TD) children, including high rates of sleep difficulties. In children with NDDs, sleep difficulties contribute to morbidity and impair cognition, emotional regulation, and neurobehavioral functioning [3]. Prevalence rates of sleep disturbances have exceeded 90% in children with certain NDDs, with insomnia being the most frequently cited sleep disorder [4]. Sleep disturbances can have a negative impact on children's quality of life (QoL) and exacerbate stress in their caregivers [3].

Despite limited safety and efficacy data in children, pharmacotherapies, both over-the-counter and prescription, are often given to treat insomnia in this population [5]. However, pediatric sleep experts recommend that psychosocial interventions be implemented first [6]. Specifically, the intervention would start with psychoeducation and healthy sleep practices, and be followed by psychological interventions such as bedtime fading or modified extinction [7-9]. Then, if psychosocial interventions are ineffective or unfeasible, medications become an option [7-9].

The existing literature has demonstrated the efficacy of treating insomnia in TD children with psychosocial interventions [10,11]. While there is less research on children with NDDs, the available evidence also demonstrates the effectiveness of these interventions. A review of nonpharmacological interventions for sleep problems in youths with chronic health conditions concluded that the effectiveness of psychosocial interventions was not exclusive to specific health conditions but had comparable effects across children with a variety of mental and physical health conditions, including NDDs [12]. Psychosocial interventions for pediatric insomnia have also been shown to improve parents' sleep and increase their feelings of competence and control [13,14].

Existing psychosocial interventions are typically delivered in conventional settings (eg, hospital clinics, outpatient professionals' offices), consisting of weekly training sessions for parents [15-18] and several visits with health care providers [19,20]. Hence, time constraints and required travel expenses to health facilities may be access barriers for families. Reaching families in rural or remote communities and those who are financially constrained or lack insurance coverage for private psychological and other necessary clinical services are significant challenges in the delivery of behavioral interventions [21].

Economic Evaluation

Economic evaluations can help guide policy making and resource allocation decisions. Little is known about the cost-effectiveness of eHealth (internet-based in this case) behavioral interventions for sleep problems in children. Many parents are interested in internet-based interventions for their children's sleep problems [22]. An internet-delivered treatment program may be an effective tool to address and overcome barriers to accessing pediatric insomnia care [22,23]. The cost-effectiveness of internet-based sleep interventions for children in comparison to usual care has not been determined for children with NDDs [22].

The value for money of internet-based interventions can be assessed using cost-effectiveness analysis (CEA) and cost-consequence analysis (CCA) [24]. A CEA incorporates cost and a single measure of effectiveness into a metric represented by an incremental cost-effectiveness ratio (ICER) [25]. An ICER is calculated by dividing the difference in cost by the difference in outcome measure between 2 interventions,

XSL•FO
RenderX

often treatment and control conditions in randomized controlled trials (RCTs). A CCA reports various costs and outcomes to enable decision makers to decide which are most relevant to their context and perspective [24]. It can capture costs to the user, system, and society and portray health, nonhealth, and nonpatient impacts [24].

An economic evaluation will be performed alongside the Better Nights, Better Days for Children with Neurodevelopmental Disorders (BNBD-NDD) RCT (ClinicalTrial.gov ID NCT02694003), which seeks to determine the efficacy of the eHealth behavioral intervention compared to usual care. BNBD-NDD is a parent-implemented eHealth behavioral program delivered to parents to enable accessible and effective care for insomnia in children with NDDs. The web-based nature of BNBD-NDD allows it to be readily scalable to reach many users. BNBD-NDD is transdiagnostic because it targets children ages 4 to 12 years with diagnoses of mildly to moderately severe attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorder (ASD), cerebral palsy (CP), and fetal alcohol spectrum disorder (FASD). Although these 4 conditions present a broad range of cognitive, physical, and social characteristics, they are all associated with higher than normal rates of insomnia [26,27].

This protocol describes the BNBD-NDD economic evaluation, consisting of a CEA to evaluate the cost-effectiveness of BNBD-NDD in children with NDD compared with usual care and a CCA to examine outcomes beyond QoL. A CEA will be undertaken using the parent-reported Pediatric Quality of Life Inventory (PedsQL) questionnaire total scores, which will assess the children's QoL. The QoL measure is used in economic evaluation because it allows comparison of the health outcomes of competing alternative interventions over time and across populations [28]. In addition, to illustrate a more comprehensive picture of BNBD-NDD's impacts, a CCA will also be conducted to examine outcomes beyond the children's health-related quality of life (HRQoL), including children's sleep, parents' daytime functioning, and psychosocial health.

Understanding the added value of BNBD-NDD is essential to informing the intervention's scale and spread. Thus, this protocol aims to complement the BNBD-NDD RCT and describe the economic evaluation from both family and societal perspectives.

Methods

Recruitment

Participants were recruited for the BNBD-NDD trial nationwide in Canada and stratified based on the parent-reported primary NDD diagnosis of their child. Potential parent participants were targeted via three groups: (1) parents of children with NDDs, (2) external stakeholders and organizations, and (3) the media. Internet-based tools were primarily used for recruitment, notably this study's website and social media, as well as print materials and presentations to health care professionals.

Inclusion Criteria

Participants must (1) reside in Canada and (2) be caregivers of children (3) ages 4 to 12 years who have been diagnosed with (4) ADHD, ASD, CP, or FASD by a health care provider and (5) meet the research criteria for insomnia. Insomnia criteria (ie, sleep onset disturbance) were characterized by at least 2 of 3 symptoms (>20 minutes to fall asleep, parent remaining in room for sleep onset, and more than 2 reunions) occurring 2 to 4 times per week for at least a month [29]. Additionally, these caregivers must have (6) regular access to a high-speed internet connection, (7) an email account, and (8) be proficient in English for everyday tasks.

Sample Size Calculation

The BNBD-NDD RCT was powered to detect a group by time interaction across the 3 data collection time points (baseline, 4-month, and 8-month) and between the BNBD-NDD and usual care groups. The primary sleep outcome was the Disorders of Initiating and Maintaining Sleep (DIMS) [22] variable. To achieve a power of 0.80 with an α of .05, 39 participants per group would have to complete the DIMS measure at 8 months. Based on this analysis and the anticipated postenrollment dropout rate of 50% from a previous BNBD RCT, an estimated 160 participants were targeted for enrollment at baseline.

Randomization and Blinding

Participants were randomized using a block stratified approach with 1:1 allocation to either the intervention (BNBD-NDD) or the usual care group and were not blinded to their assigned group. Stratification was by parent-reported primary NDD diagnosis.

Study Groups

Participants were randomized to either the intervention group or the usual care group. Both groups may use alternative resources and other programs or services during this study. The intervention group was provided access to the BNBD-NDD program for 8 months after randomization (the duration of this study). As such, participants in the intervention group were regarded as receiving BNBD-NDD plus usual care. The usual care group could access BNBD-NDD after completing all follow-up assessments at 8 months.

BNBD-NDD Intervention

BNBD-NDD is an eHealth program for parents or caregivers of children with NDDs and insomnia. The program is parent-implemented, incorporating transdiagnostic, evidence-based behavioral approaches, such as sleep education, stimulus fading, and scheduled awakenings, and presents NDD-specific strategies. The intervention is accessible via desktops, laptops, tablets, and mobile devices.

BNBD-NDD includes 5 sessions for participants to work through sequentially, with the recommended completion time ranging from 5 to 10 weeks. The sessions cover the following topics: (1) about BNBD-NDD; (2) healthy sleep practices; (3) settling to sleep independently; (4) night waking, napping, and early morning awakenings; and (5) looking back and ahead. Participants may access and complete the program at times that are convenient for them. Treatment fidelity and adherence were evaluated through process measurements and user statistics gathered by the intervention platform software. Participants may withdraw from the program at any time and are invited to provide reasons for withdrawal through open-ended questions.

Perspective

Costs and outcomes are weighed differently by various decision makers. A way to determine the most pertinent perspective is by asking whom the analysis is intended to inform [30]. As BNBD-NDD is designed as a direct-to-user product, with the program's users and beneficiaries being the parents and their children with NDDs and insomnia, this economic evaluation aims to inform them of the costs and effects of the program. The reference case costing will be completed from the perspective of the family payer (in this case, the parents). In accordance with recommendations from the Canadian Agency for Drugs and Technologies in Health, the reference case analysis will evaluate the QoL outcome for children, the primary target beneficiaries of the program [25]. In the nonreference case analysis from a societal perspective, the outcomes for caregivers (ie, daytime fatigue, psychosocial health), specific measures of children's sleep (ie, DIMS score), and societal costs (ie, treatment utilization [TU]) will also be examined.

Time Horizon

In the BNBD-NDD RCT, data collection occurred at baseline, 4 months, and 8 months. The reference case CEA and secondary CCA will use an 8-month time horizon, focusing on baseline and 8-month data; 8-month data are used to best capture the longer term costs and effects.

Outcomes for Economic Evaluation

PedsQL is an instrument that measures generic (rather than disease-specific) HRQoL and has been shown to have appropriate psychometric properties when used with children with NDDs [31]. It can be used to evaluate HRQoL in healthy children, youths, and those with medical conditions [32]. PedsQL uses a modular approach with 4 multidimensional scales on physical, emotional, social, and school functioning [33]. Parents rate each item using a 5-point Likert scale from 0 (never) to 4 (always) [31]. A Total Scale Score is calculated by adding all of the items and dividing the total by the number of items answered in all scales [33]. Mean Scale Scores are computed by dividing the sum of the items by the number of items answered in the scale [33]. Depending on the age of the participant's child, 3 parent-report versions were used (for ages 2-4 years, 5-7 years, and 8-12 years) to accommodate the age range of this study sample. The difference between the intervention and usual care groups' average Total Scale Score in parent-proxy reports of their children's PedsQL at baseline and 8 months will be evaluated in the reference case CEA. Secondary analyses will examine each of the 4 modules and age group trends; it is noted that inconsistent reporting of the school functioning section may occur due to age and the time of year of data collection (off-school period). The scoring and missing data (where applicable) will be completed in accordance with the PedsQL user manual [34].

In the CCA, the children's sleep and parental outcomes are analyzed by comparing baseline and 8-month data and looking at changes in sample averages. Based on parent-reported questionnaire data, the DIMS score quantifies the severity of children's sleeping problems. The Single Item Fatigue Impact Scale [35] and the Depression, Anxiety, and Stress Scales [36] are used to evaluate the daytime fatigue and psychosocial health, respectively, of parents. Single Item Fatigue Impact Scale is adapted from the 40-item Fatigue Impact Scale [35]. The Depression, Anxiety, and Stress Scales have demonstrated adequate construct validity and high reliability [36].

Resource Use and Costing

BNBD-NDD Cost

The direct cost of BNBD-NDD to the families is primarily the retail cost of the intervention. As the program was offered free of charge for our RCT, we used the average of parents' (proxy payers for their children) reported willingness to pay. The participating families were expected to have internet access, which was not assessed or included in the direct costs. Retail pricing will be explored further from the willingness to pay data, which obtained a hypothetical willingness to pay (HWTP) by directly asking for the maximum cost participants would pay for the program. The HWTP responses may contain hypothetical bias influenced by factors such as the absence of a budget constraint effect and strategic answering, as some may perceive their input to potentially affect future pricing [37].

Treatment Utilization

The TU questionnaire [38] estimated the health care services families sought to address their children's sleep problems, including publicly and privately funded ones. Care may be provided by family physicians, physician specialists (eg, pediatricians), and other health professionals (eg, psychologists). The mean frequency and costs of these services at baseline and at 8 months for the BNBD-NDD and usual care groups will be compared to see if BNBD-NDD impacted the usage rate. Out-of-pocket expenses reported for a health professional's or provider's help will also be assessed. Unit costs will be estimated using publicly available resources, such as the Canadian Agency for Drugs and Technologies in Health [39].

Data Analysis

Overview

For the reference case CEA analysis, the mean sample PedsQL at baseline and 8 months will be compared. Regression analyses will examine the impacts of baseline characteristics (geographical region, age groups, sex, household income, and NDD diagnosis) on the efficacy measures. For all regression analyses, the mean difference between groups will be reported, as well as the variance, *P* value, and goodness of fit using R^2.

Reference Case CEA

In the reference case analysis using the family payer perspective, the ratio of the difference in mean cost between groups to the difference in mean PedsQL total score per group will be used to estimate the ICER. An ICER will be calculated from the family's perspective.

$$\text{ICER} = \text{Costs}_{(\text{BNBD-NDD + usual care})} - \text{Costs}_{(\text{usual care})} / \text{Effect}_{(\text{BNBD-NDD + usual care})} - \text{Effect}_{(\text{usual care})}$$

Secondary CCA

The CCA will assess the impacts on children's sleep disturbance severity, parents' daytime functioning, and psychosocial health.

XSL•FO
RenderX

It adopts a broader perspective, providing a wider range of relevant costs and outcomes [24]. This allows various decision makers to focus on aspects and contexts specific to them [24]. The costs examined will extend beyond the family and include the costs of reported publicly and privately funded services sought.

Subgroup Analysis

Subgroup analyses will be performed to determine if there are any trends, similarities, or differences in the mean outcomes of the 4 NDD diagnostic groups (ADHD, ASD, CP, and FASD); the CP and FASD groups are likely to have relatively fewer participants than the ADHD and ASD groups due to their lower prevalence.

Sensitivity Analysis

Sensitivity analysis will test variations in assumptions regarding estimated costs and reported health care usage. With the retail cost of the intervention under discussion, a range of prices will be explored based on the HWTP data, and the corresponding ICERs will be calculated. Parameter uncertainties associated with TU will be explored through scenario analyses, incorporating the 95% CI of mean estimates.

Missing Data

Multiple imputation techniques are used to address missing data. This method works well for longitudinal data and is robust to violations of the nonnormality of the variables analyzed. Participants who do not complete both the baseline and the 8-month follow-up will not be included in the analysis. Where applicable, the measures' user guides on missing data will be followed. For the PedsQL, the means of completed items in the scale will be imputed when 50% or more of the items are completed [34].

Discount Rate

As all costs and outcomes assessed are within 1 year, a discount rate will not be applied [25].

Ethics Approval

All study participants provided informed consent to participate in the BNBD-NDD RCT. Ethical approval for the BNBD-NDD trial (REB-1020681) was granted by the IWK Health Centre Research Ethics Board and the associated economic evaluation by the IWK REB and the University of Calgary Conjoint Health Research Ethics Board (REB22-0694). This study complies with all applicable standards and procedures of the IWK REB, the Personal Health Information Act, the Personal Information International Disclosure Protection Act, and the Tri-Council Policy Statement: Ethical Conduct for Research Involving Humans.

Results

The BNBD-NDD RCT data collection started in June 2019 and ended in April 2022. Research funding was obtained from the Kids Brain Health Network in 2015. Ethics were approved by the IWK Ethics Board and Conjoint Health Research Ethics Board in January 2019 and June 2022, respectively. The data examining the primary outcomes of this RCT are currently being analyzed. The relevant data for the economic evaluation have been cleaned and are being prepared for analysis.

Discussion

In this paper, we have described an economic evaluation protocol for the BNBD-NDD eHealth intervention, which aims to improve insomnia in children with NDDs. The economic evaluation will identify, measure, and value the costs and outcomes of BNBD-NDD compared to usual care. The reference case CEA will assess the costs and QoL of the children, and the CCA will examine measures beyond QoL for the children and their caregivers.

The prevalence of sleep disorders has been observed to be higher in children with NDDs relative to TD children [40]. BNBD-NDD has the potential to deliver an evidence-based and cost-effective insomnia intervention to children with NDDs, which is critically important given the lack of available treatments. The eHealth delivery system may also overcome some existing barriers to treatment access. If cost-effective, this program can improve sleep outcomes and positively affect the well-being of children with NDDs and their caregivers. To our knowledge, BNBD-NDD is the first eHealth insomnia intervention for children with NDD. No published reports have evaluated internet-based interventions for insomnia in preschool- and school-aged children; 1 study has reported an effective internet intervention for sleep disturbances in infants and toddlers [41].

Some limitations of this study are the uncertainties with cost estimates, the parental-reported measures on behalf of the children, the recall bias of their children's 12-month service usage, and the lack of objective outcome data. With family and societal payer perspectives, the breadth of the costing analysis is limited by the collected cost data in the RCT and thus likely to be an underestimation of real-world costs. While the CCA provides a wider scope of relevant outcomes and costs for decision makers, the interpretation of the results may be prone to subjective bias [24]. The BNBD intervention would benefit from real-world evidence to evaluate its effectiveness and also explore its applicability to children with other medical conditions.

Despite a direct-to-user approach for the intervention, the economic evaluation can stimulate conversations with relevant stakeholders, better understand the efficacy of web-based alternatives, and provide evidence to support potential public payer funding initiatives. Dialogue on the integration of eHealth interventions in the delivery of care in the health system is another area for future examination. The findings of this study will provide users and other stakeholders with a holistic picture of the costs and impacts of BNBD-NDD and play a role in informed decision-making for resource allocation.

Acknowledgments

This research was funded by the Kids Brain Health Network, a network of Centers of Excellence. The authors thank Dr Wendy Ungar for her feedback on the economic evaluation protocol and Katie Vaughan for her facilitation of the administrative aspects of this paper.

Data Availability

The data sets generated and analyzed during this study are not publicly available as the participants of this study did not give written consent for their data to be shared publicly. Due to the sensitive nature of the research, supporting data are not available.

Authors' Contributions

XYJ led the writing of this paper. JZ and XYJ designed the economic analysis. PC is the principal investigator of the Better Nights, Better Days for Children with Neurodevelopmental Disorders (BNBD-NDD) randomized controlled trial (RCT) grant and was involved in the formulation and writing of this paper. AHD, CB, EC, GR, IS, OI, PA, RG, SS, and SKW were all involved in the design of the BNBD-NDD RCT protocol and reviewed the draft version of this paper. This paper has been approved by all the authors.

Conflicts of Interest

While there are no current conflicts of interest, it is possible that the Better Nights, Better Days program will be commercialized in the future.

Abstract

Background: Hypertension is the most prevalent chronic condition and a significant risk factor for cardiovascular and kidney diseases. The efficacy of health behavioral interventions in blood pressure (BP) control has been demonstrated by a large and expanding body of literature, with “adherence” playing a crucial role. WeChat is the most common social communication mobile app in China, and it has been shown to be an acceptable delivery platform for delivering health interventions. The WeChat-based health behavioral digital intervention program (WHBDIP) showed high feasibility and efficacy. However, the results regarding BP improvement between the WHBDIP and control groups were inconsistent.

Objective: The objective of this study is to develop a WHBDIP and assess its efficacy in controlling BP and improving adherence among patients with hypertension.

Methods: A 2-arm, parallel-group, and randomized trial design was used. Patients older than 60 years and with hypertension were randomly assigned to either the control group or the experimental group, which received a 12-week intervention. The program, primarily developed based on the Behavior Change Wheel (BCW) theory, offers health education on exercise, diet, BP monitoring, and medicine adherence (MA). It also includes other behavior interventions guided by an intervention manual, incorporating behavior change techniques (BCTs). The primary outcomes encompass BP and adherence indicators, while the secondary outcomes encompass cardiovascular function indicators, body composition indicators, learning performance, satisfaction, and acceptability. The exercise and blood pressure monitoring adherence (BPMA) indicators for the WHBDIP group were assessed weekly via WeChat during the initial 3 months, while other outcome data for both groups will be collected at the baseline assessment phase, 3 months after the intervention, and 1 year after the program.

Results: The trial will assess the efficacy of WHBDIP for patients with hypertension (N=68). The WHBDIP seeks to enhance participants' knowledge of healthy behaviors and assist patients in developing positive health behaviors to improve their health outcomes. Patient recruitment for individuals with hypertension commenced on September 5, 2022, and concluded on September 19, 2022. The 3-month intervention and phased data collection were finalized in January 2023. Data analysis will commence in August 2023, and the final 1-year health outcome results will be collected in September 2023.

Conclusions: A successful WHBDIP will establish the management mode as a feasible approach for hypertension management in the community. Additionally, it will pave the way for the development of related mobile health programs.

Introduction

Hypertension, the most prevalent chronic condition and a significant risk factor for stroke, ischemic heart disease, and kidney disease, has become a primary contributor to the global disease burden [1,2]. It is directly responsible for more than 8.5 million deaths worldwide annually [3]. Furthermore, it imposes a substantial economic burden. In China, hypertension accounts for 6.6% of the total national health expenditure [4]. Over the past 30 years, the number of adults with hypertension has risen from 650 million to 1.28 billion [1]. In China, the prevalence of hypertension in adults was 25.2% [5] with awareness, treatment, and control rates at 51.5%, 45.8%, and 16.8%, respectively [6].

Less than half of young patients with hypertension and two-thirds of eligible older patients with hypertension achieve blood pressure (BP) control goals [6]. The low control rate may be attributed to lifestyle-related risk factors, such as poor eating habits and low levels of physical activity [2]. Researchers have found that encouraging patients to follow the recommended health behaviors significantly reduces BP. For example, patients under the supervision of medication taking experienced a 5-mm Hg decrease in daily systolic blood pressure (SBP) compared to unsupervised individuals [7]. Adhering to the Dietary Approaches to Stop Hypertension (DASH) resulted in a 26% reduction in developing high BP [8], and in those already diagnosed with hypertension, SBP and diastolic blood pressure (DBP) decreased by 1.5 and 1.1 mm Hg, respectively [9]. Following various types of recommended exercise led to an SBP reduction of 7.23-8.69 mm Hg [10]. Improving BP monitoring adherence behavior resulted in SBP and DBP reductions of 2.53-4.2 and 1.45-2.4 mm Hg, respectively [11]. High medication adherence, combined with comprehensive interventions such as diet and exercise management, can achieve better BP control effects [12,13]. The results showed a reduction of 12.1 and 26.1 mm Hg in SBP and DBP, respectively, before and after comprehensive health behavior intervention [14], and a decline of 7.5 and 3.9 mm Hg for SBP and DBP, when compared with nonintegrated intervention group [15]. Considering all of this evidence, it appears that comprehensive health behavior intervention can achieve better BP control effects, with adherence being the key.

Digital health (such as mobile health [mHealth] or telehealth) intervention strategies have been used to improve hypertension management outside the hospital. These strategies enhance patient adherence behaviors and increase the feasibility of delivering convenient, continued health interventions in primary health care settings with unequal resource distribution and understaffing. Several recent meta-analyses have demonstrated that using an internet-based interactive intervention mode combining health information with decision support via a computer or mobile phone could lead to a reduction of mean SBP by 2.23-3.74 mm Hg and mean DBP by 1.14-2.99 mm Hg [16-18]. Most of the interventions conducted by the investigators aimed to influence “self-management” or “adherence behaviors” in patients with hypertension [16-18]. Another systematic review of the literature showed the improvement of patient adherence after mHealth intervention [12,17,19-21].

WeChat, a mobile app, is the most prevalent social communication tool in China, with over 1 billion monthly active users of all ages. Approximately 902 million users log into WeChat every day [22]. A substantial amount of prior research in health promotion has focused on WeChat-based programs, which have demonstrated high acceptability, feasibility, and efficacy [23]. WeChat-based health interventions have been found to increase adherence and willingness to seek treatment, improve follow-up rates, enhance health outcomes, quality of life, and self-care ability, and also promote patient satisfaction [23-28]. For hypertension management, WeChat-based programs showed improvements in BP monitoring, diet, self-efficacy, and self-management scores [29,30]. However, the effect of lowering BP is inconsistent. One study reported a significant improvement in BP (SBP: –6.9 and DBP: –3.1 mm Hg) between the intervention and control groups [30], while another study showed no statistical differences between the 2 groups [31]. Therefore, we aim to assess the effectiveness of the WeChat-based health behavioral digital intervention program (WHBDIP) in 2 groups after 3 months of intervention and at the end of an extended additional 7 months. This program involves exercise, diet, BP monitoring, and medication adherence intervention strategies. Our plan is to investigate whether this approach is accessible and effective in improving outcomes for older individuals with hypertension.

Methods

Trial Design and Setting

This is a 2-arm, parallel-group, randomized trial that includes a WeChat-based health behavioral digital intervention lasting for 12 weeks. The trial has been conducted at 2 community health centers, both located in Anhui province—1 in Hefei and the other in Bengbu. The primary data collection and evaluation will take place at 3 time points: the beginning of the project, after 3 months of intervention, and 1 year after the project starts.

Patients

In this trial, patients with hypertension were recruited through phone or verbal invitations from community health centers. Interested individuals were asked for further information by contact staff members. To promote recruitment, relevant

XSL•FO
RenderX

physical health assessments were offered for free to candidates, and unqualified candidates were excluded at this stage. Written informed consents were obtained from eligible patients before randomization. The inclusion criteria for the participants were as follows: (1) previous diagnosis of essential hypertension by medical institutions or initiation of antihypertensive drug treatment, (2) older than 60 years of age, and (3) proficiency in using smartphones and the WeChat app. Patients with the following conditions were excluded: (1) prehypertension or not taking antihypertensive drugs; (2) contraindications to exercise, such as serious cardiovascular and cerebrovascular diseases, muscle and joint pain, or inability to participate in exercise as recommended by a doctor; (3) diabetes or nephrosis; (4) participation in other health intervention programs; and (5) not having a sphygmomanometer.

Sample Size

The sample size was calculated based on the primary outcome of BP. The effect size, widely used to measure treatment effects of continuous outcomes, is calculated as the difference between groups divided by the pooled SD. A previous meta-analysis, comparing mHealth intervention treatments with other traditional treatments, with the primary outcome being BP, reported an effect size of 0.7 [17]. Assuming α=.05, β=.2, and accounting for up to 20% attrition, a sample size of 68 is needed for this study.

Intervention

WHBDIP Development

WHBDIP is a web-based individual telehealth intervention program for patients with hypertension on WeChat, which includes nondrug intervention health education and behavior change strategies. WHBDIP consists of 4 sections: exercise, diet, BP monitoring, and medication adherence behavior interventions, which together constitute a comprehensive health behavior intervention program.

The exercise intervention was based on an intelligent personalized exercise prescription. This prescription has been verified by experts and has been proved by a 1-year real-world clinical research [32]. Before prescribing, health data are collected by an intelligent health promotion system (including networked equipment and a questionnaire system) installed in the community health service center. The intelligent decision-making module of this system generates safe, reliable, and personalized prescriptions according to the complex health conditions of the residents, especially older patients with 1 or more chronic diseases. In WHBDIP, the health education content matching the exercise prescription was compiled into text and then transformed into animation or video to be included in the electronic knowledge base.

The dietary intervention was designed based on the principles of the DASH. After revising the simplified DASH grading diet index score (SDGDIS), videos related to DASH health education were produced and delivered to subjects through WeChat. Subjects were required to upload photos of their 3 meals per day (including a fist for size comparison) within 7 days. The scores (based on the SDGDIS) and qualitative evaluation text were provided to subjects during this period. After 7 days, the subjects and interveners were required to provide their respective scores.

For BP monitoring and medicine adherence (MA) intervention, we have created health education videos and used WeChat to send reminders and supervise the health behavior of the subjects. The content of health education related to WHBDIP is displayed in Table 1, and the video screenshots are shown in Figure 1.

[a]DASH: Dietary Approaches to Stop Hypertension.

[b]BP: Blood pressure.

[c]MA: Medicine adherence.

To promote adherence behavior change, we adopted the behavior change wheel (BCW), which is a systematic framework for selecting 25 behavior change techniques (BCTs) from Michie et al's [33] taxonomy that correspond to the 9 intervention functions (shown in Table 2). The use of BCTs was documented in the intervention manual.

XSL•FO
RenderX

Table 2. Implementation of BCTs[a] following Michie et al's [33] BCW[b] and taxonomy.

Intervention functions and BCTs	Examples
Education: increasing knowledge or understanding	
4.1 Instruction on how to perform the behavior	Provide healthy educational content on how to exercise and eat
5.1 Information about health consequences	Tell the intervention the benefits of exercising
4.3 Reattribution	If the subjects attributed their lack of exercise to frequent bad weather, intervenor indicated that the "real" reason might be the person's lack of motivation
Persuasion: using communication to induce positive or negative feelings or stimulate action	
15.3 Focus on past success: advise to think about or list previous successes in performing the behavior	Suggest the subjects to think about or list the successful experience of a certain behavior (quit smoking and drinking) before to convince him that he can also develop the habit of scientific exercise or diet
15.1 Verbal persuasion about capability	Tell the subjects that they can successfully increase their physical activity
13.5 Identity associated with changed behavior	Ask the subjects to articulate their new identity as "ex-inactive person"
Incentivization: creating an expectation of reward	
10.2 Material reward (behavior)	Arrange for the subjects to receive WeChat red packet (money)
10.6 Nonspecific incentive	Indicates a happy mood for completing the task, such as instructing the subjects to imagine that he has successfully completed today's exercise task, sweating profusely, and feeling happy
Coercion: creating an expectation of punishment or cost	
—[c]	—
Training: imparting skills	
8.1 Behavioral practice or rehearsal	Ask subjects to continue to rate their diet for 7 days
15.4 Self-talk	Encourage the subjects to use talk to themselves (aloud or silently) before and during exercise to encourage, support and maintain action, like "I Can!"
Restriction: using rules to reduce the opportunity to engage in the target behavior (or to increase the target behavior by reducing the opportunity to engage in competing behaviors)	
—	—
Environmental restructuring: changing the physical or social context	
12.6 Body changes	Remind the subjects to stretch before and after exercise (except health care type) to prepare their bodies
12.2 Restructuring the social environment 3.1 Social support	Encourage the subject to invite family members or friends to exercise together
Modeling: providing an example for people to aspire to or imitate	
—	—
Enablement: increasing means or reducing barriers to increase capability (beyond education and training) or opportunity (beyond environmental restructuring)	
1.1. Goal setting (behavior)	Determine the weekly exercise time based on exercise prescriptions
2.7 Feedback on outcomes of behavior	Feedback on diet score and comprehensive evaluation
2.4 Self-monitoring of behavior	Provides a subjective method to assess exercise intensity and allows subjects to self-monitor
1.9 Commitment	Sign a contract with subjects that they can do healthy behavior
1.4 Action planning	Prompt planning of a particular physical activity (running) at a particular time (before work) on certain days of the week

XSL•FO
RenderX

Intervention functions and BCTs	Examples
1.5 Review behavior goals	Examine how well subjects' performance corresponds to agreed goals such as exercise 30 minutes at a time
1.6 Discrepancy between current behavior and goal	Compare the difference between the real exercise volume and the target volume
7.1 Prompts or cues	Send medication reminder to subject
8.3 Habit formation	Ask the subjects to check in on sports and upload photos of their diets every day
7.3 Reduce prompts or cues	Reduce medication reminders
1.2 Barrier identification or problem solving	Analyze the reasons (information are collected by questionnaire) for impeding movement and provide solutions (according to intervention manual)
4.2 Information about antecedents: advise to keep a record of situations or events occurring prior not to exercise	Record the reasons for not exercising
11.2 Reduce negative emotions	Instruct the subject to perform relaxation exercises in situations when exercise brings about negative emotions

[a]BCTs: behavior change techniques.

[b]BCW: behavior change wheel.

[c]Not available.

Validation of WHBDIP

The WHBDIP (health education content and intervention plan) has been validated through a 2-round Delphi survey by a panel of experts. The panelists consisted of 15 experts, including 4 nutritionists and 1 professor of nutriology, 2 clinical cardiologists, 3 clinical nurses or nursing teachers, and 5 exercise-related experts. All of them held a bachelor's degree or higher and had at least 5 years of work experience in their respective fields. The panelists were divided into 3 groups to evaluate the content's appropriateness and relevance for exercise, diet, and BP monitoring or MA management. The content validity index (CVI) was calculated using item-level content validity index (ICVI) and rated on a 4-level scale. In the first round, the ICVI ranged from 0.6 to 0.8. Based on the experts' comments, the content was modified. In the second round, the ICVI reached 1.

Intervention Procedure and Monitoring

Prior to the experiment, we conducted a physical examination on the subjects at the intelligent health hut and used the system to generate intelligent exercise prescriptions. Health behavioral digital intervention was provided to the experimental group by 5 trained interventionists through WeChat. The interventionists sent health education materials, specific text (such as reminders to take medicine or exercise), or electronic questionnaires according to the intervention manual's procedures. They collected data or pictures about exercise, diet, self-measured BP, and medication every day during the initial 3 months. The control group received routine health interventions, including oral health education about printed exercise prescriptions, dietary guidance, BP monitoring, and the importance of regular medication. After the program, they will have free access to health education electronic materials.

Randomization, Allocation, and Blinding

This study followed a process of randomization. Before randomization, an individual not involved in subject recruitment and data collection used the SPSS software (version 23; IBM Corp) to generate 68 random numbers and assigned them to either 1 (experimental group) or 2 (control group) using visual binning. These 68 sets of random numbers were printed separately and sealed in individual envelopes. After recruiting a participant, the facilitator opened the envelopes sequentially, and the number found inside each envelope determined the group to which the particular participant belonged. In this study, we blinded data collectors both before and after the trial.

Ethics Approval

This study received approval from the Ethics Committee of Bengbu Medical College (2022-103) in June 2022. Informed written consent forms were obtained from parents with hypertension prior to the start of the study. All the participants agreed to the anonymous use of their data. Upon completing the intervention and data collection at the community health center, the participants were provided with 50 RMB (based on the current exchange rate of US $1=7.29￥, here it is about US $6.86) worth of daily necessities.

Outcomes

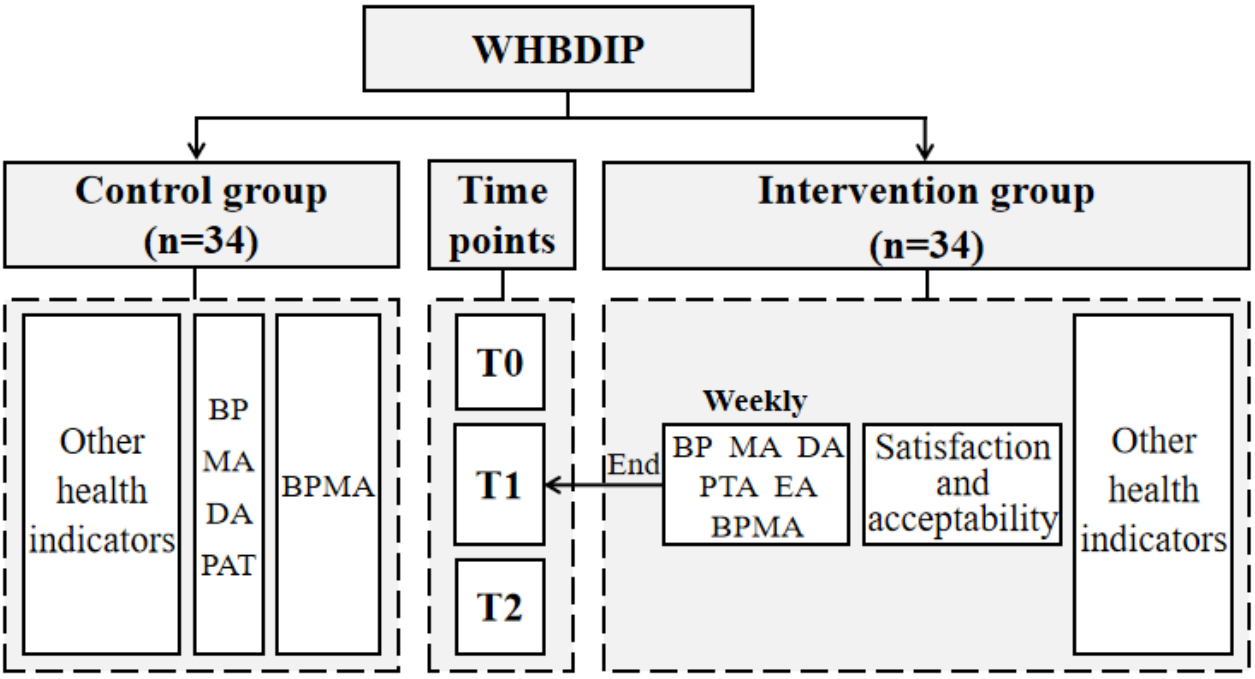
Primary Outcomes

BP will be measured using a cardiovascular function monitor (BX-CFTI-100, Institute of Intelligent Machines) at 3 time points: the first baseline assessment phase (T0), the 12-week end point assessments phase (T1), and the end of the 1-year program (T2). The assessment details have been published elsewhere [32].

Exercise adherence (EA), DA, MA, and BPMA indicators were collected once a week through WeChat for the intervention group until T1. The BPMA will also be collected at T0, T1, and

XSL•FO
RenderX

T2 for the control group. The exercise adherence indicator was calculated as the ratio of actual exercise time that meets the prescription's recommended intensity to the total time of the prescription-recommended intensity. PAT will be measured as an indicator by questioning subjects in both groups at T0, T1, and T2 about the type, duration (in minutes), and frequency (per week). It will be measured using the minutes or metabolic equivalent per week. The MA indicator will be measured at T0, T1, and T2 for both groups using the Modified Morisky Scale (Chinese version-MMS-8, Certificate Number: 8538-1877-1559-6025-5310) [34-36], which includes 8 simple questions. The rating is “poor medication adherence” for a final total score of <6 points, “moderate medication adherence” for a score of 6-7, and “good medication adherence” for a score of 8. Dietary adherence (DA) will be assessed at T1 and T2 for both groups based on their compliance with the “types of diet” and the “recommended amount of diet” (3 response levels for each question).



Secondary Outcomes

Cardiovascular function indicators and body composition indicators will be assessed at T0, T1, and T2 in the community health center. Specific details have been published elsewhere [32]. Learning performance of health education knowledge will be evaluated using a comprehensive self-made questionnaire about the material at T0 and T1. Satisfaction and acceptability of this program were assessed at T1 for the intervention group through face-to-face interviews using 3-5 semistructured questions. The questions included: (1) “Do you find the program useful?” (2) “Is it worth your time?” and (3) “Would you feel confident recommending this program?” These questions were used in previous studies [37].

Data Collection and Management

Health-related data will be collected and entered into the intelligent health promotion system at T0, T1, and T2. During the intervention, data for the intervention group were collected using WeChat (as shown in Figure 2). An independent data manager checked the database every week to ensure its integrity. Data lockup is being implemented to prevent any postmodification.

Figure 2. Figure 2. Study flowchart. BP: blood pressure; BPMA: blood pressure monitoring adherence; DA: dietary adherence; EA: exercise adherence; MA: medicine adherence; PAT: physical activity time; WHBDIP: WeChat-based health behavioral digital intervention program.

Statistical Analysis

All analyses will be performed using SPSS. Continuous variables will be presented as mean and SD values. Categorical variables will be expressed as numbers and percentages. Independent samples *t* tests and chi-square tests will be conducted to assess the significance of differences in baseline characteristics or outcomes between the control group and intervention group at 3 time points: before the start of the intervention, 12 weeks after the intervention, and 1 year after the program. Paired *t* tests and McNemar's test will be used to compare the differences in some outcomes before and after the 3-month intervention, as well as before the trial and after the end of the program. A *P* value of less than .05 will be considered statistically significant.

Results

The study was funded in December 2021. The WHBDIP trial was approved by the Ethics Committee of Bengbu Medical College in June 2022 (2022-103) and registered in August 2022 (ChiCTR2200062643). Patient recruitment for those with hypertension started on September 5, 2022, and was completed on September 19, 2022. The 3-month intervention and phased

XSL•FO
RenderX

data collection were completed in January 2023. Data analysis will commence in August 2023, and the final 1-year health outcome results will be collected in September 2023. We expect the primary outcomes to show changes in adherence indicators during the 3-month intervention, and health outcomes, including BP and other cardiovascular indicators, to change after the intervention and 1 year later. Furthermore, we will report on dropout rates and reasons for dropout during the trial.

Discussion

The WHBDIP is a WeChat-based digital health program that aims to improve the self-management of BP and promote adherence behavior change among patients with hypertension. If the effectiveness of WHBDIP can be verified, it may be attributed to several key characteristics. First, all interventions were developed based on robust evidence, and we further optimized them. Similar to DASH, a proven effective diet for patients with hypertension, we have created a map of food portions tailored to the dietary characteristics of Chinese people and included beverage options in the scoring table. Second, WHBDIP is a theory-based intervention tailored to patients with hypertension. We specified the target behavior (adherence) and conducted a scientific and systematic procedure to identify the appropriate functions from the 9 behavior functions. We then selected the corresponding BCTs from Michie et al's [33] taxonomy based on the BCW. These BCTs were compiled into the intervention manual, which will serve as the foundation for the development of the mHealth intervention program. Third, we provided tailored interventions, including intelligent personalized exercise prescriptions and different intervention contents for adherence. For example, people with different movement barriers require different persuasion techniques. Fourth, we provided one-to-one web-based health services, which could increase participant satisfaction. Fifth, this trial involved health-related professionals and followed a community-based telehealth intervention approach. Finally, we designed this trial to meet methodological demands, including adequate power, allocation concealment, and necessary blinding.

If the WHBDIP is proven to be effective, it could be integrated into the upcoming eHealth promotion program. We will develop community-based apps to promote the management of patients with hypertension, including patient terminals and health service provider terminals. The app will deliver personalized e-interventions, such as reminders, videos, and other content, to patients through specific logic that incorporates behavioral change techniques. This will enable the manual intervention to be automated. It may serve as an alternative, convenient, and cost-effective approach, deserving further experimental verification, for doctors and nurses in primary health care institutions to provide tailored and consistent health services for patients with hypertension.

The study has some limitations. First, due to the nature of the intervention, interventionists in this trial cannot be blinded. To reduce the impact, we provide detailed training and an intervention manual to minimize the subjective influence of interventionists. This way, interventions can be standardized as much as possible. Second, some outcome measures rely on patient self-report scales, which may somewhat affect the reliability of the results.

Acknowledgments

This work was supported by the Anhui Science and Technology Department (grant 202103a07020004) and the Anhui Educational Committee (grant SK2021A0432, KJ2021A1067, 2022lhpysfjd063, and gxyq2022040). The funding source had no role in the study design, data collection, management, data analysis, data interpretation, report writing, or the decision to submit for publication. ST has acquired a license to use MMAS-8 (Morisky Medication Adherence Scale 8-item) for this study from the scale developer Donald E Morisky (Certificate 8538-1877-1559-6025-5310). We wish to acknowledge the support of Donald E Morisky, the copyright holder of the scale, for this research. Furthermore, the authors would like to thank Huaqing Liu and Lihua Zhou for preparing the SDGDIS.

Data Availability

Data sharing is not applicable to this paper, as the trial is not finished. The data that will be collected at the end of the trial will be described in the next paper, which will be published in a future paper when the data become available.

Conflicts of Interest

None declared.

Abstract

Background: Social anxiety disorder (SAD), also known as social phobia, is one of the most common mental disorders worldwide. In Hong Kong, the prevalence of SAD is high, but its treatment rate is low. SAD has immense impact on academic or work performance, social life, career development, and quality of life. One of the most effective treatments for SAD is cognitive behavioral therapy (CBT), with internet-based CBT (iCBT) and virtual reality exposure therapy (VRET) showing promise in treating SAD. However, internet interventions are underdeveloped in Chinese communities including Hong Kong.

Objective: This study aims to develop an iCBT program that includes VRET, called "Ease Anxiety in Social Event Online" (Ease Online), for Hong Kong adults with SAD in a randomized controlled trial.

Methods: The 14-week Ease Online program is a guided self-help iCBT program with a blended mode of service delivery. The program comprises 9 web-based modules and 5 individual counseling sessions (including 2 VRET sessions) conducted remotely or face-to-face with a therapist to provide therapist support, as guided iCBT shows superior effects than unguided iCBT. Other program components include therapist feedback on assignments, internal messages, forums, client portfolios, web-based questionnaires, reminders, and web-based bookings. The program can be accessed either through a mobile app or program website through a PC with an internet connection. The participants are openly recruited and screened using a questionnaire and through an intake interview. Eligible participants are randomized by placing them into a web-based iCBT group, app-based iCBT group, or a waitlist control (WLC) group. Participants in the WLC group are assigned to the app-based program upon completion of the service of the 2 experimental groups. Measurements of social anxiety, depression and anxiety symptoms, psychological distress, automatic thoughts, and quality of life are administered at pretest, posttest, and 3- and 6-month follow-ups. Multivariate ANOVA with repeated measures will be performed to determine the intervention effectiveness on the continuous variables over time.

Results: Participant recruitment commenced in January 2021. As of February 2023, a total of 1811 individuals applied for the Ease Online program. In total, 401 intake interviews have been completed, and 329 eligible participants have joined the program, among whom 166 have completed the service. Data collection is still ongoing, which is expected to be completed in March 2024.

Conclusions: This study is the first of its kind in combining iCBT and VRET for the treatment of SAD in Hong Kong. At a theoretical level, this study contributes to the development and evaluation of internet-based psychological interventions in Hong Kong. At a practical level, the Ease Online program may serve as an alternative service option for SAD clients in Hong Kong if proven effective.

Introduction

Background

Social anxiety symptoms have increased significantly during the COVID-19 pandemic [1]. Social anxiety disorder (SAD) is one of the most common mental health problems, yet few seek treatment [2]. Individuals with SAD experience excessive fear and anxiety during social interactions, which is disproportionate to the social situation itself. SAD often involves negative evaluation and rejection by others and a constant fear of embarrassment or humiliation [3]. Therefore, individuals with SAD often avoid social interactions, which may have detrimental impacts on most areas of life, including their career, education, social relationships, and mental health [4]. Social anxiety usually emerges during performance situations (such as job interviews, public presentations, or attending a meeting) and interpersonal situations (such as greeting someone, drinking and eating in public, taking part in social gatherings, or shopping). In Hong Kong, the 12-month prevalence rate of SAD is reported to be 3.2% [5], which translates into an estimated 230,000 cases. However, only 8.7% of people with SAD in Hong Kong had previously sought treatment [5].

People with SAD face certain treatment barriers that prevent them from seeking mental health services, including fear of judgement, uncertainty of the resources for receiving help, and skepticism regarding anxiety disorders [6]. In Hong Kong, the barriers also include the social and self-stigmas of mental illnesses, long waiting lists for public health care, and exorbitant costs of private treatment. However, people with SAD consider the internet as a good social outlet, which not only helps them to alleviate their fear during general social interactions but also meets their social needs [7].

Cognitive behavioral therapy (CBT) is the first-line treatment for SAD [8]. Clark and Wells [9] proposed a cognitive model of social anxiety that considers social cognition, safety behaviors, self-focused attention, and somatic symptoms as the maintaining factors of social anxiety. Thus, the effective treatment components of CBT for SAD primarily include exposure to fearful conditions, cognitive restructuring, attentional bias modification, and relaxation and social skills training [10]. Telemental health services, including internet-based CBT (iCBT) and virtual reality exposure therapy (VRET), have become a worldwide trend for the treatment of mental health problems, particularly SAD, which can reduce the therapist's time required for each client [11]. For example, the average time spent in VRET is 8 minutes per session [12], and the therapist's time in iCBT can be saved by more than half for the same level of reduction in social anxiety [13].

iCBT for SAD

iCBT is used to deliver CBT on the web or through a mobile app. In a recent meta-analysis study, Andrews et al [14] showed that there are no significant differences between iCBT and face-to-face CBT in their efficacy for treating anxiety and depressive disorders, thus indicating equivalent overall effects elicited by both types of treatments. Their study also lends support to the effectiveness, acceptability, and practicality of iCBT for treating anxiety disorders. A number of randomized controlled trials (RCTs) have demonstrated the effectiveness of guided iCBT in reducing general and social anxieties, avoidance, depression, and dysfunctional thinking, as well as improving the quality of life and functioning of people with SAD [15-19]. Guided iCBT programs for SAD have shown promising diagnostic response rates [20] with complete and partial recovery rates of 34.2% and 36.8%, respectively, upon completion of the treatment [19]. The positive treatment effects are maintained at the 6-month [19], 1-year [15], 2-year [21], and 4-year [22] follow-ups. Therapist contact is reportedly a significant predictor of intervention outcomes in guided iCBT programs for SAD [23]. Therapist support is usually provided via telephone, email, videoconferences, SMS text messages, and web-based discussion forums [17,24].

The intervention skills in the various iCBT programs for SAD generally include psychoeducation, cognitive restructuring, behavioral experiments, exposure and reality testing, modifying attention bias, social skills training, developing healthy lifestyles, problem-solving, and preventing relapses [15,20,21]. The presentation formats of the iCBT program involve text, images, audio, video, text entry fields, animation, comic slides, e-books, etc [24]. Interventions include monitoring moods, performing exposure exercises and homework assignments, writing a web-based diary, answering essay questions, participating in user forums, and receiving emails or text message reminders, and awards [17,18].

VRET for SAD

One of the central components of CBT for SAD is exposure therapy in which clients are exposed to social stimuli that cause anxiety while eliminating safety behaviors so that they learn and understand that the anticipated negative consequences are ill-founded [3]. Exposure therapy can activate and modify anxious responses by having individuals confront the fear stimuli and via habituation and extinction learning, respectively, in which the fear stimuli then cease to provoke anxious responses or render them less threatening. Given that in vivo exposure therapy in real life is not frequently offered, VRET has become an important alternative for reproducing social situations [3]. Computer graphics, body tracking devices, visual displays, and other sensory input devices are integrated to immerse clients in a computer-generated virtual environment [25]. As virtual reality (VR) can elicit moderate levels of sense of presence and anxiety during virtual social interactions [26], VRET has become a promising application for treating SAD.

Meta-analyses have consistently found a significantly large effect size for VRET compared to a waitlist or psychological

XSL•FO
RenderX

placebo conditions for SAD treatment, and no significant difference in effect size between VRET and in vivo or imaginal exposure therapy [27,28], thus indicating that VRET is effective for SAD treatment with effects comparable to those of traditional exposure therapy. Specifically, VRET is effective in reducing social anxiety symptoms, such as fear and avoidance, fear of negative evaluation, self-reported public speaking anxiety, catastrophic belief expectancy, probability and cost biases, distress, perceived stress, and depressive symptoms, and increasing the length of speech time, perceived performance quality, and confidence [2,16,29,30]. The positive effects are maintained at the 3-month, 6-month, 12-month, 5.5-year, and 6-year follow-ups [29,31,32]. More than half of treated individuals no longer meet the diagnostic criteria for SAD (54%) and self-reported to be "very much" or "much" improved (68%) 6 years after treatment [31]. Thus, VRET is considered an efficacious alternative to in vivo exposure therapy [27].

Both psychological and physiological indicators are measured in VRET studies. The commonly used psychological indicators include self-reported anxiety and fear, distress, and self-confidence [33,34]. As anxiety often emerges in the form of physical symptoms, VRET studies have measured physiological responses, such as blood oxygen level [35] and heart rate [36].

This Study

Technology-assisted CBT programs have great potential to extend mental health services to people with social anxiety who are unwilling or unable to seek face-to-face therapy [23]. However, these programs are underdeveloped in Chinese societies, such as Hong Kong. This study has, therefore, developed an iCBT program with VRET, called "Ease Anxiety in Social Event Online" (Ease Online), for Hong Kong adults with SAD in an RCT.

Methods

Participants

To be included in the study, participants should be Hong Kong residents who (1) are fluent in Cantonese, (2) are aged between the 18 and 70 years, (3) obtained a score of 24 or higher on the Chinese version of the Social Phobia Inventory (SPIN) [37], (4) have a social anxiety disorder as assessed by the Structured Clinical Interview for disorders listed in the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition [38], (5) have not received any psychological treatment at the time of registration for participation in this study, (6) have access to a computer or smartphone with an internet connection, and (7) have a valid email address. We will exclude individuals who have (1) severe depression, with a score above 30 on the Beck Depression Inventory-II (BDI-II) [39]; (2) suicidal risk in the past 3 months (score of item 9 on the BDI-II is "2" or "3" and assessed to have suicidal risk in the intake interview); and (3) a severe psychiatric condition (eg, bipolar disorder, schizophrenia, or personality disorder) diagnosed by a psychiatrist or clinical psychologist.

Sample Size

The sample size was calculated by using a computer program called G*Power (version 3.1.5; Universität Düsseldorf). The statistical method used was a multivariate ANOVA with repeated measures (within-between interactions). The effect size was assumed to be 0.40 (large) [40]. The number of groups was 3 (2 experimental groups and 1 control group) and 7 measures applied (please see the *Outcome Measures* section). The α value was set at .01. The calculations resulted in a minimum sample size of 139. This study aims at recruiting 330 eligible participants, with 110 in each experimental group and the waitlist control (WLC) group, respectively.

Participant Recruitment and Screening

Participants were recruited from the general population on an ongoing basis through various means, such as advertisements on social media (Facebook and Instagram) and Google, press conferences, posters, and referrals from local nongovernmental organizations. Interested participants were asked to complete a screening questionnaire that includes the Chinese version of the Beck Anxiety Inventory (C-BAI), BDI-II, and Chinese version of the SPIN on the program website [41]. Initially qualified participants were invited for a 1.5-hour intake interview in person or via Zoom with a psychological counselor or an experienced social worker for further assessment of suitability for participation (including assessment of suicidal risk and social anxiety disorder based on the diagnostic criteria of the Structured Clinical Interview for disorders listed in the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition [38]). Marginal cases were discussed in a case meeting (which involved author J-YP, an intake worker, and a program therapist) for participation eligibility. A project assistant contacted the eligible participants to reconfirm their desire to participate before randomization took place. High-risk individuals with severe depression or suicidal risk (or both) identified at the screening stage were referred to the local mental health service sectors for further diagnosis and treatment with their consent.

Research Design

Although deterioration in a control condition can take place [42], Steinert et al [43] conducted a meta-analysis and found only small changes in the WLC groups during short-term wait periods for clients with SAD in RCTs. Thus, this study adopts a WLC group design to conduct a 3-arm RCT as shown in Table 1.

There were 2 experimental groups that joined either the web-based or app-based iCBT program (Ease Online). The WLC group received the app-based treatment immediately after the 2 experimental groups completed the program. All 3 groups completed the same web-based questionnaire at pretest, posttest, and 3- and 6-month follow-ups. The WLC group completed the questionnaire one more time at posttest after the 2 experimental groups completed the program. To increase the submission rate of questionnaire, participants were given 2 more weeks to submit an email questionnaire after the submission deadline in the program system. The RCT was conducted in cohorts for implementation feasibility. Specifically, in each cohort, around 30 qualified participants were randomized into one of the 3

XSL•FO
RenderX

groups through computer-generated random numbers, with approximately 10 in each group. The program evaluators were blinded to the allocation of the participants. The participant recruitment flowchart is shown in Figure 1.

Figure 1. Flowchart for participant recruitment in this study. Ease Online: Ease Anxiety in Social Event Online.

Intervention: the Ease Online Program

The Ease Online program is 14 weeks in duration. The program adopts a blended mode of service delivery as guided self-help iCBT has demonstrated lower attrition than nonguided self-help iCBT [18], and therapist contact has been found to be a significant predictor of retention and outcomes [23]. The

XSL•FO
RenderX

program consists of 9 web-based modules and 5 individual counseling sessions (including 2 VRET sessions). The program contents were developed on the basis of the CBT model developed by Beck [44] and CBT delivered to Chinese clients by Wong [45] and Pan and Zhuang [46]. Specifically, a variety of cognitive behavioral skills for coping with social anxiety are introduced in the 9 web-based modules, each with a specific theme. The themes of the nine web-based modules are (1) recognizing your social anxiety responses, (2) identifying automatic thoughts and cognitive distortions, (3) self-talk and positive statements, (4) behavioral experiment, (5) fear hierarchy, (6) exposure therapy, (7) identifying cognitive rules, (8) relaxing dysfunctional cognitive rules, and (9) saying bye-bye to social anxiety. The CBT skills are briefed and debriefed by using an animation video and demonstrated through 4 case videos. Each web-based module starts with a mood check for social anxiety in the past week and ends with a session review and an assignment that helps clients to apply the learned skills to cope with their own social anxiety. Other components of the program include therapist feedback on assignments, internal messages, forums, client portfolios, web-based questionnaires, reminders, and web-based bookings. An introduction video of the program provides a navigation on all of the program components after the clients log into the system. The client platform has a web-based version in which clients can log into the program website or a mobile app that can be downloaded through Google Play or Apple Store. After being randomized into the program, clients were provided an account to log into the system. Clients who are assigned a PC web account cannot log in through the app and vice versa. All clients were assigned to a therapist who not only provided web-based feedback on their assignments and responded to their private messages, but also offered 5 individual counseling sessions that monitored the progress of the clients and addressed any challenges that the clients encountered when working on the web-based modules. There is also a backstage management platform for the therapist, which offers different functions including creating cohorts, managing bookings and forums, providing feedback on client exercises, monitoring client progress, etc. The therapist helped the clients understand and review the module contents and apply the CBT skills into their own situations in 5 individual counseling sessions that were conducted either in person or on Zoom or WhatsApp.

A VR system for exposure therapy has also been developed for this program, which includes 5 virtual scenarios: (1) interviewing for a job, (2) delivering a presentation, (3) participating in work performance evaluation, (4) expressing disagreement, and (5) drinking in public. The VR system uses an 180° video of real humans. There is a storyline for each VR scenario and a couple of interactions between the client and the VR environment, which are guided by a prerecorded voice-over. The clients wear a head-mounted display and respond by moving their head. The voice responses of the clients are recorded in the VR system for replay. The technologies used for the development of the VR system include voice recording, VR180 stitching, VR game engine development, VR motion tracking on the target point, and an auto-trigger based on the user's headset direction. An administration control panel has been developed for the therapist to control the VR interaction. In the beginning of each VRET session, the therapist provides a short briefing and asks the client to choose one VR scenario. Then, the client participates in the VRET for no longer than 15 minutes. The therapist then proceeds to debrief the client upon completion of each VRET session and submits a session report on the Ease Online system. Examples of VRET photographs are shown in Figure 2.

The program sessions outlined in Table 2 are released to the client on a weekly basis. The treatment schedule is programmed into the Ease Online system. Progress is recorded as a score when the client completes a task, and a total score is calculated as the total progress. All of the program videos are tailored for Hong Kong people and developed from local cases. The Cantonese language is used in the program. To ensure data security and privacy, 2-factor authentication is adopted when logging in with a password that is preset by the user and a one-time password sent to his/her email address. All of the collected electronic data are encrypted. The program is hosted on the server of the Information and Technology Office of the university where the author is employed. Before the program launched, a user acceptance test was conducted by the author and project staff, and bugs were fixed accordingly by the programmer of this project.

[a]F2F: face-to-face session (in-person or on Zoom/WhatsApp).

[b]VR: virtual reality.

Therapist Credibility

The therapist for the Ease Online program has a master's degree in counseling (clinical mental health) and is registered as a certified counselor in both the United States and Canada. She has 9 years of counseling experience in Hong Kong. The intake worker is a registered social worker in Hong Kong who has a bachelor's and a master's degree in social work and counseling experience that spans more than 30 years in a variety of settings. The intake interviews were conducted by both the therapist and the intake worker, and all the service and initial screenings were delivered and conducted by the therapist—both are native Cantonese speakers.

Compliance With the Intervention

Several strategies were adopted to ensure compliance with the intervention: (1) progress reports were completed and submitted by the therapist after each individual counseling session to record the understanding of the clients of the web-based modules and their difficulties in learning them, and applying CBT skills to cope with their own social anxiety; (2) the therapist completed and submitted a progress report in the system after each VRET session to record the session contents, including the VRET experience of the client, skills that the clients have learned to cope with social anxiety, and client feedback; the VRET process was recorded for debriefing in each VRET session; and (3) all the tasks completed by the clients were recorded in the system. A reward score was assigned to clients when they completed a task. Clients were provided a program workbook as an incentive if they completed 80% of the intervention contents.

Outcome Measures

Primary Outcome Measures

The Chinese version of the SPIN [37,47] was used to assess the severity of social phobia symptoms. The measure consists of 17 items with 3 subscales: fear, avoidance, and physiological response. Participants were asked to rate their distress for each symptom during the past week on a 5-point Likert scale that ranges from "0" (not at all) to "4" (very much so). All of the item scores were summed up into a total score that ranged from 0 to 68, with a higher score indicating a higher level of anxiety. Sample items included "fear of others watching," "avoid talking to others," and "feeling bothered by blushing." The α coefficient is .89 for the Chinese version of the SPIN [37].

Secondary Outcome Measures

The C-BAI [48,49] was used to measure the cognitive and somatic symptoms of anxiety. Participants were asked to rate 21 items on a 4-point Likert scale. Item scores were summed, with a higher total score indicating a higher level of anxiety. Sample items included "unable to relax" and "heart pounding or racing." The α coefficient is .95 for the C-BAI [49].

The Chinese version of the BDI-II [39,50] was used to measure depressive symptoms. Participants were asked to rate 21 items on a 4-point Likert scale. The item scores were summed, with a higher total score indicating a higher level of depression. Sample items included "sadness" and "loss of pleasure." The α coefficient is .86 for the Chinese version of the BDI-II [50].

The Chinese version of the General Health Questionnaire-12 [51] was adopted to evaluate psychological distress. The 0-0-1-1 scoring method was used to calculate the scale score (which ranged from 0 to 12), with higher scores indicating higher levels

XSL•FO
RenderX

of psychological distress. The Cronbach α is .87 in a Hong Kong Chinese sample [52].

The Chinese Automatic Thoughts Questionnaire [53] contains 14 items for assessing positive and negative automatic thoughts. Participants were asked to rate the frequency of each thought in the past week on a 5-point Likert scale (which ranged from 1="not at all" to 5="all the time"). Item scores were summed up as the 2 subscale scores, with higher scores indicating more positive and negative automatic thoughts, respectively. Sample items included "I am worthless" and "No matter what happens, I know I'll make it." The Cronbach α is .83 in a Hong Kong Chinese sample [53].

The Chinese adaptation of the abbreviated version of the World Health Organization Quality of life Scale [54] was used to assess quality of life. This measure consists of 28 items, including 2 items that measure the overall quality of life and 26 items that measure physical and psychological health, social relationships, and the environment. Each item was rated on a 5-point Likert scale that ranged from 1="very dissatisfied" to 5="very satisfied," with a higher score indicating better quality of life. The Cronbach α ranges from .59 to .78 and test-retest reliability ranges from 0.72 to 0.83 for this scale [54].

The Chinese version of the Internalized Stigma of Mental Illness scale [55,56] was used to evaluate the subjective experiences of self-stigma on mental illness. The measure consists of 24 items and 4 subscales: shame or alienation, stereotype endorsement, perceived discrimination, and social withdrawal. Participants were asked to rate items on a 4-point Likert scale that ranged from 1="strongly disagree" to 4="strongly agree." All items were averaged as a scale score, with a higher score indicating a higher level of self-stigma. The Cronbach α is .93 in a Hong Kong Chinese sample [56].

In addition, before and after each VRET session, physical arousal through heart rate and blood oxygen levels were measured with a smart watch that the clients wore on their wrist.

Ethical Considerations

Ethics approval was granted by the Human Research Ethics Committee (REC/18-19/0241) of the Hong Kong Baptist University. Participation in this study is voluntary and free of charge. Participants could withdraw at any time without any repercussions. High-risk cases identified at the screening stage were referred to local nongovernmental organizations or governmental social service sectors upon the consent of the applicant. Each participant was assigned a code number for identification in the program database to protect their privacy and anonymity.

Data Analysis

Intent-to-treat analysis, which is the least biased way to estimate an intervention's effects [57], was used for data analysis. Missing data will be managed using multiple imputation [58]. Multivariate ANOVA with repeated measures will be performed to test the intervention's effectiveness on continuous variables over time. Time (pretest, posttest, and 3- and 6-month follow-ups), condition (web-based iCBT, app-based iCBT, and WLC), and the interaction of time-by-condition will be specified as the categorical fixed factors. Medication and demographic factors (eg, gender, age, and marital status) will be specified as fixed covariates to control the potential confounding effects. Cohen *d* will be calculated as the index of the effect size both within and between groups.

Results

The Ease Online program was developed between July 2019 and December 2020 and officially launched in a press conference on January 18, 2021. The principal investigator and project staff have since been involved in promoting the program and recruiting, screening, and referring participants, taking part in intake interviews and case meetings, conducting service delivery and monitoring duties, collecting data, modifying and enhancing the system, providing technical support, responding to enquiries, and other tasks. As of February 2023, a total of 1811 individuals were enrolled in the Ease Online program. A total of 401 intake interviews have been completed, and 329 participants have joined the program, among whom 166 have completed the intervention. A total of 1924 written comments have been provided for client assignments, 604 individual counseling sessions have taken place, and 392 VRET sessions have been conducted. Data collection is still ongoing, which is expected to be completed in March 2024.

Discussion

Overview

SAD often has a high prevalence and low treatment rate. People with SAD often underperform and underachieve. Treatment of SAD can not only improve their achievement and quality of life, but also increase productivity in the society as a whole. This study is the first of its kind in combining iCBT and VRET for the treatment of social anxiety in Hong Kong. At a theoretical level, this study will contribute to the development and evaluation of internet-based psychological interventions in Chinese communities. At a practical level, if proven to be effective, this study will provide an alternative e–mental health service option for people in Hong Kong with easy access. In addition, if adopted by local social service sectors, the Ease Online program will fill in a large service gap between the overwhelming service demand by mental health clients and the insufficiency of mental health professionals in Hong Kong.

Lessons Learnt

In the process of developing the Ease Online program, several lessons have been learnt: (1) considering the extremely low treatment rate of SAD in Hong Kong (8.7%) [5], iCBT serves as a more preferred and accessible treatment option for Hong Kong clients with SAD; flexibility in time and space as well as the web-based format might encourage people with SAD to seek treatment in a way that is less threatening to them. (2) Culturally relevant intervention contents are important. All of the case demonstration videos were tailored for Hong Kong clients with SAD based on local cases, which increases their relevance and resonates with the real-life situations of the clients. The program focuses on working with culturally relevant beliefs related to social anxiety by choosing CBT skills that

XSL•FO
RenderX

have been suitable for Chinese clients in previous studies; for example, the "pie chart" technique is used to relax the cognitive rule of "I have to make no mistakes to be a good offspring." (3) Compared with cartoons or 3D characters, the use of real humans in VR videos may increase the sense of reality and presence in VR situations. (4) Guided self-help iCBT in service delivery, including therapist support in the form of exercise feedback and counseling sessions, is important to help clients to apply the CBT skills learned from the web-based modules to deal with their social anxiety. (5) Compared to text-based iCBT, Hong Kong people prefer video-based iCBT. As Hong Kong people are generally very busy, they may not have time to read long passages of text. Watching short videos that present the key CBT skills with case demonstration is more acceptable to Hong Kong clients. (6) Participant screening using a screening questionnaire and through intake interviews and case meetings ensures eligibility and screening out of high-risk cases and referring other resources to them. (7) Both the web-based platform and the mobile app are developed as computers and smartphones are widely used in Hong Kong. (8) Aside from psychological assessment, the use of physiological assessments, such as heart rate and blood oxygen levels, in VRET can provide more objective evaluations.

Limitations

There are several limitations of this study that should be considered. First, only completed tasks are recorded in the system, but there are no records of therapist time and use time of the client in the system. User time can be recorded in the system in future research to calculate the average therapist time spent and the amount of time for which the clients use the system. Second, the number of missing data at posttest and follow-up is quite high—this may be related to the busy lifestyle in Hong Kong and nature of free services provided in this study, although various means including email and phone calls have been used to remind clients to complete the web-based questionnaires after the intervention. Different approaches need to be used in future research to increase the response rate of postintervention assessments. Third, although several strategies are adopted ensuring compliance with the intervention, future research may include independent ratings by certified cognitive behavioral therapists of a random selection of the progress reports of the individual counseling and VRET sessions as well as assignment feedback. Fourth, participants are mainly recruited via open recruitment, which may cause recruitment difficulties and a high nonresponse rate after enrollment. Collaboration with local social service sectors is suggested in future research for participant recruitment and follow-up with service delivery and data collection. Fifth, in the VR system, 180° videos are produced, which may limit the view of clients in the VR environment. Future research may aim to develop 360° videos for the VRET system. Finally, 5 VR scenarios are developed in this study; future research may aim to develop more VR scenarios to allow clients to choose social situations that are more relevant to them.

Acknowledgments

This study is financially supported by the Research Impact Fund in Research Grants Council in Hong Kong (project R2018-18). I would like to thank Professor Per Carlbring for his advice during the process of grant application for this project. I thank Mr Chun Man Leung and AESIR Ltd for developing the Ease Online platform and virtual reality exposure therapy system used in this study, respectively. I also thank Ms Selina Sou and Ms Mei Yu Ho for service delivery and administration in this project, respectively.

Conflicts of Interest

None declared.

Protocol

Effectiveness, Acceptability, and Feasibility of a Telehealth HIV Pre-Exposure Prophylaxis Care Intervention Among Young Cisgender Men and Transgender Women Who Have Sex With Men: Protocol for a Randomized Controlled Trial

Abstract

Background: Despite its promise for HIV prevention, the uptake of pre-exposure prophylaxis (PrEP) has been slow, and there have been substantial inequities in PrEP access. Young men who have sex with men and transgender women of color are most in need of PrEP and least likely to have that need fulfilled. PrEP telehealth care, which provides remote PrEP care via electronic communication, seems well suited to address several of the challenges of PrEP provision, including discomfort with stigmatizing and difficult-to-access health care systems, transportation challenges, and privacy concerns, and address disparities in PrEP access. Research suggests that PrEP telehealth care has promise and is a favored option for many prospective recipients of PrEP. However, despite growing attention to telehealth approaches as an avenue for increasing access to PrEP amidst the COVID-19 pandemic, there have been no published randomized controlled trials (RCTs) on PrEP telehealth care to date, making it difficult to draw strong conclusions about the advantages or disadvantages of telehealth compared with usual PrEP care. We developed PrEPTECH, a telehealth intervention that focuses specifically on alleviating issues of stigma, access, cost, and confidentiality for young people with risk factors for HIV infection who are seeking PrEP care. Leveraging data from the 2017 observational pilot study, we redesigned and enhanced PrEPTECH.

Objective: This study aims to assess the effectiveness, acceptability, and feasibility of a telehealth HIV PrEP care intervention, PrEPTECH, in increasing PrEP uptake.

Methods: This is the protocol for an RCT of young cisgender men and transgender women who have sex with men in 4 regions within the United States: the San Francisco Bay Area, California; Los Angeles County, California; Miami-Dade County, Florida; and Broward County, Florida. Participants in the intervention arm received access to a web-based telehealth program, PrEPTECH, which offers a fully web-based pathway to PrEP, whereas those in the control arm received access to a dynamic web page containing publicly available informational resources about PrEP. Follow-up data collection occurred at 3 and 6 months. An analysis will be conducted on outcomes, including PrEP initiation, persistence, adherence, coverage, and medication prescription, as well as PrEPTECH acceptability and feasibility.

Results: The study was funded in 2019 and received institutional review board approval in 2020. The PrEPTECH intervention was developed over the next 1.5 years. Study recruitment was launched in February 2022 and completed in September 2022, with 229 participants recruited in total. Data collection was completed in April 2023.

Conclusions: The results of this RCT will offer valuable evidence regarding the effectiveness, acceptability, and feasibility of telehealth HIV PrEP care interventions among young cisgender men and transgender women who have sex with men.

Introduction

Background

The use of antiretroviral medications as pre-exposure prophylaxis (PrEP) is an effective biomedical HIV prevention approach first approved by the US Food and Drug Administration in 2012 [1]. Copious research has established that HIV PrEP presents few significant safety risks and substantially reduces the likelihood of contracting an HIV infection in individuals at risk when taken consistently. Research has confirmed the effectiveness of PrEP for adolescent men who have sex with men [2] and transgender women [3] when it is taken consistently.

Despite its promise for HIV prevention [4,5], the uptake of PrEP has been slow, although it has improved recently, and there have been substantial inequities in PrEP access. PrEP is indicated for an estimated 1.2 million people in the United States according to the Centers for Disease Control and Prevention, but in 2020, only 24.7% of those for whom PrEP was recommended were prescribed it (compared with approximately 3% in 2015) [6]. There are substantial racial and gender disparities in PrEP uptake. Specifically, 4 in 10 Black/African American men who have sex with men and 2 in 10 Hispanic/Latino men who have sex with men will be diagnosed with HIV infection in their lifetime, compared with only 1 in 10 White men who have sex with men [7]. However, PrEP coverage (the percentage of those with an indication for PrEP who received a PrEP prescription) ranges from 65.4% among White people to 15.7% among Hispanic/Latino people to 9.1% among Black/African American people [6]. The prevalence of HIV among transgender women in the United States is 14%, over 30 times higher than that in the US population overall [8], but a nationally representative study of transgender people found that 3% of transgender respondents who were having sex with cisgender men or transgender women were taking PrEP [9]. People aged 16 to 24 years have the lowest rates of PrEP uptake of any age group, with only 15.6% of those with an indication for PrEP receiving a prescription for PrEP in 2020 (Centers for Disease Control and Prevention) [6]. Adherence to and persistence in the use of PrEP are also less favorable among Black/African American men who have sex with men and youth [10,11]. There is a dearth of research on the rates of adherence to and continuation of PrEP among transgender women [12]. In sum, young people of color, particularly young men who have sex with men and transgender women of color, are most in need of PrEP access and least likely to have that need fulfilled.

Researchers have identified a range of factors that may interfere with initiating and adhering to PrEP, including a lack of awareness or knowledge of PrEP, poverty, health system inaccessibility, stigma, concerns about side effects, competing stressors, and low HIV risk perception [13-17]. Health system factors that impede PrEP access include primary care providers' lack of familiarity or comfort with dispensing PrEP care, racial and ethnic bias, homophobia, and transphobia among health care providers, and distrust in the medical system among potential PrEP recipients [18]. Logistical difficulties, such as the lack of transportation, prevent people seeking PrEP from reaching PrEP clinics, which are sparser in areas with higher poverty, larger Black/African American and Hispanic/Latino populations, and lower rates of insurance coverage [19]. Concerns about insurance and the ability to pay can also present obstacles. Obstacles to the continuation of PrEP include health system barriers, acute medication side effects, decreased sexual risk-taking and perceived HIV risk, and health system factors such as cost and difficulty attending appointments [20-22].

Telehealth or telemedicine, the use of electronic communication to improve patient health [23], seems well suited to addressing many of the challenges of PrEP dissemination and has become increasingly relevant during the COVID-19 pandemic [24]. Telehealth interventions may remove obstacles within the health care system that complicate beginning and remaining on PrEP. Telehealth may simplify the process of obtaining PrEP and lessen the impact of stigma by allowing participants to access PrEP more privately [25]. A survey of a nationwide cohort of men who have sex with men who were HIV negative and had not initiated PrEP found that the vast majority said that they would prefer to undergo follow-up home testing and receive mail-delivered PrEP after an initial in-person appointment to start PrEP care (termed "home-based care" in the study) over regular follow-up at a clinic [26]. Men who were younger or reported being distant from the nearest lesbian, gay, bisexual, transgender, and queer (LGBTQ+)–friendly health care provider were more likely to prefer home-based PrEP care, as were those who had more potential exposure to HIV infection and a stronger intention to start PrEP. A meta-ethnography reviewing data from 11 unique qualitative studies of men who have sex with men in the United States concluded that structural interventions, including telehealth for PrEP, may help circumvent barriers to PrEP for some men who have sex with men, such as difficulty obtaining transportation and maintaining engagement with treatment [14].

Many PrEP care providers, such as health care providers, have generally turned to telehealth approaches because of the evident need for alternatives to in-person care since the beginning of the COVID-19 pandemic [27,28]. A small study of patient

XSL•FO
RenderX

satisfaction following a clinic's transition to telehealth-delivered PrEP care midpandemic found a preference for telehealth PrEP visits over traditional in-clinic PrEP visits [29]. The ranks of commercial and nonprofit providers of PrEP telehealth care have grown in the past few years, with multiple nationwide companies providing telehealth care, alongside numerous local efforts, in the United States [22].

PrEP Telehealth Delivery

Despite growing attention to telehealth approaches as an avenue for dispensing PrEP, research on PrEP telehealth delivery has been mostly limited to general reports on implementation [30]. PrEP telehealth projects that researchers have reported on include Iowa TelePrEP, a public health–partnered regional PrEP telehealth project; a telehealth extension of a Seattle PrEP clinic; a San Francisco clinic transitioning to a telehealth-focused model in the midst of the COVID-19 pandemic; and PlushCare and Nurx, 2 commercial providers of telehealth PrEP care. Research on user experience and preferences has largely found that patients are receptive to PrEP telehealth and largely report positive experiences. A qualitative report on user experience with the Nurx telehealth PrEP service found strongly favorable responses and appreciation for the service's achievement of a balance between efficiency (simplicity, speed, and convenience) and humanity (feeling of personalized service, connection, and care) [31]. Research on the San Francisco clinic transitioning to telehealth found that telehealth-based care was preferred by many prospective PrEP users because of the convenience and perceived safety of telehealth, whereas technical barriers and unfamiliarity of the platform were considered disadvantages of PrEP telehealth [32]. In addition, in a PrEP telehealth pilot that enrolled 40 participants and provided PrEP to 20 participants, only 13% (n=5) of the participants said that they would have preferred in-person–only PrEP care to exclusive telehealth care or a blend of telehealth and in-person care [33].

The limited research on the rates of PrEP uptake in the PrEP telehealth setting suggests that PrEP telehealth can be effective. Most Iowa TelePrEP clients who completed video-based telehealth visits (91%) started PrEP, and the intervention had a 61% retention rate at 6 months, indicating that widely available technology can be a viable tool for delivering PrEP in small urban and rural settings [25]. In the mixed methods evaluation of their laboratory testing site versus home testing options for routine monitoring, home kit use was associated with higher completion of some tests (extragenital swabs) and lower completion of others (blood tests); self-efficacy in using kits, time, convenience, privacy, and confidentiality were the primary factors influencing the use of home test kits [26]. In addition, a report on the telehealth extension of a Seattle PrEP clinic, which described implementation and compared 10 patients who opted to receive telehealth care with 38 patients who did not opt to receive telehealth care, found no significant differences between the groups in the proportion of participants prescribed PrEP, attendance at their first follow-up visit, and adherence at 1 month but found low rates of attendance at the 3-month visit among patients who opted to receive telehealth PrEP who had not yet been referred to another health care provider for PrEP.

We developed PrEPTECH, a telehealth intervention that focuses specifically on alleviating issues of stigma, access, cost, adherence, and confidentiality in young people with risk factors for HIV infection who are seeking PrEP care. A 2017 observational pilot study of PrEPTECH found that the intervention helped users bypass some of the documented barriers to PrEP access, uptake, and adherence [34]. The 25 men who have sex with men who were HIV negative, were aged 18 to 25 years, were from the San Francisco Bay Area, and enrolled in the pilot study reported high satisfaction with PrEPTECH, and over 85% expressed preference for telehealth-delivered PrEP care over clinic-delivered PrEP care. Leveraging the data from the pilot study, we redesigned and enhanced PrEPTECH and are now testing whether the updated platform enhances PrEP uptake among young cisgender men and transgender women who have sex with men through a randomized controlled trial (RCT). Ultimately, this study will add to the growing evidence base about the effectiveness, feasibility, and acceptability of telehealth HIV PrEP care.

Methods

Study Design

This study is an RCT for assessing the effectiveness, acceptability, and feasibility of a telehealth HIV PrEP care intervention, PrEPTECH, in increasing PrEP uptake over 6 months among young cisgender men and transgender women who have sex with men in 4 regions within the United States, namely the San Francisco Bay Area, California; Los Angeles County, California; Miami-Dade County, Florida; and Broward County, Florida, when compared with those of standardized web-based PrEP information resources.

Study Objectives

The study has two primary objectives: (1) to test the effectiveness of a telehealth intervention, PrEPTECH, in enhancing PrEP uptake in comparison with that of a condition in which only standardized web-based PrEP information resources are provided and (2) to assess the acceptability and feasibility of PrEPTECH as a telehealth HIV PrEP care intervention for young cisgender men and transgender women who have sex with men.

In addition, the study has two secondary objectives: (1) to test the effectiveness of a telehealth intervention, PrEPTECH, in improving adherence to PrEP in comparison with that of a condition in which only web-based standardized PrEP information resources are provided and (2) to examine the moderators of PrEP use, including HIV risk perception, PrEP attitudes, sexual behaviors associated with HIV risk, and insurance status.

Study Hypotheses

We hypothesize that participants in the intervention arm will show higher rates of PrEP initiation at both 3 and 6 months than those in the control arm. We also hypothesize that PrEPTECH is an acceptable and feasible telehealth HIV PrEP care intervention for young cisgender men and transgender women who have sex with men.

XSL•FO
RenderX

Study Setting

The study will be completed digitally among self-referred participants living in the San Francisco Bay Area, California (the 9 counties of Alameda, Contra Costa, Marin, Napa, San Mateo, Santa Clara, Solano, Sonoma, and San Francisco); Los Angeles County, California; Miami-Dade County, Florida; or Broward County, Florida.

Sample Size

We calculated the sample size to provide adequate statistical power for our first objective, which is to test the effectiveness of a telehealth intervention, PrEPTECH, in enhancing PrEP uptake. Data suggest that PrEP uptake among relevant populations is low. Only 16% of young people aged 16 to 24 years use PrEP [6]. We also reviewed recent RCTs aimed at increasing PrEP uptake in comparable study populations. A pilot study of linkage to PrEP care among men who have sex with men and transgender women identified as partners of people diagnosed with a sexually transmitted infection (STI) found an uptake rate of PrEP of 11% among controls receiving standard HIV prevention programming, including PrEP care [31]. In a pilot trial of a 2-session motivational interviewing–based behavioral intervention, 28% of controls receiving treatment as usual at an urban STI clinic received a PrEP prescription [35]. Furthermore, 2 RCTs of web-based interventions for increasing PrEP uptake among sexual minorities with published protocols estimated anticipated control arm uptake ranging from 2% to 15% for the purpose of their power analyses [36,37].

Using this recent research on PrEP uptake in relevant populations and comparable research projects, including ongoing RCTs of digital interventions, we assumed 20% PrEP uptake in the control population. We proposed a minimum sample size target of 192 participants. Retaining 83.3% (160/192) of these participants at the 90-day and 180-day follow-up was our benchmark, as a loss to follow-up of greater than 20% in RCTs is seen as potentially introducing a source of bias [38]. We calculated statistical power using the following assumptions: power $(1 - \beta)=.80$, significance level $(\alpha)=.05$, PrEP uptake in the control group of 20%, and PrEP uptake in the intervention group of ≥40%. The power analysis results indicate a required sample size target of 96 per group or 80 per group after anticipated attrition.

Eligibility Criteria

To be eligible, participants must live in the San Francisco Bay Area, California (the 9 counties of Alameda, Contra Costa, Marin, Napa, San Mateo, Santa Clara, Solano, Sonoma, and San Francisco); Los Angeles County, California; Miami-Dade County, Florida; or Broward County, Florida. Participants must self-report having sex with men and identify as a cisgender male and be aged 15 to 17 years (in California only; minors in Broward or Miami-Dade County will not be eligible), identify as a cisgender male and be aged 18 to 27 years, or identify as a transgender female (or assigned male at birth and identify as a woman) and be aged 18 to 27 years (transgender females outside this age range will not be not eligible). In addition, participants, in keeping with guidelines for the provision of PrEP for sexual risk factors, must qualify for PrEP by self-reporting being diagnosed with an STI (including chlamydia, genital herpes, gonorrhea, syphilis, genital warts, human papilloma virus infection, and trichomoniasis) in the past 6 months or self-reporting condomless anal intercourse in the past 90 days [39]. Having a current known HIV-positive sexual partner and an indication for PrEP based on injection drug use were not included as eligibility criteria because of their expected rarity in our young study population. Among individuals aged 21 to 30 years, 1.5% reported ever injecting a drug not under a physician's orders and only 0.5% reported sharing needles in this way in their lifetime [40], and in a study of youths aged 12 to 24 years at high risk for HIV infection, only 7.7% reported ever having sex with a person living with HIV [41]. Only participants who attested to feeling comfortable reading and speaking in English were included, as, owing to development costs, creating a version of the website in Spanish was not feasible and other services associated with the intervention, including laboratory and pharmacy services, were in the English language only. Participants are not eligible if they have taken PrEP in the past 30 days; have ever been diagnosed with HIV infection, hepatitis B infection, chronic kidney, liver, or bone disease; or do not meet the eligibility criteria.

Recruitment and Randomization

To recruit potential participants, we contracted with an LGBTQ+ marketing and communications company to run paid advertising campaigns on social media platforms (eg, Facebook [Meta Platforms, Inc] and Instagram [Meta Platforms, Inc]) and LGBTQ+ dating apps (eg, Grindr [Kunlun Tech Co Ltd], Scruff [Perry Street Software Inc], Jack'd [Perry Street Software Inc], and Adam4Adam [A4A Network Inc]). The advertisements were targeted to the age and geographic eligibility criteria of the study and included a diverse array of men who have sex with men and transgender people, prominently featuring Black/African American and Hispanic/Latino individuals.

In addition to web-based recruitment, we identified community-based organization partners in each geographic location of the study and paid them to conduct web-based and in-person outreach. Community partners received printed assets (eg, palm cards and flyers) with the link to the study website and a QR code linked to the study website, as well as social media assets, including graphics sized for multiple social media platforms (eg, Instagram, Facebook, and Twitter [Twitter, Inc]), suggested captions, and potential hashtags.

Upon recruitment, prospective participants were directed to the study website and asked to complete an eligibility screener. Participants who were eligible completed an informed consent process.

To ensure that participants understood the risks that PrEP and participation in this study entail, the informed consent text outlined the risks in a detailed plain language summary. Taking advantage of the functionality available in a web-based setting, comprehension questions were incorporated into the informed consent text; prospective participants could not advance through the document until each question was correctly answered. We received a waiver of parental permission and, therefore, did not require or seek parental consent for minor participants.

XSL•FO
RenderX

Participants who correctly answered the comprehension questions and consented to participate were brought to a baseline survey; upon completion, they were randomized into one of the two study arms. Only those who met the eligibility criteria and consented to participate were included in the study.

Eligible participants were randomized equally between the intervention arm, a web-based telehealth program offering a fully web-based pathway to PrEP, and the control arm, a dynamic web page containing publicly available informational resources about PrEP. We intended to ensure equal allocation of participants across the 4 study areas and equal numbers of adolescent cisgender males and adult transgender females in each study arm (approximately 20 individuals belonging to each subgroup in each study condition).

Community Advisory Board

During the development of the PrEPTECH intervention, we convened a 6-member community advisory board (CAB), composed of individuals who met the age and geographic eligibility criteria for the study and identified as a cisgender male or transgender female. Over the course of 5 web-based meetings, CAB members provided critical input and feedback on visual design, user experience, survey tools, recruitment approaches, and marketing and communication efforts. CAB members provided general guidance on how to appeal to prospective participants, suggesting that we highlight the incentive, potential to help the community through participation in this research, and benefits of PrEP. They offered the tagline used in the study's marketing materials, "PrEP on your own terms," following their discussion of the value of emphasizing PrEP as a personal exercise of autonomy, and, over several sessions, provided feedback on and later selected images and designs proposed by an in-house graphic designer for use on the PrEPTECH website and marketing materials. Each CAB member also took a draft survey and submitted feedback on any questions that they felt confused by or uncomfortable with; we also solicited input from the CAB about important topics that might be missing from the survey and on potential barriers to PrEP access that should be asked about.

Intervention

Participants allocated to the intervention arm of the study gained access to a web-based telehealth platform called PrEPTECH, which provides PrEP education via self-guided reading material, access to laboratory testing for PrEP eligibility delivered to a participant's home, and optional SMS text messages or email reminders to aid in medication adherence. PrEPTECH also provides access to telehealth care and PrEP prescriptions for eligible patients asynchronously through a web-based form or synchronously through telephone appointments with the study clinician, an infectious disease physician with expertise in PrEP care licensed in California and Florida. The PrEPTECH intervention tested here is an extension of the piloted PrEPTECH intervention. A brief report on the results of the pilot also discusses the development of the initial intervention by a multidisciplinary team in concert with a previous CAB [42]. It was adjusted to serve a larger group and to be completely web-based. In the second version of PrEPTECH, we incorporated a home laboratory testing kit service, built a platform for offering web-based health evaluations, and developed back-end systems for PrEPTECH to enable the clinical team to review submitted information and communicate with participants. The site was also redesigned for mobile platform compatibility.

All participants who completed at-home laboratory testing and an asynchronous or telephone appointment with the study clinician for whom PrEP was indicated received a prescription for Truvada (emtricitabine, 200 mg or tenofovir disoproxil fumarate, 300 mg). Adult cisgender male participants aged 18 to 27 years received a free 30-day supply of PrEP and subsequently had to pay for PrEP medication through insurance, through patient assistance programs, or out of pocket, should they choose to continue taking PrEP. Adolescent cisgender male participants aged 15 to 17 years and adult transgender female participants aged 18 to 27 years received free PrEP medication for the duration of their 6-month participation in the study because these subgroups were not included in the pilot study of PrEPTECH. Knowing less about the suitability of this intervention for these susceptible populations, the study team opted to provide free medication to them for the duration of the study. PrEPTECH also provides support for signing up for PrEP access programs, prescription transfer, and coordination with community partners.

After randomization to the PrEPTECH group, participants entered the PrEP education section, which included information about use, side effects, and effectiveness, and completed quiz questions to ensure comprehension. Next, a myLAB Box home testing kit for HIV, hepatitis B, syphilis, creatinine, gonorrhea, and chlamydia was sent to an address of their choice (typically, their home) [43]. Participants collected the specimens required through swab and finger prick and sent them via a postage paid mailer. If the participant tested negative for HIV antibodies or another STI, the web-based results were made available to the participants, and they were prompted to complete a medical intake questionnaire. This questionnaire was reviewed by the study clinician to confirm that there were no contraindications to PrEP medication for the participant. Synchronous telehealth appointments (telephone or video calls) were provided to all adolescent participants because it was anticipated that they might have a greater need for explanation and guidance that could best be offered in this format. For all other participants, synchronous telehealth appointments were offered as needed or requested.

If the study clinician was satisfied that the participant was eligible, he would issue a 6-month prescription for PrEP. A free initial supply of PrEP would be filled by Ridgeway Pharmacy, a mail order pharmacy serving both California and Florida, and mailed to a location of the participant's choice (typically, their home) [42]. For adult cisgender male participants, this initial shipment would be a 30-day supply of PrEP, but for adolescent cisgender male or adult transgender female participants, a 90-day free supply was sent. If a participant tested positive for HIV antibodies or another STI or any significant laboratory abnormalities were found, rather than reporting the results directly to the participant, a synchronous telehealth appointment would immediately be scheduled, and the study clinician would share the laboratory results, provide any necessary counseling,

XSL•FO
RenderX

and refer the participant to a community provider for care. These participants would remain included in the study and would still be prompted to take the 90- and 180-day surveys. Then, 30 days after the prescription was sent, participants completed a second medical intake questionnaire, which was reviewed by the study clinician to assess any side effects or challenges encountered in taking PrEP. Participants could also request a synchronous appointment with the study clinician at any time during the study. Furthermore, 3 months (90 days) after enrollment, participants completed a second myLAB Box home testing kit for HIV, syphilis, gonorrhea, and chlamydia, as well as a third medical intake questionnaire, which was reviewed by the study clinician, with similar follow-up procedures as before. Follow-up laboratory tests did not include PrEP adherence measures such as hair sample or blood spot test, as they cannot be performed in the commercial laboratory with which we are working. Communication about steps toward accessing treatment is made through emails and texts, depending on the preferences expressed by the user, which can be indicated on the website itself.

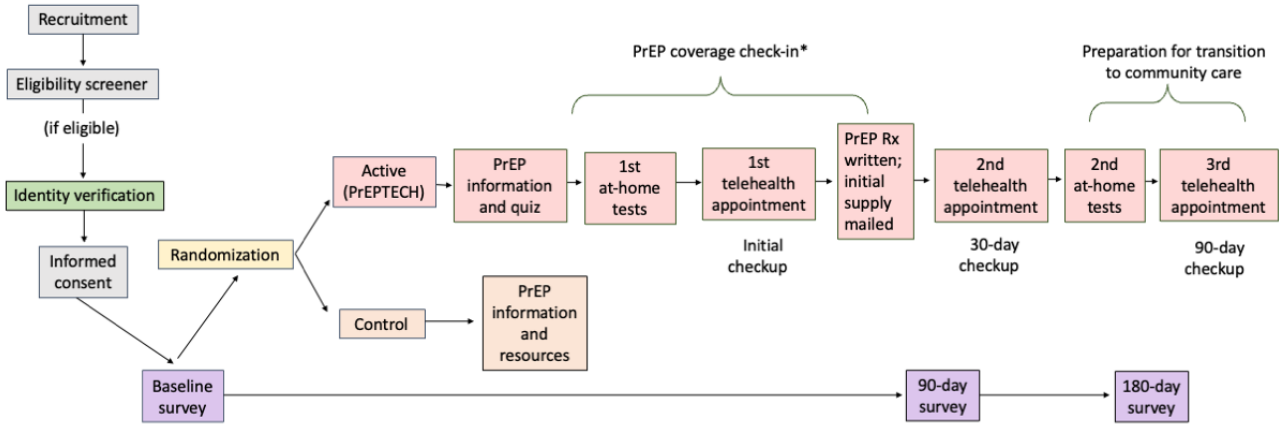
Following their completion of the PrEP knowledge module, participants were queried about their insurance coverage and preferences with regard to paying for PrEP beyond their free supply. Using this information, the study staff worked with each participant to identify a means of payment, should the participant choose to continue taking PrEP. Participants could opt to use their existing insurance or pay out of pocket, in which case they would contact a pharmacy of their choice and request a transfer of the prescription. If they did not have insurance, they could seek coverage through Ready, Set, PrEP, a nationwide program that covers the cost of PrEP [44]. Ready, Set, PrEP allows care providers and patient navigators to sign up prospective participants. Participants would be given the option of signing up for Ready, Set, PrEP themselves, in which case the PrEPTECH platform provided detailed instructions for correctly completing their application, or they may authorize the study team staff to sign up on their behalf. Alternatively, if a participant opted for a community partner referral, they would be connected to an organization offering PrEP navigation in their geographic area. Near the end of a participant's time in the study, additional information and offers of support for transitioning to community care were provided again, including referrals to community partners.

Sample images from the PrEPTECH intervention can be found in Multimedia Appendix 1.

Control

Participants allocated to the control arm of the study gained access to a dynamic web page containing publicly available standardized informational resources about PrEP, including information on eligibility, use, side effects, effectiveness, access, and payment, as well as specific PrEP resources for transgender females. This web page also provides a list of alternative telehealth-based PrEP providers and contact information for community partners offering PrEP navigation in each geographic area.

The personal landing page for each participant was customized based on their study arm and subgroup (adolescent, adult transgender woman, or adult cisgender man who has sex with men). Participants allocated to the control condition could not access any of the PrEPTECH features, which were not displayed to them. A second panel on the control arm participants' landing page shows what surveys they have taken and are currently eligible to take.



Participant Timeline

The entire 6-month web-based study is completed on the PrEPTECH website. A sequential illustration of participants' experiences is shown in Figure 1.

1. Recruited prospective participants review web-based materials on the PrEPTECH website and elect whether to create a web account, which requires them to verify their email address and phone number and provide their name.
2. After creating an account, prospective participants are screened for eligibility via a web-based survey. Those meeting the inclusion criteria proceed to step 3.
3. Each participant then verifies their identity by providing a photo of themselves with a photo ID card or a link to a public social media profile that shows their name with a visible photo of themselves.
4. Participants who provide identity verification are invited to complete the baseline web-based survey.
5. Each participant is randomized after baseline completion, informed of their assignment, and provided with standardized web-based resources on PrEP access or brought to the first step of the PrEPTECH intervention.
6. All participants are invited to take the midpoint survey 90 days after the baseline survey.
7. All participants are invited to take the final survey 180 days after the baseline survey.

XSL•FO
RenderX

Figure 1. PrEPTECH study and intervention participant experience. *For adult men who have sex with men who are initially provided with a 30-day supply of free pre-exposure prophylaxis (PrEP), information and guidance on paying for PrEP (through insurance, patient access programs or self-pay) is provided concurrently with the provision of at-home laboratories and the initial telehealth appointment. Rx: prescription.

Data Collection and Management

Study data come from surveys completed by participants at three time points, namely (1) before randomization (baseline); (2) 3 months (90 days) after enrollment; and (3) 6 months (180 days) after enrollment, as well as study implementation records that document participant follow-up activities and participant progress through the intervention. Additional study data come from the laboratory tests and medical intake forms collected before the provision of the first PrEP prescription and approximately 90 days later, completed by participants in the intervention arm.

All survey data are collected digitally and entered directly by participants via embedded surveys hosted by Qualtrics (Qualtrics International, Inc) into the PrEPTECH study website. For participants in the intervention arm, laboratory test and medical intake information is collected via myLAB Box (laboratory test) and an embedded survey hosted by Qualtrics (medical intake). Medication prescription information is transferred electronically, using DrChrono (EverCommerce), to Ridgeway Pharmacy.

Participants receive automated email and SMS text message reminders to complete all surveys, with additional customized follow-up via email and SMS text message from the study team. To maximize the response rate and study retention, participants are compensated with web-based gift cards for the completion of each survey: US $40 at baseline, US $50 at 3 months, and US $60 at 6 months.

Upon randomization, each participant was assigned a unique identifier used throughout the study. However, data will be associated with personal identifiers while the study is ongoing, as this is necessary for participant follow-up. Electronic data will be stored for 3 years after the conclusion of the study. All data relevant to the study will ultimately reside in ETR Associates' Amazon Web Services system (Amazon Web Services, Inc) using Aptible (Aptible Inc) to ensure Health Insurance Portability and Accountability Act compliance.

Outcomes

Primary Outcomes

PrEP initiation at 3 months after enrollment will be assessed using participant self-report of having taken at least one dose of PrEP medication between study enrollment and midpoint survey administration.

Secondary Outcomes

PrEP Initiation

PrEP initiation at 6 months after enrollment will be assessed using participant self-report of having taken at least one dose of PrEP medication at any point during the intervention period.

PrEP Persistence

PrEP persistence at 3 and 6 months after enrollment will be assessed using participant self-report of having taken at least one dose of PrEP medication during both the first and second 90-day periods of the intervention.

PrEP Adherence

PrEP adherence at 3 and 6 months after enrollment will be assessed through multiple measures. Continuous adherence will be assessed using participant self-report of the number of doses of PrEP taken in the past 30 days, excluding participants taking event-based PrEP, as adherence would need to be conceptualized differently for this approach to PrEP administration. Categorical adherence will be assessed using participant self-report of taking a dose of PrEP medication for at least four days per week, "all of the last 4 weeks (4 out of 4 weeks)" or "most of the last 4 weeks (3 out of 4 weeks)," excluding participants taking event-based PrEP.

PrEP Coverage

PrEP coverage at 3 and 6 months after enrollment will be assessed using participant self-report of the number of instances in the past 30 days of vaginal or anal sex in which there was no protection from event-driven PrEP (defined as taking PrEP between 2 and 24 hours ahead of the sex act and ≥2 doses 24 and 48 hours after the first dose), continuous PrEP (defined as taking a minimum of 4 doses of PrEP within a week of the sex

XSL•FO
RenderX

act), or long-acting PrEP (defined as taking injectable PrEP within 2 months before the sex act).

PrEP Medication Prescription

PrEP medication prescription at 3 and 6 months after enrollment will be assessed through multiple measures, including self-report of having received a PrEP prescription at any point during the intervention, as well as documented medication prescription through study electronic health records (among eligible intervention arm participants only).

PrEPTECH Acceptability and Feasibility

The acceptability and feasibility of PrEPTECH as a telehealth HIV PrEP care intervention for young cisgender men and transgender women who have sex with men will be assessed through multiple measures, including the likelihood of recommending PrEPTECH; preference for continuing PrEPTECH beyond the study; and other variables assessing the perceived trustworthiness, privacy, helpfulness, and convenience of and comfort with PrEPTECH. We will also calculate a mean System Usability Scale score, which is a standard scale for evaluating web apps [45], and conduct a thematic analysis of responses to 4 free-text questions about participants' perception of and experience with the PrEPTECH intervention and barriers to PrEP access encountered during the study. We will also examine clinical data, data on study attrition and completion, and other data from study implementation records.

Demographics

Participants' age, sex, gender, gender identity, sex partners' gender, sexual orientation, race, ethnicity, educational attainment, and living situation (living alone or with housemates or family) and whether languages other than English are spoken at participants' home will be assessed.

Moderators and Mediators

The following parameters will be assessed at baseline as potential moderators of PrEP uptake: history of PrEP use, HIV risk perception (assessed using the Perceived Risk of HIV Scale) [46], PrEP attitudes (assessed using a PrEP attitude and stigma scale with scores ranging from 10 to 50) [47], behaviors associated with HIV risk (eg, instances of anal intercourse without a condom in the past 90 days), health insurance status, and reasons for enrolling in the study (using a predefined list of possible reasons formulated by the study staff with input from the CAB). A series of questions assess the barriers to PrEP access participants may have encountered during the study period as a potential mediator of differences in PrEP uptake. Participants are asked to attest to whether they have encountered specific PrEP access barriers compiled in consultation with the CAB and with reference to the literature falling into the categories of financial or insurance coverage, health care access, medical concerns, privacy, PrEP stigma, and practical considerations (including loss, theft or selling of medication). A single item on the 2 follow-up surveys will also ask all participants to rate whether they have a source of PrEP that meets their needs.

Data Analysis

Overview

We will report the participant flow through the trial and the results in line with the CONSORT (Consolidated Standards of Reporting Trials) guidelines [48]. All analyses will be carried out following intention-to-treat principles. Data from participants will be allocated to the arm they were initially assigned to, regardless of whether they complete the intervention.

Data analysis will be conducted in SPSS (version 29 or higher; IBM Corp). Descriptive statistics will be calculated to describe the sample at baseline. Binary and categorical variables will be assessed through counts and percentages, and continuous variables will be assessed through means and SDs (medians will be computed for highly skewed variables). To assess baseline equivalence between the intervention and control arms of the study, regression analyses will be performed using age, race, ethnicity, gender, and educational attainment as dependent variables, with intervention condition as the independent variable. The groups will be considered not equivalent at baseline if a given variable differs significantly ($P<.05$) between the intervention arms. Differential and overall attrition will also be assessed using the What Works Clearinghouse recommended approach [49]. We expect ≤5% of the data to be missing; therefore, a complete case analysis is planned with no outcome or baseline imputation. However, if missing data go beyond 5%, then multiple imputation will be explored and run using the *mice package* in R (R Foundation for Statistical Computing) [50].

Primary and Secondary Outcome Analyses

Objective 1

To assess the effectiveness of PrEPTECH in enhancing PrEP uptake in comparison with the control condition, multiple logistic regression will be applied with the primary outcome (taking at least one dose of PrEP in the last 90 days, a dichotomous variable) as the dependent variable. The model will also include indicator variables denoting (1) the intervention group, (2) the number of days between the baseline and follow-up surveys (if there is a large range, which we do not expect), (3) the standard demographics of age at baseline and race and ethnicity at baseline, and (4) a set of a priori demographics and outcome-related covariates that screened positively as candidates for inclusion. A priori covariates that will be screened as candidates for inclusion into the model include gender, educational attainment, health insurance status, state, location, language spoken at home, sexual orientation, gender of sex partners, sexual risk factors, and the participants' relationships with the persons they are living with. If there is high correlation ($r>0.50$) between some of these indicators, they will be excluded from the model. Bivariate analyses will be used to test for relationships between the outcome variable and potential covariates, with a threshold of $P<.15$. The standardized effect size of the intervention on PrEP uptake will also be calculated to determine the magnitude of the effect of the intervention.

XSL•FO
RenderX

Objective 2

To evaluate the acceptability of PrEPTECH as a telehealth HIV PrEP care intervention for young cisgender men and transgender women who have sex with men, we will assess participants' likelihood of recommending PrEPTECH; participants' preference for continuing PrEPTECH beyond the study; and other variables assessing the perceived trustworthiness, privacy, helpfulness, and convenience of and comfort with PrEPTECH among those in the intervention group. The percentage of participants expressing agreement or strong agreement with each item will be calculated. The System Usability Scale score will be calculated according to published guidelines to obtain a score out of 100 [45]. In addition, free-text answers to 3 questions about the benefits and drawbacks of PrEPTECH and how participants would characterize the intervention to a friend will be analyzed using a thematic approach.

The feasibility of PrEPTECH as a telehealth HIV PrEP care intervention for young cisgender men and transgender women who have sex with men will be assessed through a review of the study records. Clinical data will be used to assess loss to follow-up at various intermediate points in the intervention (eg, failure to return at-home laboratory kits or complete asynchronous medical intake forms). Records of clinical communications, written prescriptions, and efforts to assist intervention arm participants and to remind them to complete intervention steps will also be reviewed, with the number of contacts required at various stages calculated.

Objective 3

To examine the effects of PrEPTECH on adherence to PrEP, we will examine continuous measures. In each case, a multiple linear regression model will be applied. As described under *Objective 1*, the model will include (1) the intervention group, (2) the number of days between the baseline and follow-up surveys (if applicable), (3) the standard demographics of age at baseline and race and ethnicity at baseline, and (4) a priori demographics and outcome-related covariates that screened positively as candidates for inclusion. Variables will be screened in as described earlier.

The standardized effect size of the intervention on PrEP adherence will also be calculated to determine the magnitude of the effect of the intervention.

Objective 4

To examine the moderators of PrEP use, including HIV risk perception, PrEP attitudes, indications of sexual risk, insurance status, and reason for enrolling in the study, we will create multiple logistic regression models with PrEP uptake at 3 and 6 months as the outcome variable, intervention group as the predictor, and the potential moderator as an interaction term. The moderator will be considered statistically significant if $P<.05$.

A more detailed statistical analysis plan will be agreed upon before final analysis.

Ethical Considerations

This study has been approved by the institutional review board (number 0000283) of ETR Associates and is registered on ClinicalTrials.gov (NCT04902820) [51].

Results

This study was funded in 2019 with institutional review board approval in 2020. The PrEPTECH intervention was built over the next 1.5 years. Study recruitment was launched in February 2022 and completed in September 2022, with 229 participants recruited in total. Data collection was completed in April 2023, and analysis will be complete in September 2023. We expect to publish the results by the end of 2023.

Discussion

Overview

Despite the rapid expansion of telehealth services for PrEP in recent years, formal and rigorous evidence of their effectiveness is sparse. We describe the protocol for an RCT to assess the effectiveness, acceptability, and feasibility of a telehealth HIV PrEP care intervention, PrEPTECH, in increasing PrEP uptake among young cisgender men and transgender women who have sex with men. We hypothesize that participants in the intervention arm will show higher rates of PrEP uptake at both 3 and 6 months than those in the control arm and that PrEPTECH is a feasible and acceptable telehealth HIV PrEP care intervention for young cisgender men and transgender women who have sex with men.

Limitations

One key limitation of this study is that it will rely on self-report data for PrEP uptake and adherence. In self-report, study participants may tend to overestimate their PrEP use. The use of electronic monitoring (such as medication event monitoring systems) and measurement of plasma or blood concentration yield more reliable measures of true PrEP use [52,53]; however, these were cost prohibitive for this study. Because we are using the same measurement approaches across both randomized groups, we do not anticipate differential bias across the study arms.

It is also worth noting that based on previous research from the PrEPTECH pilot study [36], in our original study proposal, we assumed 50% PrEP uptake in the control population and, therefore, calculated a sample size target of 400 participants, anticipating retaining 80% (n=320) of these participants at 180-day follow-up. However, 6 months into data collection, we revised our sample size calculations using the latest data on PrEP uptake in relevant populations and comparable research projects, including ongoing RCTs of digital interventions, to ensure that the participant sample size was adequate yet feasible given the resources required to enroll and retain participants.

Conclusions

The study findings will be disseminated through open-access journals and academic conferences. A summary of the results will also be shared with all community partners, CAB members,

XSL•FO
RenderX

and study participants and published via our agency's website, newsletter, and social media channels. We anticipate that the study results will offer valuable evidence about the effectiveness, acceptability, and feasibility of telehealth HIV PrEP care interventions in this population.

Acknowledgments

The authors thank their current and former ETR colleagues who supported the design and implementation of this study: Bhupendra Sheoran, Laiah Idelson, Jay Lykens, Emma Schlamm, Sarah Han, Ryan Carmody, Jason Burrage, Angela Cesaro, Nixa Sanchez, David Torres-Mendoza, Olivia Stevenson, and Colleen Sargent. They thank and gratefully acknowledge their community partners CAN Community Health, Pridelines, the Unique Women's Coalition, and the San Francisco AIDS Foundation, as well as the members of the PrEPTECH community advisory board for their contribution to the success of this study.

This study was funded by Gilead Sciences (IN-US-276-5489). The funder had no role in study design, data collection, data analysis, or data interpretation. Gilead scientists reviewed the draft of the manuscript and shared their feedback for the consideration of the authors. They did not request final approval of the manuscript.

Data Availability

The data sets generated and analyzed during this study are not publicly available because of participant consent restrictions. However, the data sets are available from the corresponding author upon reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: Obstructive sleep apnea (OSA) is characterized by recurrent, intermittent partial or complete obstruction of the upper respiratory tract during sleep, which negatively affects the patient's daily quality of life (QoL). Middle-aged and older men who smoke and have obesity are most at risk. Even though the use of continuous positive airway pressure (CPAP) during sleep remains the gold standard treatment, various rehabilitation methods, such as exercise, respiratory therapy, myofunctional therapy, and nutritional lifestyle interventions, also appear to be effective. Moreover, it is increasingly recommended to use alternative or additional therapy options in combination with CPAP therapy.

Objective: This study aims to evaluate if a comprehensive home-based, remotely supervised rehabilitation program (tele-RHB), in combination with standard therapy, can improve OSA severity by decreasing the apnea-hypopnea index (AHI); improve objective parameters of polysomnographic, spirometric, anthropometric, and body composition examinations; improve lipid profile, maximal mouth pressure, and functional capacity tests; and enhance the subjective perception of QoL, as well as daytime sleepiness in male participants with moderate to severe OSA. Our hypothesis is that a combination of the tele-RHB program and CPAP therapy will be more effective by improving OSA severity and the abovementioned parameters.

Methods: This randomized controlled trial aims to recruit 50 male participants between the ages of 30 and 60 years with newly diagnosed moderate to severe OSA. Participants will be randomized 1:1, either to a 12-week tele-RHB program along with CPAP therapy or to CPAP therapy alone. After the completion of the intervention, the participants will be invited to complete a 1-year follow-up. The primary outcomes will be the polysomnographic value of AHI, Epworth Sleepiness Scale score, 36-Item Short Form Health Survey (SF-36) score, percentage of body fat, 6-minute walk test distance covered, as well as maximal inspiratory and expiratory mouth pressure values. Secondary outcomes will include polysomnographic values of oxygen desaturation index, supine AHI, total sleep time, average heart rate, mean oxygen saturation, and the percentage of time with oxygen saturation below 90%; anthropometric measurements of neck, waist, and hip circumference; BMI values; forced vital capacity; forced expiratory volume in 1 second; World Health Organization's tool to measure QoL (WHOQOL-BREF) score; and lipid profile values.

Results: Study recruitment began on October 25, 2021, and the estimated study completion date is December 2024. Analyses will be performed to examine whether the combination of the tele-RHB program and CPAP therapy will be more effective in the reduction of OSA severity and improvement of QoL, body composition and circumferences, exercise tolerance, lipid profile, as well as respiratory muscle and lung function, compared to CPAP therapy alone.

XSL•FO
RenderX

Conclusions: The study will evaluate the effect of a comprehensive tele-RHB program on selected parameters mentioned above in male participants. The results of this intervention could help the further development of novel additional therapeutic home-based options for OSA.

Introduction

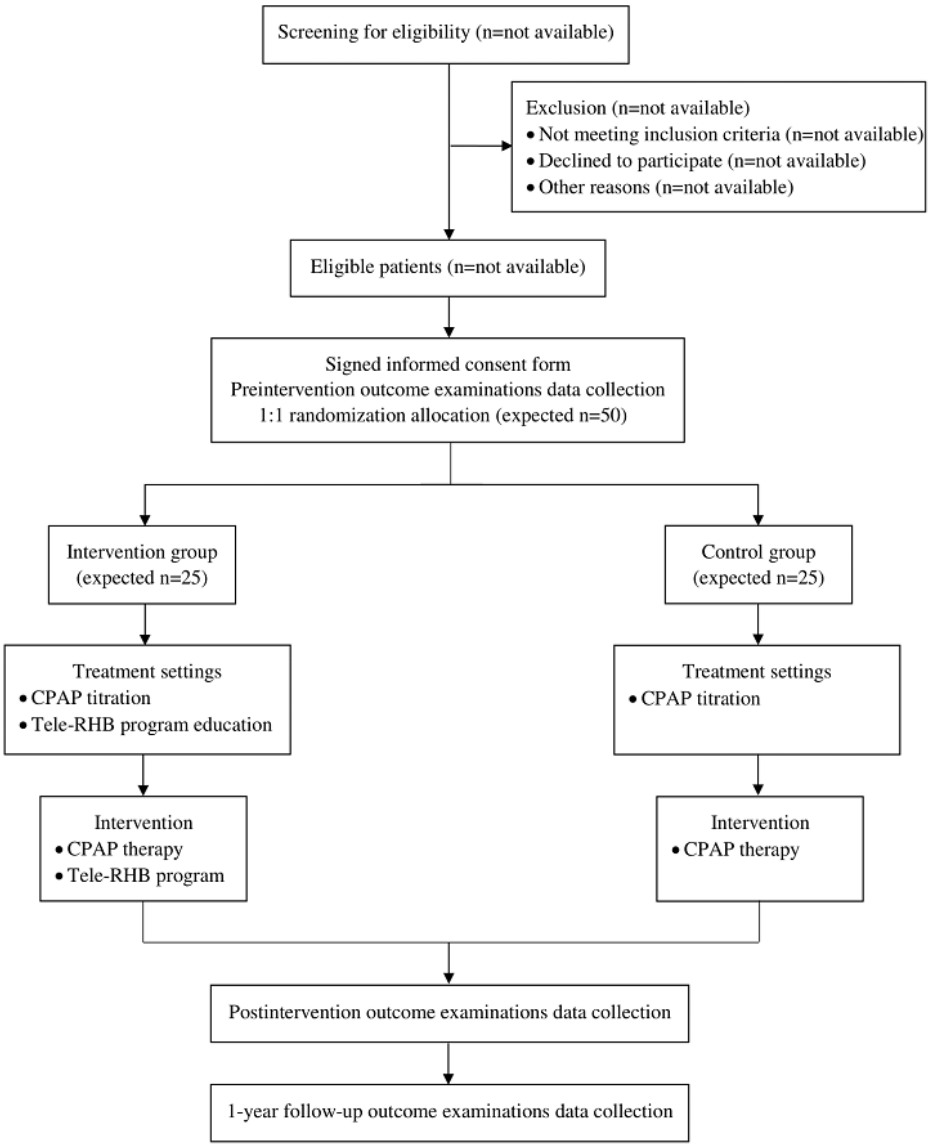
Background

Obstructive sleep apnea (OSA), the most common type of sleep-related breathing disorder [1], is characterized by recurrent, intermittent partial or complete collapse or obstruction of the upper respiratory tract during sleep [2]. Risk factors for its development include male gender, middle and older age, tobacco use, and obesity [3,4]. The high worldwide prevalence and increased risk of morbidity and mortality, especially due to cardiovascular diseases, make OSA a serious health-related global problem [5-7]. In addition, OSA can negatively affect the patient's quality of daily life (QoL) [8]. For instance, excessive daytime sleepiness; impaired cognitive functions; work performance; ability to concentrate; or the occurrence of depression, headaches, snoring, and nocturnal urination; or disharmony in social interactions are particularly limiting [9,10]. The gold-standard treatment for OSA is continuous positive airway pressure (CPAP). The aim of CPAP therapy is to reduce the frequency of apneic and hypopneic pauses during sleep [11,12]. It is increasingly recommended to use alternative or additional therapy options in combination with CPAP [13]. These options include lifestyle and nutrition interventions, physical activity, pharmacotherapy, and behavioral therapy [13]. A recent meta-analysis has shown that a positive effect of exercise therapy, together with a reduction-diet intervention, leads to a significant reduction in the severity of OSA [14]. Based on several meta-analyses, the severity of the disease could be improved either by adjusting to a more nutritional lifestyle [14-16] or by implementing a physical intervention [17,18]. A significant reduction in the apnea-hypopnea index (AHI) was also achieved by training orofacial muscles with oropharyngeal exercises (ie, myofunctional therapy) [19]. According to Camacho et al [19], myofunctional therapy could represent an additional part of OSA therapy. Even the standard treatment representing CPAP therapy or mandibular advancement devices should also include exercise training [20]. A recent meta-analysis also showed a positive effect of respiratory therapy and respiratory muscle training elements in influencing OSA [21]. However, the authors stated that further research is needed to confirm the effect of additional therapeutic options already mentioned [12,15,17-19,21].

Aerobic and respiratory muscles training, oropharyngeal exercises, and regimen recommendations concerning lifestyle, nutrition, and behavior changes are individual components of the comprehensive home-based remotely supervised rehabilitation (tele-RHB) program conceived in this study. No recent literature has been found that deals with the effects of a similar and thus complex remotely supervised intervention. The absence of such an intervention in the context of OSA, as a possible therapeutic option for additional at-home training in combination with CPAP therapy, was the reason for conducting our research.

Objective

This study protocol describes the first-ever randomized controlled trial to solely evaluate the effectiveness of the tele-RHB program among male adults with moderate to severe OSA. This study aims to assess whether completing a comprehensive telerehabilitation program and CPAP therapy positively affects the severity of OSA, QoL, body composition and circumferences, exercise tolerance, lipid profile, and respiratory muscle and lung function. Our hypothesis is that a combination of tele-RHB program and CPAP therapy will be more effective in the reduction of OSA severity and improvement of QoL, body composition, exercise tolerance, lipid profile, as well as respiratory muscle and lung function, compared to CPAP therapy alone.



Methods

Study Design

This study is a 2-arm parallel single-blind randomized controlled trial (registered on ClinicalTrials.gov: NCT04759456), with the per-protocol analysis investigating the effect of the tele-RHB program among 50 male patients with newly diagnosed OSA indicated to CPAP therapy. Patients were recruited from the Sleep Centre of the International Clinical Research Center of St Anne's University Hospital in Brno (FNUSA-ICRC). After providing informed consent, the patients will be randomized to the 12-week tele-RHB program along with CPAP therapy; 25 patients will be randomized to the intervention arm, and 25 will be in the control arm (CPAP therapy alone) in a 1:1 ratio, following the methods described below (Figure 1).

XSL•FO
RenderX

Figure 1. Flow diagram of the study protocol. CPAP: continuous positive airway pressure; tele-RHB: comprehensive home-based remotely supervised rehabilitation.

Ethical Considerations

The study protocol follows the Declaration of Helsinki and received approval from the Ethics Committee of the University Hospital Brno in the Czech Republic (06-090920/EK). Participation in the study will be voluntary, without any compensation or remuneration, and participants will be allowed to withdraw from the study at any moment without providing a reason.

All participants will provide written informed consent. This informed consent form provides details about the purpose of the study, requirements for study participation, randomization process, personal data processing, storage and protection process, and contact information for research team staff. The original informed consent allows the secondary analysis of obtained data without additional consent.

All participants' obtained data will be pseudonymized and deidentified; only an authorized person of the study research team will be able to identify the participants on the basis of personal data. The obtained data will be published anonymously, and no report or publication will contain any data that could lead to the participants' identification.

Inclusion Criteria

Participants will be eligible if they are male patients, aged 30-60 years, have newly diagnosed OSA with an AHI ≥15 episodes per hour, are indicated to CPAP therapy, and are interested in our adjunct tele-RHB program.

Exclusion Criteria

Participants are excluded if they have another type of OSA treatment, chronic corticosteroid therapy or long-term oxygen therapy; they are also excluded if they have at least one of the following health problems: central sleep apnea, chronic obstructive pulmonary disease III or IV, severe pulmonary hypertension, New York Heart Association III or IV, acute coronary syndrome, heart failure, ejection fraction <40%, electrocardiographic-documented heart arrhythmia, severe heart valve disease, cerebrovascular disease, psychiatric disease, and physical disability; in addition, they will be excluded if they do

XSL•FO
RenderX

not cooperate during the intervention or do not follow the tele-RHB program and CPAP therapy protocol.

Recruitment, Enrollment, and Procedure

The patients who meet the inclusion criteria will be recruited from the Sleep Centre of the FNUSA-ICRC. The details of the study overview are shown in Table 1. On the first visit, patients will undergo polysomnography (PSG), blood sampling for lipid profile, and completion of the Epworth Sleepiness Scale (ESS) with a known score. Those who are found to have moderate to severe OSA will be contacted for further intervention alongside the standard CPAP therapy. These patients will be verbally informed and will receive an information leaflet about the ongoing study of the 12-week tele-RHB program. Then, they will complete anthropometric and spirometric examinations, measurements of maximal inspiratory mouth pressure (MIP) and maximal expiratory mouth pressure (MEP) as well as body composition, 6-minute walk test (6MWT), and QoL questionnaires in the Cardiovascular Rehabilitation Clinic at the University Hospital Brno (CRC-UHB). After that, during the interview with a physiotherapist, participants will receive detailed and comprehensive information regarding their possible participation in the study. Then, potential participants will be given at least 24 hours to decide before signing the informed consent.

On the second visit, patients who agreed to participate in the study will sign the informed consent form and will be then randomized 1:1 to the intervention or control group.

On the third visit, participants of both groups will undergo individual titration of CPAP therapy at the Sleep Centre of the FNUSA-ICRC. The intervention group will subsequently receive education about the tele-RHB program, along with theoretical and practical instruction on its individual components in the CRC-UHB. Participants of the intervention group will also receive a training brochure containing information needed for the tele-RHB program with remote supervision by a physiotherapist.

After the completion of the 12-week tele-RHB program, on the fourth visit, participants of both groups will undergo the same examinations and measurements as those conducted at the baseline, at the Sleep Centre of the FNUSA-ICRC and in the CRC-UHB.

After 1 year from the 12-week tele-RHB program's completion, on the fifth visit, participants of both groups will undergo the same examinations and measurements as they did at the baseline in both health facilities.

Randomization

Participants will be randomized 1:1 to the intervention and control group by a noninvestigating member of the research group in the CRC-UHB with the help of the website "randomization.com" [22] into 6 blocks of 8 and 1 block of 2 participants. Participants and caregivers will be instructed not to comment on their ongoing therapy. The outcome assessor will be blinded. Physiotherapists who educate the intervention group participants about the tele-RHB program and who carry out regular teleconsultations during this program are the only unblinded members of the research group.

Measures

Measurements and Examinations

All participants will take part in baseline, postintervention, and follow-up examinations. PSG will be performed by trained medical staff in accordance with recent guidelines [23]. The variables extracted from PSG will be AHI, oxygen desaturation index, supine AHI, total sleep time, average heart rate, mean oxygen saturation (SpO_2), and the percentage of time with SpO_2 saturation below 90%. PSG will be performed with Grael 4K PSG:EEG (Compumedics Limited). All of the above-mentioned data will be collected without the CPAP device in use.

Standardized questionnaires, including the 36-item Short Form Health Survey (SF-36), the World Health Organization's tool to assess QoL (WHOQOL-BREF) [24], and ESS, will be filled in by all participants under the supervision of a medical specialist. The ESS questionnaire will be a tool for the participant's subjective daytime sleepiness, and the SF-36 and WHOQOL-BREF questionnaires will assess the subjective perception of QoL.

Participants will undergo a bioelectrical impedance examination with InBody 370S (BridgePower Corp) to evaluate changes in body composition performed by trained medical personnel. Data on the participant's sex, age, height, weight, and BMI will also be recorded. The monitored parameter will be the value of the percentage of body fat.

Participants will undergo a standardized 6MWT in accordance with American Thoracic Society guidelines to objectively assess their functional capacity by trained medical personnel [25]. The monitored parameter will be the distance in meters, which the participants will be able to walk in 6 minutes.

MIP and MEP will be measured with MicroRPM Respiratory Pressure Meter (Micro Direct Inc) and will be performed by a medical specialist based on recent recommendations for testing respiratory muscles [26,27].

Anthropometric parameters of the neck, waist, and hip circumference will be measured with a tape measure by trained medical staff. The current BMI value will also be calculated from actual body height and weight.

All participants undergo a standardized spirometric examination performed by a medical specialist with Spirobank II Basic (Medical International Research) in accordance with recommended procedures to objectively evaluate their lung function [28]. The parameters of forced vital capacity and forced expiratory volume in 1 second will be monitored.

All participants' CPAP devices will be regularly remotely monitored by a Sleep Centre medical doctor to track CPAP compliance and adherence to treatment during their sleep-at-home conditions. Participants will use one of the following devices: AirSense 10 AutoSet (ResMed Inc) or Prisma 20A Auto CPAP (Löwenstein Medical Technology GmbH + Co. KG).

Participants will have laboratory blood tests with the intention of finding out the current values of their lipid profile. Values of the total cholesterol, triacylglycerols, high-density lipoprotein (HDL) cholesterol, low-density lipoproteins (LDL) cholesterol, and non-HDL cholesterol will be detected.

Primary Outcomes

Primary outcomes include changes from baseline in AHI, obtained from PSG; ESS score; SF-36 score; percentage of body fat; 6MWT distance; as well as MIP and MEP values.

Secondary Outcomes

Secondary outcomes include changes from baseline in oxygen desaturation index, supine AHI, total sleep time, average heart rate, mean SpO_2, the percentage of time with oxygen saturation below 90%, obtained from PSG; neck, waist, and hip circumference; BMI values; forced vital capacity and forced expiratory volume in 1 second values; WHOQOL-BREF score; CPAP adherence; as well as total cholesterol, triacylglycerols, HDL cholesterol, LDL cholesterol, and non-HDL cholesterol values.

Intervention Group

Participants of the intervention group will undergo home-based 12-week tele-RHB program with regular teleconsultations via phone calls and emails at least 1-2 times a week with a physiotherapist. Teleconsultations will include telemonitoring and analysis of previously completed training sessions and the current course of the program; additionally, telecoaching for upcoming training sessions and motivation to continue the program will also be provided. Participants will also record the details of their completed training sessions during the intervention in a training diary and will regularly send it to the physiotherapist for evaluation. As previously stated, participants will receive a training brochure with a detailed description of the tele-RHB program and its components (Multimedia Appendix 1). Tele-RHB program will include nutrition, health-related lifestyle and behavior change recommendations, and a minimum of 5 times a week—each lasting 30 minutes—of moderate-intensity aerobic training; in addition, there will be 10 minutes of inspiratory and 10 minutes of expiratory muscle training with breathing devices (Threshold IMT and Threshold PEP) and 10 minutes of oropharyngeal exercise along with individually titrated CPAP therapy. After the completion of the 12-week tele-RHB program, participants should be motivated to continue performing this comprehensive rehabilitation program in home conditions during the 1-year follow-up, but without the regular remote supervision by a physiotherapist. This tele-RHB program was developed based on previous

XSL•FO
RenderX

research or guideline recommendations for patients with OSA or cardiovascular diseases [6,29-36].

Control Group

Participants of the control group will undergo individually titrated CPAP therapy alone, throughout 12 weeks.

Data Analysis

Statistical Analysis

TIBCO Statistica (TIBCO Software Inc) will be used for statistical analysis of the obtained data. Statistical analysis will be performed by a person blinded to the experimental conditions. The Shapiro-Wilk test will be used to assess the normality of the data obtained. To compare participants' baseline and postintervention obtained data within the same group, a paired 2-tailed *t* test will be used for statistical analysis. When comparing the baseline and postintervention data of the participants between both groups, an unpaired *t* test will be used. The level of statistical significance will be set as $P<.05$. The acquired data will be securely collected on an encrypted external hard drive.

Sample Size

A power analysis was performed based on a previous study by Hupin et al [37], and the expected improvement in AHI was estimated to be approximately 8 (SD 10) episodes per hour at the end of the program versus the baseline. The number of participants in each of the two groups (n=25), necessary to achieve such an effect size, was calculated by statistical analysis at 80% statistical power with $\alpha=.05$.

Results

Study recruitment began on October 25, 2021, and the estimated study completion date is December 2024. Analyses will be performed to examine whether the combination of the tele-RHB program and CPAP therapy will be more effective in the reduction of OSA severity and improvement of QoL, body composition and circumferences, exercise tolerance, lipid profile, as well as respiratory muscle and lung function, compared to CPAP therapy alone.

Discussion

OSA is a severe global problem [6,7,38], negatively affecting the QoL and its various aspects [8,38]. Furthermore, although CPAP therapy is currently considered the gold standard of treatment [38], adherence to its long-term use is low [39]. According to Aardoom et al [40], about 30% to 80% of patients with OSA are nonadherent to their CPAP therapy. However, CPAP adherence and therapy compliance can be improved by a telemedicine-based approach (ie, eHealth) containing regular teleconsultations via video calls [41]. According to Hnatiak et al's [42] opinion, an additional therapy consisting of the implementation of the tele-RHB program could also improve the severity of OSA or even help with adherence to CPAP therapy. In addition, our comprehensive program, consisting of effective elements of rehabilitation, includes aerobic exercise training [17,18], oropharyngeal training [19], and respiratory muscle training [21], along with recommendations focusing on nutrition, lifestyle, and behavior changes [14-16].

The development of this tele-RHB program for the examined population was based on currently available knowledge. The comprehensive tele-RHB program was designed according to information about effective additional treatment options for OSA mentioned earlier. The study included only middle-aged and older male adults due to the risk of more frequent OSA occurrences in these individuals [3,4]. Thus, significant risk factors for the development of OSA also include middle [4] or older age, smoking [3], and obesity [3,4].

A possible limitation may be the lack of direct physiotherapist supervision during the remotely monitored intervention in a home-based setting. According to Hnatiak et al [42], regular communication of participants with physiotherapists during the intervention should help the standard course of the intervention. Thus, we assume that the completion of this intervention will produce interesting results that will help the further development of additional therapeutic options for OSA.

Our study intends to determine whether the completion of a tele-RHB program positively affects OSA in middle-aged and older men, and therefore, provide evidence for a possible recommendation of this tele-RHB program as an effective adjunctive treatment to CPAP therapy in male patients. The study will focus on the expected improvement in OSA severity, QoL, body composition, exercise tolerance, lipid profile, as well as respiratory muscles and lung function, resulting from the completed intervention.

Abstract

Background: A common yet untested assumption of cognitive training in children is that activities should be adaptive, with difficulty adjusted to the individual's performance in order to maximize improvements on untrained tasks (known as transfer). Working memory training provides the ideal testbed to systematically examine this assumption as it is one of the most widely studied domains in the cognitive training literature, and is critical for children's learning, including following instructions and reasoning.

Objective: This trial aimed to examine children's outcomes of working memory training using adaptive, self-select (child selects difficulty level), and stepwise (difficulty level increases incrementally) approaches to setting the difficulty of training activities compared to an active control condition immediately and 6-month postintervention. While the aim is exploratory, we hypothesized that children allocated to a working memory training condition would show greater improvements: (1) on near transfer measures compared to intermediate and far transfer measures and (2) immediately postintervention compared to 6-month postintervention.

Methods: This double-blinded, active-controlled, parallel-group randomized trial aimed to recruit 128 children aged 7 to 11 years from 1 metropolitan primary school in Melbourne, Australia. Following baseline testing, children were randomized into 1 of 4 conditions: adaptive, self-select, or stepwise working memory training, or active control. An experimental intervention embedded in Minecraft was developed for teachers to deliver in class over 2 consecutive weeks (10 × 20-minute sessions). The working memory training comprised 2 training activities with processing demands similar to daily activities: backward span and following instructions. The control comprised creative activities. Pre- and postintervention, children completed a set of working memory tests (near and intermediate transfer) and the Raven's Standard Progressive Matrices (far transfer) to determine training outcomes, as well as motivation questionnaires to determine if motivations toward learning and the intervention were similar across conditions. Caregivers completed the ADHD-Rating Scale-5 to measure their child's attention (far transfer). Statistical analysis will include traditional null hypothesis significance testing and Bayesian methods to quantify evidence for both the null and alternative hypotheses.

Results: Data collection concluded in December 2022. Data are currently being processed and analyzed.

Conclusions: This trial will determine whether the adaptive approach to setting the difficulty of training activities maximizes cognitive training outcomes for children. This trial has several strengths: it adopts best practices for cognitive training studies

(design, methods, and analysis plan); uses a range of measures to detect discrete levels of transfer; has a 6-month postintervention assessment; is appropriately powered; and uses an experimental working memory training intervention based on our current understanding of the cognitive mechanisms of training. Findings will inform future research and design of cognitive training interventions and highlight the value of the evidence-based principles of cognitive training.

Introduction

Background

Cognitive training interventions targeting core cognitive abilities such as working memory, attention, and problem-solving are in demand. Supporters of cognitive training explain that repeated practice on an activity will lead to performance gains that can transfer to improved performance on untrained tasks, an outcome known as transfer [1-4]. Transfer is the ultimate goal of cognitive training, and this intervention method is therefore of considerable interest to practitioners in health and education sectors seeking to prevent and ameliorate the disadvantage associated with low cognitive abilities, including inattention and learning related challenges (eg, psychologists, psychiatrists, and other mental health professionals; speech and language therapists; pediatricians; and teachers, special education needs coordinators, and specialist teachers). Transfer has been described on a continuum, ranging from near transfer to far transfer. *Near transfer* refers to improvement on measures structurally similar to the training activity, for example, performance on a measure using the same paradigm as the training activity but different stimulus, mode of presentation, or response modality. *Far transfer* focuses on performances on measures beyond the trained cognitive domain that rely on the trained skill. More recently, researchers have also been examining *intermediate transfer*, which describes improvement on measures that assess the same cognitive domain but use a different paradigm to the training activity. Working memory training benefits typically diminish with time, and with decreasing similarities between the training activity and outcome measure, providing consistent evidence for near transfer, less evidence for intermediate transfer, and little convincing evidence for far transfer [5-8].

A key design feature of cognitive training that is assumed to maximize training outcomes is *adaptivity* of the training activities. In this approach, the difficulty of the training activity is adjusted to the trainee's performance, thought to sufficiently challenge the trainee's cognitive limits to induce plasticity [9-12]. Indeed, most commercially available cognitive training programs are adaptive. Initial support for adaptive cognitive training in children came from studies demonstrating greater training effects and transfer following adaptive training, in which training difficulty varied, compared to a nonadaptive control, in which training difficulty was fixed at a low level [11,13-16]. This design is problematic for evaluating the adaptive method, with adaptivity and difficulty of the training activities confounded: children in the adaptive condition were exposed to varying difficulty levels, but those in the nonadaptive condition only experienced a single difficulty level. To address this important limitation, von Bastian and Eschen [7] systematically examined in adults the outcomes of working memory training with difficulty of the training activities being adaptive, self-selected, or randomized compared to an active control. The adults in the adaptive condition outperformed those in the active control condition on the training activity, but this was also the finding for the self-selected and randomized conditions. While near transfer effects were not examined, none of the training conditions showed improvements on intermediate or far transfer tests. The authors postulated that varying the difficulty level of the training activities may be sufficient to induce training effects, and that training and transfer effects may not be modulated by a specific approach to setting the difficulty of a training activity. These findings question the common assumption that an adaptive approach is superior for maximizing cognitive training outcomes.

Working memory training provides the ideal testbed to systematically examine the assumption that the adaptive approach maximizes cognitive training outcomes. It is one of the most widely studied domains in the cognitive training literature [17,18]. Working memory is a mental workspace capable of holding and processing information for brief periods in the course of ongoing cognitive activity [19]. This ability is critical for children's learning as it facilitates a host of complex cognitive activities such as comprehension, reasoning, and problem-solving [20]. Indeed, low working memory is commonly associated with poor scholastic attainments [20,21]. Meta-analyses examining near transfer effects following cognitive training reveal the highest effect sizes for training targeting working memory (g=0.50) than either inhibitory control (g=0.24) or cognitive flexibility (g=0.37) [6,17]. Evidence from high-quality trials also demonstrates near transfer effects of working memory training programs in children, such as Cogmed [15,22] and Braintwister [16,23]. However, there is less support for intermediate transfer, and the evidence for far transfer is negligible when methodological issues, such as the lack of an active control group, are taken into account [6,8,17,22,24-26].

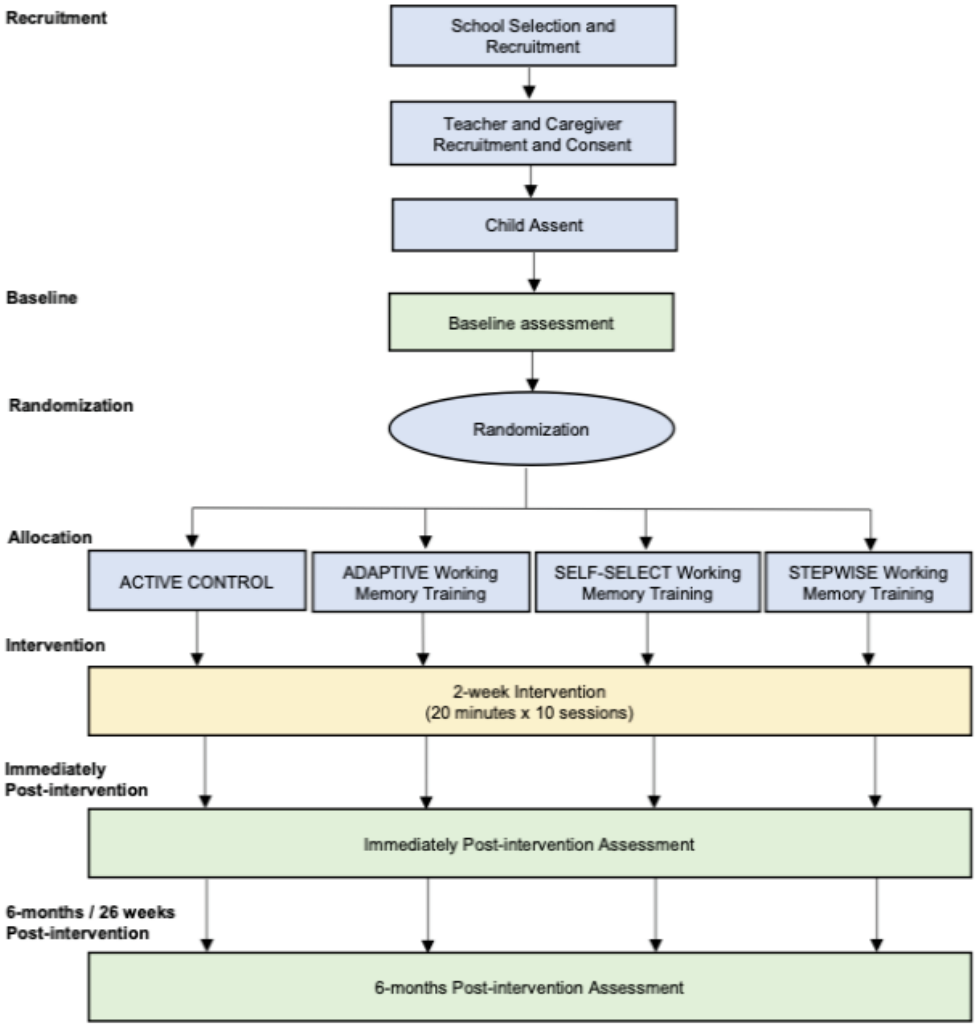
Aims and Hypotheses

This randomized controlled trial assessed the common assumption that cognitive training in children should be adaptive. The trial aimed to examine children's outcomes of working memory training using adaptive, self-select, and stepwise approaches to setting the the difficulty of training activities compared to an active control condition immediately and 6-month postintervention. Although the aim is exploratory, we hypothesized that children allocated to the working memory training conditions would show greater improvements: (1) on near transfer compared to intermediate and far transfer measures and (2) immediately postintervention compared to 6-month postintervention.

Methods



Ethics Approval

This trial was approved by the Monash University Human Research Ethics Committee (24305) in January 2021 and Melbourne Archdiocese Catholic Schools (1066) in February 2021. It was registered with the Australian New Zealand Clinical Trials Registry (ACTRN12621000990820) on July 28, 2021. We note that due to time constraints associated with COVID-19 lockdowns in Melbourne, Australia, the first participant was enrolled in the trial on July 13, 2021, when approval from the Australian New Zealand Clinical Trials Registry was pending, resulting in the trial's retrospective registration status.

Design and Blinding

This double-blinded, active-controlled, parallel-group, randomized superiority trial is part of the larger Common Assumptions of Cognitive Training (COMET) study. Researchers involved in child assessments were blinded to the child's intervention allocation and past assessment results. Teachers, caregivers, and children were informed that the study was examining children's thinking skills, and they were unaware of the different conditions. Thus, participants were unaware that this was a randomized controlled trial with different conditions, thereby preserving blinding. This trial was conducted and will be reported according to CONSORT (Consolidated Standards of Reporting Trials) guidelines. Figure 1 summarizes the trial design. This trial was expected to run for 15 months, with school selection and recruitment taking 3 months, and consent, data collection, and intervention carried out over 12 months.

Figure 1. Trial design.

XSL•FO
RenderX

Setting

The research was conducted in a primary school in metropolitan Melbourne in the state of Victoria (population of 6.6 million in 2022), Australia [27].

School Recruitment

Eligible primary schools were within 20 km of the Monash University Clayton campus (for practical reasons) and had at least 197 children in grades 2 to 5 (to achieve the required sample size based on power calculations). Schools were randomly invited until one agreed to participate.

Participant Recruitment

All children in grades 2 to 5 (7 to 11 years) at the participating school were invited to participate in this trial. The grade 2 to 5 teachers distributed the caregiver explanatory statement and caregiver consent form for the children to take home to their caregivers. Caregivers were asked to provide consent for completing questionnaires about themselves and their child, and for their child to participate in cognitive testing. The children returned the completed consent forms to their teachers to pass on to the research team. Child assent was obtained during the baseline child testing session. Consent was sought from the teachers for their involvement in obtaining caregiver consent.

Eligibility Criteria

Children were included if they had caregiver consent, and provided written assent to participate. They were excluded if they had caregiver-reported vision impairment that cannot be corrected by glasses, including color vision deficiency, hearing impairment that cannot be corrected by a hearing aid, fine motor impairment, or intellectual disability that would prevent participation in the intervention.

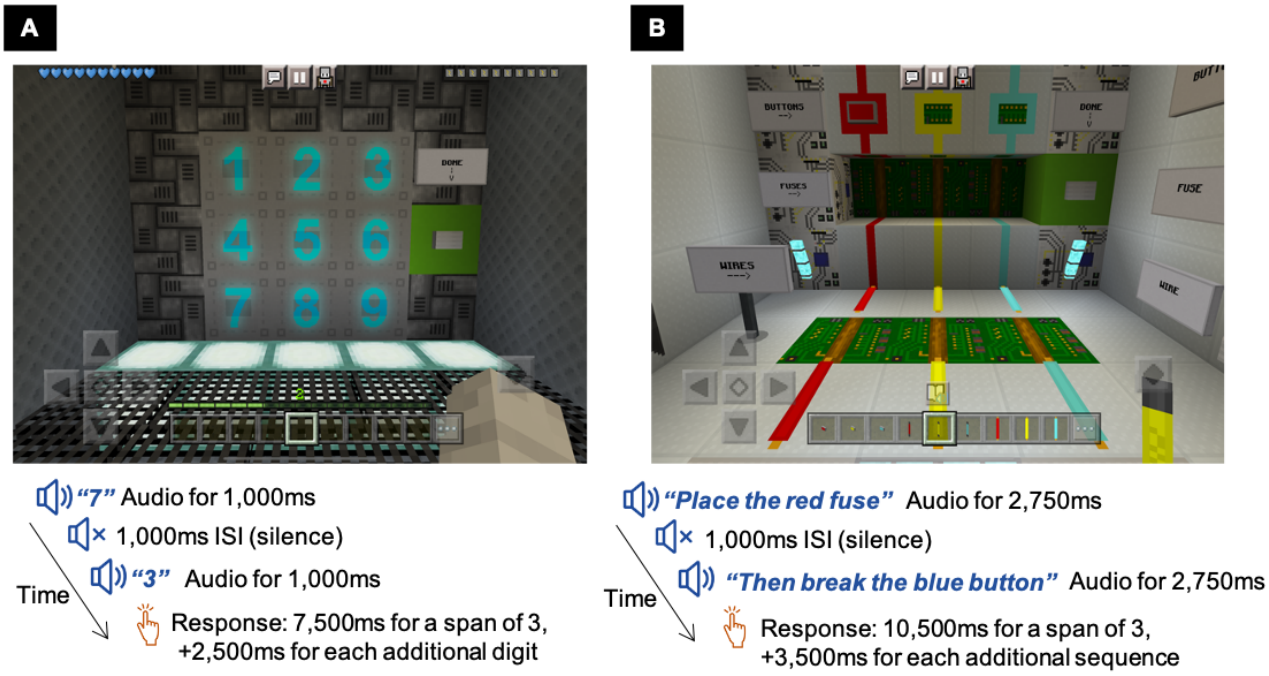
Randomization

Following baseline testing, children were randomized to 1 of the 4 number-coded conditions (adaptive, self-select, stepwise working memory training, or active control) using a randomization scheme generated in advance and set up in Research Electronic Data Capture (REDCap) hosted at Monash University by the trial statistician (JFW) who was not involved in data collection. Specifically, block sizes of variable size (4 or 8) were used to assure allocation concealment and preguessing of the allocation sequence at the end of each block. Randomization was stratified by age at baseline: 7 to 8 years, 9 to 10 years, and 11 years.

Intervention

Overview

The Brain Space Program intervention was designed and developed by our team in Minecraft Education (Mojang Studios and Xbox Game Studios) for the COMET project (not an official Minecraft product, not approved by or associated with Mojang), and in this trial includes 3 working memory training conditions (adaptive, self-select, and stepwise) and an active control condition. All conditions were in the same Minecraft environment and had the same motivating features, including a “space mission” narrative for each session and the acquisition of experience points that could be used at the end of each training session for creative activities.



The teacher delivered the intervention in class. Children completed a session lasting 20 minutes on each school day for 2 consecutive weeks (total 10 sessions, total dose 200 minutes). Children individually performed the intervention on an iPad with headphones (provided by the researchers) to reduce distraction. To account for missed sessions (eg, child absences, school events, and public holidays), children were allowed to complete up to 3 training sessions per day during the intervention period. Researchers were in the classroom during the intervention period to ensure protocol adherence and compliance.

Working Memory Training Conditions

The working memory training consisted of 2 activities that required the child to temporarily store and manipulate verbally presented information: a backward span activity and a following instructions activity (see Figure 2). These paradigms were selected based on the current understanding of the cognitive mechanisms of training. Importantly, first, processing demands are sufficiently unfamiliar so the child is required to generate novel cognitive routines (strategies) that improve efficiency in performance and can be applied to new activities with sufficient overlap in task structure [5,6]. Second, processing demands overlap with daily activities, such as following teacher directions, leading to potential practical benefits [2,28].

XSL•FO
RenderX

Figure 2. The working memory training activities: (A) backward span and (B) following instructions. ms = milliseconds, ISI = Interstimulus Interval.

In the backward span training activity, a series of digits were presented auditorily, and the child had to remember and immediately recall in reverse order the sequence of items by tapping the digits on the iPad screen. The difficulty level was manipulated by increasing the number of digits to be recalled. The following instructions training activity is based on a classroom analog test of working memory developed by Gathercole et al [29]. In this training activity, the child was introduced to 3 objects, each object comes in 3 colors, and 2 actions that require different tapping responses on the iPad screen. The child had to remember and immediately implement an action-color-object sequence (eg, break the red wire, then place the blue button, reflecting a span of 2) by using the relevant tapping response on the screen of the iPad with the corresponding color-objects. Difficulty level was manipulated by increasing the number of action-color-objects in the sequence the child has to perform. Each activity comprised 5 blocks of trials per session, and each block had 4 trials of a span level (per session: total 20 backward span trials, then 20 following instructions trials).

In this trial, there were three different working memory training conditions, each with a different approach to adjusting the difficulty level of the training activities: (1) *adaptive* condition, the difficulty level adapted to the child's performance during each training session on a block-by-block basis for the first 4 blocks (adapted between block 1 to 2, block 2 to 3, and block 3 to 4, and block 5 retained the same difficulty as block 4) within the training sessions for each activity; (2) *self-select* condition, the child decided at the end of each session if they would like a training activity to be easier, the same, or more difficult in the next session; and (3) *stepwise* condition, the difficulty level increased incrementally across sessions and this progression was predetermined and stratified by age based on current understanding of the development of children's working memory: 7 years, 8 to 9 years, and 10 to 11 years [30].

Active Control Condition

The active control involved the child completing a series of creative building and discovery activities each session. The activities were embedded in the same environment as the working memory training activities, and therefore the condition can be considered a placebo [1]. The activities were selected based on a review of activities available on the Minecraft Education website for school teachers to use with children aged 7 to 11 years in the classroom that do not require working memory [31].

Measures

Overview

Table 1 summarizes the measures, respondents, administration time points, as well as the primary outcomes of this trial.

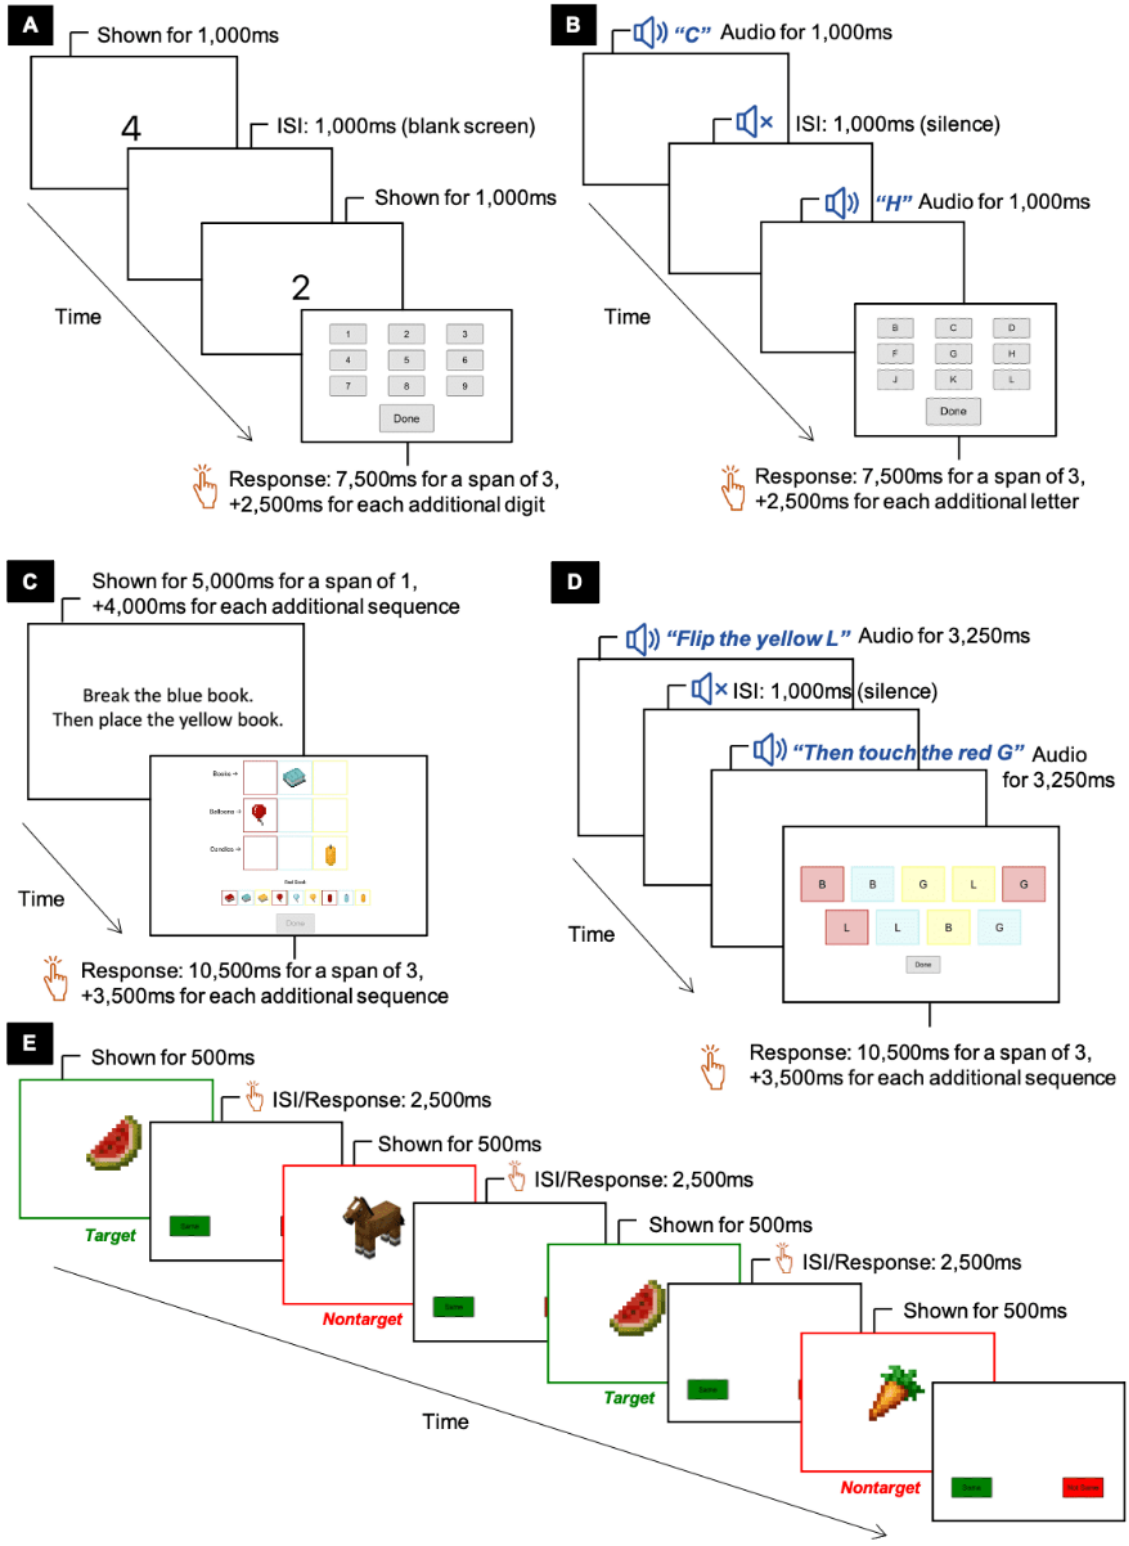
[c]ADHD-5-RS: ADHD-Rating Scale-5, home version.

Child Characteristics

Caregivers completed a participant information questionnaire that collected demographic information about their child, including their child's sex, developmental and medical history, and family socioeconomic risk factors [32].

Training Outcomes

Near Transfer



A set of four experimental working memory tests that have the same paradigms as the training activities, but different stimulus features, provided measures of near transfer (Table 2, Figures 3A to 3D): (1) *backward span* tests, digits and letters versions, and (2) *following instructions* tests, objects and letters versions [6]. For each test, there were 4 trials per block of a span level. Responses were self-paced with a cut-off duration for response time adjusted per span level. The span level increased by 1 if the child scored 3 or more out of the 4 trials in that block (≥75% accuracy); otherwise, the test ended. The tests, including instructions, practice items, and corrective feedback, were delivered via an iPad-based web app developed for this research. These multiple near transfer tests provide the opportunity to detect discrete levels of transfer by minimizing confounders associated with training effects [4].

Table 2. Comparison of the working memory training activities and near transfer tests. Responses provided on an iPad by tapping on-screen buttons.

Activity or test	Stimulus type	Stimulus, presentation	Response modality (response layout)
Backward span			
Training activity	Digits	Auditory	Motor (3×3 keypad)
Near transfer test	Digits	Visual	Motor (3×3 keypad)
Near transfer test	Letters	Auditory	Motor (3×3 keypad)
Following instructions			
Training activity	Items: space objects; actions: place, break	Auditory	Motor (3×3 grid)
Near transfer test	Items: common everyday objects and animals; actions: place, break	Visual	Motor (3×3 grid)
Near transfer test	Items: letter cards; actions: touch, flip	Auditory	Motor (2-row keyboard)

XSL•FO

Figure 3. The experimental working memory transfer tests delivered on an iPad: (A) backward span digits, (B) backward span letters, (C) following instructions objects, (D) following instructions letters, (E) 2-back objects. (A) to (D) depict each test at a span level of 2. ms = milliseconds, ISI = Interstimulus Interval.

Intermediate Transfer

An experimental n-back test measured intermediate transfer (Figure 3E). In this *2-back* test, the child was presented with a continuous stream of 22 common objects and animals (eg, carrot, flower, and cat; 6 targets and 16 nontargets), and the child had to decide for each object if it matched the object that was presented 2 items ago [5,33,34]. The child responded by tapping the "same" or "not same" on-screen button within the time limit. This test was delivered via the same iPad-based web app as the near transfer tests.

Far Transfer

Far transfer measures assessed children's reasoning and attention. Children's reasoning ability was measured using the Raven's Standard Progressive Matrices (SPM), standardized

XSL•FO
RenderX

for individuals aged 6.5 to 80 years [35,36]. The Raven's SPM contains 5 sets (A to E) of 12 items. Each item has a geometric design with a missing piece on the bottom right. The child had to select the correct figure that would complete the overall geometric design vertically and horizontally from 6 or 8 possible options. The items increased in difficulty within sets and across sets. Children were allowed as much time as they needed to complete the task. The Raven's SPM has excellent split half-reliability and test-retest reliability (>0.80), and its concurrent validity is well established [37]. There is a moderately strong correlation (0.50 to 0.70) between SPM and conventional intelligence tests such as Stanford-Binet and Wechsler's tests [38].

Children's inattention and hyperactivity-impulsivity behaviors were assessed using the caregiver-rated ADHD-Rating Scale-5 (ADHD-RS-5, home version), standardized for children and adolescents aged 5 to 17 years [39]. The ADHD-RS-5 has an inattention subscale (9 items) and a hyperactivity-impulsivity subscale (9 items) that closely follow the Diagnostic and Statistical Manual of Mental Disorders (Fifth Edition) criteria for attention-deficit/hyperactivity disorder. Caregivers rated their child's behaviors at home based on the previous 6 months, and at the immediate postintervention time point based on the past 2 weeks to assess any changes observed during the intervention period. Internal consistency of the symptom subscales (0.61 to 0.83) and concurrent validity were established by high correlations (>0.78) with respective subscales from the Connors Parent Rating Scale [39].

Child Motivation

Overview

Intrinsic motivation, an internal drive to seek out new and challenging experiences to learn and expand one's abilities [40], has been associated with performances on cognitive training activities and outcomes in children [41-43] and adults [44]. We measured aspects of children's motivation to rule out the potential influence of differences in expectations between the working memory training conditions and the active control [1,45].

Motivation Toward Classroom Activities

Children's motivation toward typical classroom activities was measured using the Intrinsic Motivation Scale (IMS) [46]. The IMS consists of 3 subscales: challenge (6 items; eg, I like hard work because it's difficult), curiosity (6 items; eg, I ask questions in class because I want to learn new things), and independent mastery (5 items; eg, I like to try to figure things out at school on my own). The child responded using a 3-point Likert scale (yes: 3 points; sometimes: 2 points; no: 1 point). The IMS has very high internal consistency (0.90) and high test-retest reliability with a 6-week interval (0.74) [46].

Motivation Toward the Intervention

Children's motivations toward the intervention were measured using a modified Intrinsic Motivation Inventory (IMI) [47], which has been used in child cognitive training studies [41-43]. This modified IMI consists of 4 subscales: interest or enjoyment (7 items; eg, it was fun to do), perceived competence (6 items; eg, I think I am pretty good at the training), effort or importance (5 items; eg, I put a lot of effort into it), and value or usefulness (4 items; eg, I think the training could help me). Identical to the IMS, the child responded on a 3-point Likert scale. This modified IMI has been used in a previous randomized control trial of working memory training with similar-aged children and has high internal consistency (≥0.74) [41].

Data Management and Confidentiality

Personal and trial data were collected and managed using REDCap electronic data capture tools hosted and managed by Helix (Monash University) [48,49]. Personal data required to disseminate the caregiver questionnaires were held securely and will not be used for any other purpose. Given the sample size, the trial's timeframe, and the minimal risks associated with participation, there is no data monitoring committee.

Procedures

Children participated in testing sessions, and caregivers completed behavioral questionnaires at baseline, immediately, and 6 months postintervention. The baseline and immediately postintervention measures were completed 1 week before and after the intervention, respectively. The 6-month postintervention measures were completed approximately 26 weeks postintervention (±8 weeks due to school term breaks).

Children were tested in small groups of 6 to 8. The group child testing sessions were led by a doctoral provisional psychologist and conducted in a quiet room on the primary school campus. The test order and administration protocol was the same at each time point. Children first completed the working memory measures on an iPad with headphones to reduce distraction, the Raven's SPM, and then motivation questionnaires. General task instructions were delivered to the children as a group. Children were encouraged to ask clarifying questions, and the researcher responded with standardized additional instructions and ensured the child understood how to complete the task before proceeding with testing.

Power Calculations and Sample Size

Calculations in G*Power (effect size f^2=0.07; 80% power; α=.05) [50,51] indicated a sample size of 29 children per condition would be required to detect a small to moderate effect of each working memory training condition (adaptive, self-select, and stepwise) compared to the active control on the near transfer measures immediately postintervention (primary outcome). This effect size was based on previous research, which indicates working memory training programs produce a small to moderate effect compared to a control condition on near transfer measures [6,17]. The target sample size was increased to 32 children per condition to account for 10% attrition [22]. Our previous school-based trial of a working memory training program had a 65% child recruitment rate [22]. Thus, to achieve our target sample size, the participating primary school had to have at least 197 children enrolled in grades 2 to 5.

Statistical Analysis

Primary analyses will be intention to treat (ITT) with sensitivity analyses only with children who completed the allocated intervention. Primary analyses will be separate linear regressions

XSL•FO
RenderX

for each primary outcome at the primary end point (immediately postintervention) as the dependent variable, the outcome at baseline and the stratification factor (age) as covariates, and conditions (dummy coded with the active control as the reference) as the independent variables. Statistical significance will be set at α=.05 (2-tailed). If outcomes do not meet the normality assumption, a nonparametric bootstrap will be used. Effect sizes and 95% CI will be reported to demonstrate the magnitude of differences in outcomes between each training condition relative to the active control. Bayesian methods will be used to quantify the strength of evidence in favor of the null hypothesis and the alternative hypothesis. Interpretation of results will consider the strength of effects and *P* values. The same analytic approach will be applied to secondary outcomes and to both primary and secondary outcomes at the 6-month postintervention time point.

Results

This trial was supported by internal research funding from the School of Psychological Sciences and the Turner Institute for Brain and Mental Health at Monash University, awarded in December 2019. Data collection was attempted in July 2021 but was ceased shortly after due to COVID-19 lockdowns in Melbourne. Data collection occurred from February 2022 to December 2022. Data are currently being processed and analyzed. It is anticipated that the results of this trial will be published by 2024.

Discussion

The potential transfer of skills learned from a cognitive training intervention to other untrained activities is of interest to practitioners in health and education sectors, and families. Cognitive training interventions are intensive and typically comprise adaptive training activities, yet whether this approach to setting the difficulty of training activities maximizes transfer effects has only been systematically evaluated once in adults [7]. This trial aims to examine outcomes of working memory training using adaptive, self-select, and stepwise approaches to setting the difficulty level of training activities compared to an active control condition. This will be the first trial to systematically examine methods of setting the difficulty of working memory training activities in children. Our design includes evaluation of nonadaptive approaches (self-select and stepwise) and thereby eliminates task difficulty as a confounder, which was an important limitation of initial studies in the field.

This trial has important strengths. The trial design, methods, and analysis plan are in line with best-practice standards for cognitive training trials [1]. The trial was randomized, participants and assessors were blinded, and an active control condition was used. The active control condition (instead of a passive or no-contact control) was designed to be believable as an intervention, indistinguishable from the working memory training conditions in terms of the environment and motivating features, and thus was designed to ensure children experience a similar level of engagement, and experimenter and teacher attention to children allocated to the working memory training conditions. The set of outcome measures was designed to detect discrete levels of near transfer by minimizing confounders associated with training effects [4], and intermediate and far transfer effects are measured too. Training outcomes were assessed immediately postintervention and again at 6-month postintervention to determine any persisting training benefits. The trial is sufficiently powered to detect differences between the working memory training conditions and the active control condition. Importantly, our novel experimental working memory training interventions are designed specifically for this research and reflect the current understanding of the cognitive mechanisms of training: the processing demands of the training activities are (1) sufficiently unfamiliar such that the child needs to generate novel cognitive routines to do well, and the routines can then be applied to new activities that are similar but untrained; and (2) overlap with daily activities, such as following teacher directions, which overlap with daily activities. This is the first time the following instructions paradigm has been used as a working memory training activity. The nonadaptive approaches used in this trial reflect a similar approach to learning that children experience in daily activities, such as having autonomy over their learning (self-select), and mastering simpler concepts before complex concepts (stepwise). Motivation questionnaires will be used in analyses to determine if children in the training and active control conditions have similar motivation toward learning in the classroom and expectations of the intervention.

It is acknowledged that this trial was not powered to detect potential differences between the adaptive, self-select, and stepwise working memory training conditions. The lack of research and effect sizes from nonadaptive approaches makes calculating appropriate power challenging. We anticipate the differences in effect sizes between the 3 conditions will be small, and therefore a particularly large sample size would be required and this may not be practical or feasible.

This trial will determine whether the adaptive approach to setting the difficulty of working memory training activities is superior for maximizing training outcomes. It is our intention to present findings at national and international conferences and publish findings in peer-reviewed journal papers. Families and staff of the participating school will receive a summary of the findings. Findings will contribute to our understanding of the design of effective working memory training interventions, discrete levels of transfer of working memory training, and the malleability of cognitive functions in children. Knowledge gained could have implications for other types of cognitive training that target core domains such as attention and inhibitory control, and for other populations, including aging and dementia [3]. This work could help highlight the value of evidence-based principles of cognitive training and shift the focus from studying the effectiveness of different programs to more rigorous evaluations of the foundational principles of cognitive training. In summary, the results have the potential to influence the future direction and application of cognitive training.

Abstract

Background: Individual face-to-face cognitive behavioral therapy is known to be effective for bulimia nervosa (BN). Since foods vary considerably between regions and cultures in which patients live, cultural adaptation of the treatment program is particularly important in cognitive behavioral therapy for BN. Recently, an internet-based cognitive behavioral therapy (ICBT) program was developed for Japanese women with BN, adapted to the Japanese food culture. However, no previous randomized controlled trial has examined the effectiveness of ICBT.

Objective: This paper presents a research protocol for strategies to examine the effects of guided ICBT.

Methods: This study is designed as a multicenter, prospective, assessor-blinded randomized controlled trial. The treatment groups will be divided into treatment as usual (TAU) alone as the control group and ICBT combined with TAU as the intervention group. The primary outcome is the total of binge eating and purging behaviors assessed before and after treatment by an independent assessor. Secondary outcomes will include measures of eating disorder severity, depression, anxiety, quality of life, treatment satisfaction, and working alliances. Treatment satisfaction and working alliances will be measured post assessment only. Other measures will be assessed at baseline, post intervention, and follow-up, and the outcomes will be analyzed on an intention-to-treat basis.

XSL•FO
RenderX

Results: This study will be conducted at 7 different medical institutions in Japan from August 2022 to October 2026. Recruitment of participants began on August 19, 2022, and recruitment is scheduled to continue until July 2024. The first participants were registered on September 8, 2022.

Conclusions: This is the first multicenter randomized controlled trial in Japan comparing the effectiveness of ICBT and TAU in patients with BN.

Introduction

Background

Bulimia nervosa (BN) is an eating disorder characterized by binge eating, purging or fasting, and concerns associated with body shape and weight [1]. Patients with BN often have a distorted body image despite being at standard levels with regard to shape and weight [2]. Consequently, they perform frequent purging or fasting or excessive exercise on the basis of a subjectively abnormal perception of their body shape and weight [3]. Body image distortion involves perceptual disturbances and body dissatisfaction [4]. Repeated episodes of binge eating and inappropriate compensatory behaviors can cause serious physical and mental health concerns. Vomiting after overeating may result in thickened skin on the knuckles, broken teeth, and thyroid dysfunction due to problems with metabolic rate and caloric intake [5,6]. In terms of mental health, patients with BN frequently show low self-esteem, self-harming behaviors, suicidal tendencies, depression, anxiety disorders, sleep disorders, and fatigue or exhaustion [7-12].

Prevalence of BN and Accessibility to the Treatment

Epidemiological studies confirm that eating disorders are highly prevalent, particularly among women: 2.58% of women in Western countries [13]. The overall observed prevalence of eating disorders was 3.5% between 2000 and 2006 and increased to 7.8% between 2013 and 2018 [14]. A recent meta-analysis estimated that the lifetime and 12-month prevalence of eating disorders was 0.91% and 0.43%, respectively, while the lifetime prevalence of BN was 0.63% [13]. Face-to-face cognitive behavioral therapy (CBT) has been shown to be effective for eating disorders [15], but poor access to treatment remains a problem [16]. In fact, only 19%-36% of people with eating disorders have access to treatment within 1 year [17-19], and 35%-40% of these patients receive standard treatment for eating disorders [20,21]. Furthermore, treatment for eating disorders is sought an average of 5-15 years after the onset of the disorder [16,22]. Access to these appropriate treatments is often hampered by physical barriers, lack of practitioners, and stigma. These problems are particularly associated with face-to-face delivery. Web-mediated interventions may be effective in initiating appropriate early treatment [23,24]. CBT via the internet can dramatically improve access to treatment, especially in developed countries, in which the internet infrastructure is well-developed and information communication devices are widely used.

A New CBT Model for BN

Enhanced CBT has been shown to be effective in treating eating disorders, including BN. Enhanced CBT encourages the early establishment of healthy and safe eating habits and facilitates behavioral changes and cognitive modification through psychoeducation and self-monitoring. In addition, accumulating evidence from many clinical studies is being integrated to establish CBT techniques that have shown promise for the treatment of eating disorders. In a network analysis, fear of weight gain was suggested to be central to the psychopathology of BN, and hypersensitivity to physical sensations was shown to bridge BN with anxiety or depression [25]. Based on the evidence, this network meta-analysis argued that focusing on the fear of weight gain during exposure therapy and interventions focused on interoceptive exposure is effective in treating BN. However, several other CBTs may also be effective in treating BN, including attentional bias correction training to correct the direction of excessive attention to the body, weight, and food [26], relaxation, and mindfulness to reduce physiological responses such as anxiety and tension [27], traumatic memory care for experiences of being criticized for one's body type and appearance [28], and impulse control, such as cue exposure [29]. A therapist's manual for CBT of BN that systematically summarizes these CBT components has been published by Hamatani and Matsumoto [30]. Our research group recently developed a web-based program based on this CBT therapist's manual by checking the cultural adaptability in Japan [31].

Objectives

As mentioned earlier, we developed an internet-based cognitive behavioral therapy (ICBT) program for BN that is adapted to Japanese culture and based on Japanese food culture [30,31]. This paper describes the study protocol for a randomized controlled trial (RCT) involving female patients with BN and is designed to evaluate its clinical effects. We will include an intervention group receiving ICBT in addition to treatment as usual (TAU) and a control group receiving TAU alone.

XSL•FO
RenderX

Methods

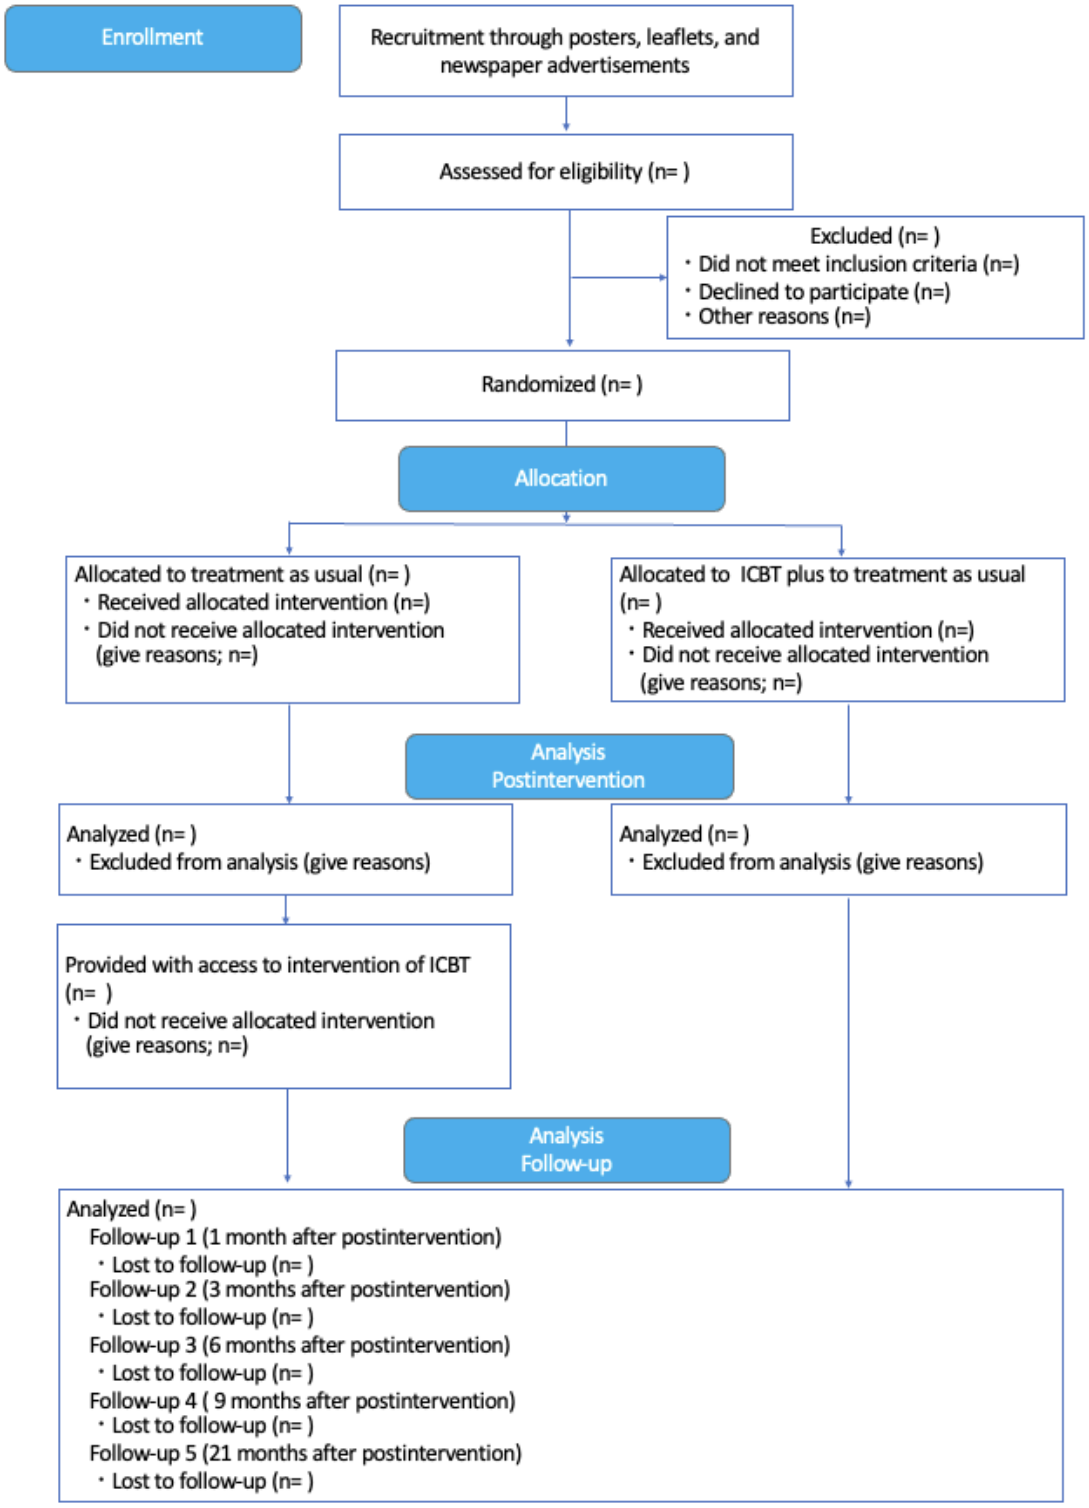
Study Design

This study is designed as a multicenter, prospective, randomized, assessor-blinded clinical trial. The RCT and follow-up study are planned from August 2022 to October 2026 (UMIN000048732). It will be conducted at the following 7 institutions (6 university hospitals and a national medical center) in Japan: University of Fukui Hospital, Kagoshima University Hospital, Chiba University Hospital, Tokushima University Hospital, Dokkyo Medical University, Tohoku University Hospital, and National Center for Neurology and Psychiatry.

Participants and Eligibility Criteria

Eligible participants will be women aged 13-65 years (1) diagnosed with BN according to the Diagnostic and Statistical Manual of Mental Disorders criteria during a clinical interview [1]; (2) having a BMI over 17.5 kg/m^2; (3) using computers, tablets, smartphones, etc, on a daily basis, with access to the internet and the minimum necessary information and communications technology skills; and (4) with no history of CBT in the last 2 years. Exclusion criteria include (1) serious mental disorders such as organic brain disorders, psychotic disorders, and drug dependence; (2) imminent risk of suicide; (3) repeated engagement in antisocial behavior; (4) serious progressive physical disease; and (5) difficulty in exposure to feared objects due to severe stress reactions or dissociation symptoms due to acute stress disorder or posttraumatic stress disorder. The purpose of the study is to investigate the effects of an ICBT program that has been adapted based on the culture of Japanese women. Men and women differ in their caloric needs, and most studies regarding eating disorders include female patients. This intervention program is based on the findings of previous studies; therefore, only women will be recruited. In addition, information and communication technology literacy varies considerably by patient age in Japan, with older adults having lower information and communication technology literacy. The intervention in this study is mainly self-help CBT using a web-based platform. Therefore, patients aged 65 years and older will be excluded from the study.

Recruitment



From August 2022 to July 2024, we will recruit 60 out-participants with female BN through posters, flyers, web or app advertisements (Google Ads, Twitter, and Facebook), newspaper advertisements, etc, posted at medical institutions throughout Japan. Since all participants will continue to be treated, they will be required to obtain clearance from their primary care physician prior to their study enrollment. The participants pay for TAU, but guided ICBT is free. Participants will be rewarded US $82.51 after intervention or waiting completion, regardless of group allocation. These include the amount of time patients spent on the trial and the difficulty of recruiting patients. To participate in this study, some hospitals will require referrals, which may cost the participant money.

Procedure

Participants will be directed to a website for this study by the various media mentioned earlier. There they will access the study website to apply for enrollment in the study. The clinical trial office at the University of Fukui that receives this application will coordinate the informed consent and eligibility test. Written informed consent will be solicited after the participants are provided research briefing either face-to-face or in a video call. Similarly, in the case of a minor, written informed consent from a legal representative is required. Next, they will complete a screening survey and a structured interview using Mini International Neuropsychiatric Interview version 5 [32,33]. Finally, they will be asked to complete a baseline data questionnaire on the web. The decision regarding the participant's exclusion or inclusion in the study will be made after they have completed the questionnaire. See Figure 1 for the flow of participants in this RCT.

XSL•FO
RenderX

Figure 1. Flowchart of the recruitment and assessments during this study. ICBT: internet-based cognitive behavioral therapy.

Interventions

Guided ICBT Program

This ICBT program is based on the treatment manual for BN in Japanese [30]. The ICBT program consists of 1 assessment module and 12 treatment modules, each dedicated to one theme, along with reporting of the development process [31]. Each module includes psychoeducation and practice exercises on CBTs. Each module begins with a video containing complex supporting explanations and messages of encouragement (see Table 1 for details). A secure web-based platform [34] will be used for communication between therapists and participants, distribution of program materials, and collection of assessments. At the start of the intervention, participants will receive an email containing their username and a link to create their own password so that they can log into the platform. Participants will be provided access to 1 new module each week for the duration of the 12-week intervention, starting with module 1.

XSL•FO
RenderX

For the first week, an assessment module (module 0) will be provided together with module 1. Once accessible, the modules will be available throughout the treatment duration. Participants who have not viewed the material or practiced it for a particular week will be sent a reminder once a week. If they have any questions, they can contact their therapists via the secure messaging feature on the platform. The therapist is a well-trained and experienced cognitive behavioral therapist (SH). The therapist will receive supervision from KM on the treatment of BN.

Table 1. The internet-based cognitive behavioral therapy modules in the randomized controlled trial.

	Module	Explanation
0	Assessment and goal-setting	First, a description of how to use the program and how the program is structured. Data on the user's basic clinical background, family composition, and chief complaint are collected. Then, treatment goals are set at the end.
1	Psychoeducation and cognitive behavioral model	An overview of the DSM-5[a] diagnostic classification [1] is provided and the epidemiological features of BN[b] [35]. Psychoeducation about CBT[c] for BN is introduced. Perceptions, attention, images, emotions, memories, thoughts, and the vicious circles of habitual behaviors are created graphically [30].
2	Relaxation and mindfulness medication	An introduction to the autonomic nervous system and training in breathing techniques, progressive muscle relaxation, and mindfulness meditation are provided [27,29].
3	Metacognitive training	Metacognition, one of the cognitive functions, is vulnerable in eating disorders [36], and there is evidence that cognitive weakness affects QOL[d] [37]. Metacognitive interventions may improve eating disorder severity, depression, and QOL [24,38]. This involves dichotomous thinking, emotional judgment, jumping to conclusions, and perfectionism, among others [30,31].
4	Attention bias modification and modification of interpretation for appearance	People with eating disorders tend to focus on body shape, weight, and food overload [39,40]. Exercises are provided that shift attention from food stimuli to neutral stimuli [41,42]. People with eating disorders frequently rate their body shape and weight negatively [43]. When recognizing the threatening bias of one's natural body shape and weight, the client can use techniques of relaxation and metacognition to handle concerns about perceived body shape and weight.
5	Behavioral experiment for binge eating	Behavioral experiments will be used to see that eating does not lead to uncontrolled weight gain [44].
6	Management of healthy food contents and eating habits	Self-monitoring using food diaries reduces the frequency of binge eating in web-based programs [45]. We propose a Japanese food menu to achieve a well-balanced diet [31]. This approach was developed based on a nutritional rehabilitation called "mechanical diet" by Garner et al [46].
7	Creating an anxiety hierarchy chart and stepwise exposure	Addressing fears associated with overeating can reduce overeating in BN [47,48].
8	Exposure to cues preceding binge eating and purging	Triggers for overeating and purging vary from person to person; however, exposure to such cues can reduce overeating and purging [29].
9	Cognitive restructuring	Negative self-statements associated with eating disorders are frequently observed in BN [49]. Such self-assertions shape the person's own identity and values [50]. Cognitive restructuring fosters alternative ways of thinking about these self-statements (adaptive thinking).
10	Rewriting of traumatic memory for image of the body	There are often individuals with BN who have negative childhood experiences [51]. If the interpretation of a traumatic memory is tormenting the patient, it should be rewritten to make it safer.
11	Schema work	Rescripting dysfunctional beliefs (schemas) may reduce the frequency of binge eating and purging as well as body shape concerns [52]. Dysfunctional beliefs are organized and alternative beliefs are written down.
12	Prevention of relapse	A summary of what participants have learned from the treatment will be solicited and used to plan future efforts to further reduce symptoms and prevent relapse.

[a]DSM-5: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition.

[b]BN: bulimia nervosa.

[c]CBT: cognitive behavioral therapy.

[d]QOL: quality of life.

TAU (Control Group)

Participants will be allowed to continue receiving counseling, psychotropics, and other medications for the duration of the study. No new drug therapy or additional changes will be recommended during the study period by the study staff. However, the participant's primary care physician will not be prevented from modifying medications and refer participants to counseling or second-line therapy if deemed clinically appropriate. All changes in TAU will be documented along with the reasons for these changes. Participants in the control group (TAU) will be offered ICBT after a waiting period as well.

XSL•FO
RenderX

Measures

Demographic Data

Participants will be asked about age, educational level, marital status, employment status, BMI, age at BN onset, duration of BN, comorbidities, and the presence or absence of psychotropic or antidepressant drug use.

Primary Outcome

The primary outcome will be the weekly combined frequency of binge eating and purging behaviors. These will be measured by an independent assessor whose allocations are masked.

Secondary Outcomes

Secondary self-reported outcomes will be the Eating Disorders Examination Questionnaire [53,54], Patient Health Questionnaire-9 [55,56], Generalized Anxiety Disorder Scale-7 [56,57], EQ-5D [58,59], Brunnsviken Brief Quality of Life Scale [60] at baseline, postintervention, and follow-up (1-, 3-, 6-, 9-, and 21-month follow-ups). Assessments based on the Working Alliance Inventory-Short Form [61] and Client Satisfaction Questionnaire [62,63] will be performed only after the treatment.

Sample Size

The required sample size was calculated using statistical analysis software (G*Power, version 3.1; Heinrich-Heine-Universitaet Duesseldorf). An effect size of Cohen *d*=0.90 from a previous study was used as a reference [64]. The significance level was set at *P* values <.05 for 2-sided tests. The power was set to 80%. The required sample size (assigned number of participants) will be 60 when considering a 30% noncompletion rate based on a previous study [65]. Completers in this study are defined as those who complete at least 80% of the module [65]. In addition, dropouts in this study are defined as those who drop out by not providing postevaluation data or those who discontinue their participation due to adverse events.

Randomization

Participants confirmed to be eligible and enrolled will be randomized in a 1:1 ratio to either the intervention (TAU added guided ICBT) or TAU alone groups by the truncated binomial design using UMIN's (University Hospital Medical Information Network) computer program (UMIN Center). The truncated binomial design is that complete randomization will be performed until the number of randomizations to any group reaches n/2, after which all subjects are allocated to the other group to prevent an imbalance in the number of people.

Statistical Analysis Plan

Statistical analysis will be performed using SPSS Statistics software (version 29; IBM Corp). Statistical analysis will be performed in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines and based on the intention-to-treat principle (Multimedia Appendix 1). Missing data will be handled by multiple imputations. Unpaired *t* test and Fisher exact test will be used to investigate the difference between the 2 groups at baseline. To compare treatment effects, we will use analysis of covariance for primary and all secondary outcomes. As a covariate, we plan to include a scale that is significantly different between the 2 groups at baseline. We also will perform a per-protocol analysis by excluding patients who deviate from the protocol. Analysis of covariance will also be performed on the follow-up data. However, if there are many missing values, we would consider generalized linear mixed models. All *P* values are 2-tailed, and *P* values <.05 will be considered statistically significant.

Ethical Considerations

The clinical trial protocol was approved by the Research Ethics Committee of the University of Fukui on August 15, 2022 (20220054), and was registered in the UMIN Domestic Clinical Trial Database (UMIN000048732). Each participant will then be informed that all participants will receive TAU from the general practitioner and that half of the participants will receive ICBT in addition to TAU. All adverse events will be reported, and serious adverse events will be reported immediately to the institutional review board. An adverse event is defined as any symptom or illness occurring during a clinical trial, whether related to the ICBT program or not. The results of the trial will be published in the appropriate journal, regardless of the outcomes. The trial will be implemented and reported in accordance with the CONSORT recommendations.

Results

Recruitment began on August 19, 2022, following the attainment of ethics approval on August 15, 2022, and the granting of permission to conduct the study on August 18, 2022. The first participant was enrolled on September 8, 2022, and recruitment is scheduled until July 2024. First, we plan to report the results using pre-post data from the RCT design. Subsequently, we will also report the 2-year long-term effects of those who received ICBT.

Discussion

Anticipated Findings

This paper presents the research protocol for the first RCT designed to investigate the effectiveness of therapist-guided ICBT for female Japanese patients with BN. Notably, a recent RCT demonstrated the efficacy of ICBT for binge eating disorder and other specified feeding or eating disorders [66]. However, although that study, conducted in the Netherlands, showed promising results for guided ICBT in these eating disorders, it involved participants with varying BMI of 19.5 or 40.0 kg/m^2 and did not include patients specifically diagnosed with BN. In contrast, this study protocol uses specific eligibility criteria, focusing solely on individuals with BN as the primary diagnosis while excluding other eating disorders, such as binge eating disorder. Consequently, the patient cohort to be included in our RCT is anticipated to be homogenous, thereby bolstering confidence in the treatment's effectiveness. Meanwhile, a systematic review and meta-analysis examining e-therapy's impact on eating disorders reported inconclusive evidence regarding the effect on overeating frequency in patients with BN [67]. Although this meta-analysis found improvements in various aspects, such as binge eating, vomiting, and laxative misuse, and in the discontinuation rate of overeating symptoms

XSL•FO
RenderX

at the intervention's conclusion, the estimates were imprecise due to the heterogeneity in the quality of studies included in the analysis. Therefore, the authors concluded that e-therapy, including guided ICBT, could be effective for the management of eating disorders; however, further research is needed. A recent single-arm ICBT study targeting patients with eating disorders, including BN, reported positive outcomes [65]. In evidence-based medicine, individual RCT holds the highest level of evidence among single clinical trials [68]. Nevertheless, the outcomes of single-arm clinical trials lacking a control group should be interpreted with caution. In this context, our RCT may expand the understanding of the efficacy of guided ICBT for BN. To our knowledge, even recent RCTs have not provided effect estimates for patients with BN alone, as they also included other eating disorders [69,70]. Therefore, this study, by adhering closely to the RCT protocol described herein, will be well-positioned to offer valuable insights into the efficacy of guided ICBT on the frequency of overeating and purging along with any secondary symptoms in patients with BN. Furthermore, to the best of our knowledge, this is the first study designed to examine the effects of ICBT on behavioral changes related to eating styles in Japan. This is especially significant given Japan's distinct food culture and medical system that sets it apart from Western countries. The investigation into the effects of ICBT for BN within the context of Japan carries particular importance, as it navigates cultural nuances and differences in the medical system. Therefore, a multicenter study design is more likely to reduce bias and yield findings with broader generalizability.

Limitation

One limitation of the study is that it would not allow elucidation of the specific effects of the ICBT program because it does not use a psychological placebo group to control for nonspecific factors.

Conclusions

This RCT aims to validate and prove evidence for the efficacy of a Japanese culture–adapted ICBT program for female patients with BN. This will allow discussion of efficacy beyond the preliminary results obtained to date. The low availability of CBT is an international problem, and the implementation rate of CBT in Japanese psychiatric clinics is extremely low at 6.2% [71]. If positive results are obtained from this RCT, more patients with BN could receive early treatment, which could lead to early improvement in eating disorders that tend to be prolonged and chronic.

Acknowledgments

We would like to express our utmost gratitude to George Vlaescu for his role as webmaster. This work is supported by the Grants-in-Aid for Scientific Research from the Japan Society for the Promotion of Science (grant JP22H00985), Lotte Research Promotion Grant, and the Collaborative Research Program of the Collaborative Research Network for Asian Children With Developmental Disorders: MEXT Policy Initiative FY2022, under joint research conducted through the initiative.

Data Availability

Data sharing is not applicable to this paper as no data sets were generated or analyzed during this study.

Authors' Contributions

SH initiated the project, planned the research, obtained funding, and wrote the paper. KM, YH, HK, and YM are funded research collaborators who contributed significantly to the study conception or design. GA participated in data management and write-up of the report. YT, SN, RK, AS, YS, SF, NS, MN, RO, and RS contributed significantly at the various stages of research and development toward practical implementation. YM oversaw the overall conduct of the study. All authors read, critically revised, and approved the final paper.

Conflicts of Interest

None declared.

Abstract

Background: Generalized anxiety disorder (GAD) is a prevalent anxiety disorder, with cognitive behavioral therapy (CBT) being the gold standard treatment. However, it is inaccessible and costly to many, as the mental health industry is overwhelmed by the demand for treatment. This means effective, accessible, and time-saving strategies must be developed to combat these problems. Web-based interventions for mental health disorders are an innovative and promising way to address these barriers. While electronically delivered CBT (e-CBT) has already proved productive and scalable for treating anxiety, other less resource-intensive interventions can be innovated. Checking up on mental health face-to-face has been shown to provide similar benefits to patients with anxiety disorders previously, but more research is needed to evaluate the efficacy of web-based delivery of this intervention.

Objective: This study will compare the efficacy of e-CBT and a web-based mental health check-in program to treat GAD. These programs will both be delivered through a secure, web-based care delivery platform.

Methods: We will randomly allocate participants (N=100) who are 18 years or older with a confirmed diagnosis of GAD to either an e-CBT program or a mental health check-in program over 12 weeks to address their anxiety symptoms. Participants in the e-CBT arm will complete predesigned modules and homework assignments while receiving personalized feedback and asynchronous interaction with a therapist through the platform. Participants in the mental health check-in arm will be contacted weekly through the web-based platform's written chat feature (messaging system). Therapists will ask the participants a series of predesigned questions that revolve around a different theme each week to prompt conversation. Using clinically validated questionnaires, the efficacy of the e-CBT arm will be compared to the mental health check-in arm. These questionnaires will be completed at baseline, week 6, and week 12.

Results: The study received ethics approval in April 2021, and participant recruitment began in May 2021. Participant recruitment has been conducted through targeted advertisements and physician referrals. Complete data collection and analysis are expected to conclude by August 2023. Linear and binomial regression (continuous and categorical outcomes, respectively) will be conducted.

XSL•FO
RenderX

Conclusions: To the research team's knowledge, this will be the first study to date comparing the efficacy of e-CBT with a web-based mental health check-in program to treat GAD. The findings from this study can help progress the development of more scalable, accessible, and efficacious mental health treatments.

Introduction

Overview

Generalized anxiety disorder (GAD) is a prevalent and debilitating mental health disorder. More than 450 million people are living with mental and behavioral disorders, with many being unable to receive adequate treatment [1-3]. Cognitive behavioral therapy (CBT) is considered one of the first-line treatments for GAD; however, it is not without its drawbacks [4-7]. CBT is often inaccessible to patients because it requires in-person time commitment during work hours, travel to appointments, high costs, and potential exposure to social stigma [8]. CBT is extremely resource-intensive, requiring a large time commitment from a trained mental health professional. With the prevalence of mental health disorders as high as they are, the demand for this first-line therapy is not being met by North American health care systems, leaving them overwhelmed and patients unable to receive treatment [8,9]. Innovative interventions that optimize resources without sacrificing the quality of care are required to meet this demand.

Fortunately, web-based interventions for mental health disorders are growing in prevalence and are a promising way to address the barriers associated with in-person treatment, such as accessibility and convenience [10-15]. The structured nature of CBT has allowed it to be effectively adapted into a web-based format (electronically delivered CBT; e-CBT) where patients can access standard concepts remotely and in their own time. While e-CBT has already proven productive and scalable for treating anxiety disorders [10,16-19], developing less-intensive interventions that still benefit patients could allow for even more scalability. Not all patients may require the full structure of e-CBT and could still benefit from a less-intensive option, such as structured mental health conversations with a care provider. Checking in on individual mental health has previously shown benefits to patients with anxiety disorders, but much of this research has investigated in-person approaches and synchronous web-based deliveries [20-22]. Transferring this to a web-based asynchronous messaging format could allow for increased privacy, accessibility, temporal flexibility, and decreased cost and geographical barriers. Understanding how the delivery of e-CBT compares to a web-based delivery of mental health check-in conversations with a care provider can provide insight into the application of this as a viable intervention in the future.

Objectives

The primary objective will be to compare the efficacy of an e-CBT program to a web-based mental health check-in program. Additionally, the individual effects of each treatment will be evaluated using clinically validated symptomology questionnaires.

Methods

Study Design

This study will use an open-label randomized controlled trial design to investigate the effects of e-CBT versus a web-based check-in program for GAD. Participants will be randomly assigned, in a ratio of 1:1, to either a 12-week e-CBT program tailored to GAD or a 12-week mental health check-in program to address their symptoms. In addition to these interventions, participants will continue with treatment as usual (ie, lifestyle, family physician appointments, and medications).

Participants

Participants (total=100; e-CBT=50; and check-in=50) will be recruited in Kingston, Ontario, from outpatient psychiatry clinics at both Kingston Health Sciences Centre sites (Hotel Dieu Hospital and Kingston General Hospital). Additional recruitment from Providence Care Hospital, family doctors, physicians, clinicians, and self-referrals will occur. Once informed consent is obtained, participants will be evaluated by a psychiatrist on the research team through secure video appointments to make or confirm a diagnosis of GAD using the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) [23].

Inclusion criteria include being aged 18 years or older at the start of the study, having a diagnosis of GAD according to the DSM-5 criteria by an attending psychiatrist on the research team, having the competence to consent to participate, having the ability to speak and read English, and having consistent and reliable access to the internet. Exclusion criteria include active psychosis, acute mania, severe alcohol or substance use disorders, and active suicidal or homicidal ideation. To avoid any confounding effect on the efficacy of this e-CBT program, participants currently receiving or having received CBT in the past year will also be excluded from this study to avoid confounding effects of treatment. If eligible for the study, participants will be randomly assigned to either the e-CBT program (n=50) or the mental health check-in program (n=50). Following the completion of the study, participants who were

XSL•FO
RenderX

randomly assigned to the mental health check-in arm will be offered the e-CBT program if they are interested. During the informed consent process, it will be explained to all participants that this program is not a crisis resource and that they will not always have access to their therapist. In the case of an emergency, participants will be directed to the proper resources (ie, emergency department and crisis lines), and this event will be reported to the principal investigator.

Procedures

CBT Arm

The e-CBT modules are designed to instill balanced and constructive coping strategies in participants. During the e-CBT program, the focus will be on essential thinking and behavioral skills to assist participants in becoming more engaged in day-to-day activities (Table 1). Additional focus will be placed on the connection between thoughts, behaviors, emotions, physical reactions, and the environment. All care providers are research assistants hired by the principal investigator. They all undergo training in psychotherapy delivery and additional training by the principal investigator on the research team, who is also a licensed therapist and an expert in web-based delivery, before interacting with participants. During this training, therapists complete feedback on practice homework, which is reviewed to ensure adequate quality of work. All care providers are supervised by a licensed therapist [10-12,16,24-26] who will review feedback before submission.

Table 1. Overview of the 12-week electronically delivered CBT[a] program content.

Week	Session	Description
1	What is generalized anxiety disorder?	Provides expectations for the course and introduces anxiety and CBT.
2	The 5-part model	Introduces the concept of the 5-part model and how a situation, thoughts, feelings, physical reactions, and behaviors are connected and how they interact.
3	Strategies for stressful situations	Provides an overview of helpful strategies that can be used in stressful situations, including pleasurable activities and helpful breathing techniques.
4	Situation, thoughts, feelings, physical reactions, and behaviors	Provides a further detailed exploration of the 5-part model and how changes in one area can affect the other 4 parts.
5	The thought record	Highlights the first 3 columns of the thought record; a tool used to help understand the connection between feelings, behaviors, and thoughts. The first 3 columns include the situation, followed by the feelings and automatic thoughts associated with it.
6	Automatic thoughts	This delves into the role of automatic thoughts and how they influence feelings. The focus of this session is to understand how to identify automatic thoughts and specifically identify the most dominant idea, or "hot thought," when presented with a stressful situation. Common thinking errors are also discussed in this session.
7	Activity scheduling	Provides a break from learning about the thought record and instead explains how to use an activity record; a tool designed to record and plan weekly activities. This session focuses on how tracking activities can inform mood changes and reinforce the scheduling of pleasurable activities.
8	Evidence	Focuses on the fourth and fifth columns of the thought record, which are designed to help gather the information that supports or does not support the identified hot thought.
9	Alternative and balanced thinking	Focuses on the final 2 columns of the thought record, which reflect on the evidence columns to help find an alternative or balanced view of the situation. The last column invites the viewer to rerate their feelings based on the completion of the thought record.
10	Experiments	Explain the importance of conducting experiments to start believing alternative or balanced thoughts from the thought record and initiating changes in ineffective thinking patterns.
11	Action plans	Centered around identifying a problem that needs to be solved and provides a framework for creating a plan for solving the problem.
12	Review	The final session is a review of the course and summarizes the main CBT concepts and tools that have been taught throughout the program.

[a]CBT: cognitive behavioral therapy.

The e-CBT care plan consists of 12 weekly sessions of approximately 30 slides and interactive content, delivered through the Online Psychotherapy Tool (OPTT), a secure, web-based, cloud-based mental health care delivery platform. The e-CBT module content will mirror in-person standard CBT content, including different weekly topics, general information, skill overviews, and homework. Participants will be instructed to go through the content and complete homework at the end of the session, which will help them practice the skills they learned during that session. Homework will be submitted directly through OPTT and reviewed by the care provider assigned to the participant, who will provide personalized feedback within 3 days of submission. Care providers will have access to predesigned session-specific feedback templates to use as a basic structure to write their feedback. Doing so reduces the time needed to respond to each patient; therefore, the number of patients each care provider can handle increases. On average, developing this feedback will take a care provider 15-20 minutes per patient. In addition to the weekly feedback, participants have the option to message their care provider through the

XSL•FO
RenderX

platform throughout the week regarding any questions or concerns they may have.

Mental Health Check-In Arm

Participants in the mental health check-in arm will have weekly interactions with a care provider through the chat feature in OPTT. The care provider will reach out weekly using structured question prompts to initiate interaction with the patient (Table 2).

Table 2. Mental health check-in weekly procedures and question prompts.

Week	Topic	Question prompts
1	Mood	Tell me about yourself. How have you been feeling lately? How has the pandemic affected your mood? What differences have you noticed in your mood compared to the past?
2	Sleep	How have you been? Tell me about your week. I want to ask about your sleep. How many hours do you get? Do you feel rested? Do you think you need to make any changes to your sleep hygiene?
3	Activity	How was your week? How has your anxiety level been? What do you usually do to stay active during the day? Are there any indoor activities you can do at your place? Have you been using any online exercise programs?
4	Hobbies	What did you do in the past week? Do you have any hobbies? How long have you been doing them? Have you found any new activities that you enjoy recently?
5	Friendship	How was your week? How has the pandemic affected your relationship with your friends? Have you stayed in touch with your close friends during the pandemic? How often do you interact with your friends?
6	New events	How have you been? Have there been any new events in the past weeks? Are you planning to do anything new this week? Are you planning to do anything new this week? Are you expecting to hear any news from your family/friends?
7	Job and study	How have you been? Tell me about your week. How are you managing your day-to-day responsibilities (eg, job, school, personal, etc)?
8	Diet and food	How was your week? Let's talk about your eating habits. How does your anxiety affect your appetite? Are you satisfied with your diet? How often do you cook? Do you prefer homemade food or take-out?
9	Books, movies, and television	How was your week? Has your anxiety affected your concentration? Do you like reading books? What is the last book you read? Are there any books you would recommend to your friends? What shows do you enjoy watching? What are some shows you would recommend to your friends?
10	Phone, apps, and games	Tell me about your week. How many hours a day do you usually spend on your phone? What is your favourite app? Do you play any games? What kinds of games do you like to play (eg, board games, cards, video games, etc)?
11	Habits	How have you been? How was your week? What do you think are some of your healthy habits? What are some habits you would like to change?
12	Accomplishments	How was your week? How did you find this program? Were the weekly check-ins helpful? Overall, was this program helpful for you? Why or why not? Are you interested in an online cognitive behavioural therapy program? Why or why not?

Outcome Evaluation and Analysis

Participants in both arms will complete the following clinically validated questionnaires at baseline: State-Trait Anxiety Inventory (STAI) [27], Quality of Life Enjoyment and Satisfaction Questionnaire-Short Form (Q-LES-Q-SF) [28], Generalized Anxiety Disorder-7 item (GAD-7) [29], Depression Anxiety Stress Scale-42 item (DASS-42) [30], and a demographic questionnaire. All questionnaires will be completed through OPTT. The STAI, Q-LES-Q-SF, GAD-7, and DASS-42 will be completed again during week 6 and week 12. Using data from previous research incorporating this e-CBT program, a sample of 50 participants in each group was determined to be sufficient for an effect size of 0.5, a power of 0.8, and an α of .05 [31].

Before analysis, the data will be examined for missing, nonsensical, and outlying variables. Missing data will be removed on a per-protocol basis, with a statistical analysis significance level set at .05. Demographic information (ie, age, gender, and race) will be assessed between groups and program noncompleters using independent sample *t* tests. A 2×3 repeated measures ANOVA will be completed for each questionnaire score at the time points to investigate the differences between the 2 groups. An intention-to-treat analysis will be completed to assess whether the outcome of treatment impacts participants' likelihood of not completing the program. Data will also be assessed with linear mixed-effects models with random effects as patient identification and fixed effects as treatment, time, and their interaction. SPSS (version 24; IBM Corp) will be used for all statistical analyses.

Data Privacy

Participants will only be identifiable by an anonymous identification number, and all files are stored securely on a server with password encryption. Participant data will only be accessible by the care providers directly assigned to the participant, and anonymized data will be provided to the analysis team members. Participants can withdraw from the study at any point and request that their data be removed from the analysis.

OPTT is compliant with the Health Insurance Portability and Accountability Act, the Personal Information Protection and Electronic Documents Act, and Service Organization Control-2.

XSL•FO
RenderX

Additionally, all servers and databases are hosted in the Amazon Web Service cloud infrastructure, which is managed by MedStack to assure all privacy and security regulations are met. OPTT does not collect any identifiable personal information or IP addresses for privacy purposes. OPTT only collects anonymized metadata to improve its service quality and provide advanced analytics to the clinician team. OPTT encrypts all data, and no employee has direct access to participant data. All encrypted backups will be kept in the S3 storage that is dedicated to Queen's University.

Ethic Approval

The study was approved (File 6032033) by the Queen's University Health Science and Affiliated Teaching Hospitals Research Ethics Board in April 2021.

Results

The recruitment of participants for this study began in May 2021. Participant recruitment has been conducted through social media advertisements, physical advertisements, and physician referrals. To date, 50 participants have been recruited. Data collection is expected to conclude by August 2023, and data analyses are expected to be completed by September 2024, with linear regression analysis (for continuous outcomes) and binomial regression analysis (for categorical outcomes) being conducted.

Discussion

This study protocol outlines the methods to compare a 12-week e-CBT program and a 12-week check-in program for the management of GAD symptoms. Additionally, the individual effects of each treatment will be evaluated using clinically validated symptomology questionnaires.

GAD is a prevalent mental health disorder that demands resource-intensive interventions to properly address symptoms. CBT is currently one of the first-line treatments for GAD, but it tends to be inaccessible to patients and requires a high level of time commitment from mental health care professionals. Using the internet to deliver mental health treatments has become a promising solution in recent years, with e-CBT being scalable, accessible, and effective in treating GAD [16-18,32-34]. Now that e-CBT is an effective treatment option for patients with GAD, understanding ways to tailor the care to each patient, with varying intensity levels, is crucial for the future of scalability [11,12,16,24-26]. Checking in on patients' mental health is another form of mental health care that can be less resource-intensive while still offering benefits to patients with GAD. Delivering this electronically and asynchronously would allow for more accessible access to treatment while also providing decreased time commitment, allowing more patients to be helped. There is less research on the impact of a check-in intervention over messaging services, identifying a knowledge gap. By directly comparing this check-in intervention to e-CBT, the efficacy and feasibility of implementing this as a treatment option in a web-based mental health clinic can be investigated. This comparison is original to previous literature, providing a direct comparison between e-CBT and mental health check-ins to investigate whether this is a viable resource to implement in a real-world setting. Most previous literature has investigated the comparison of e-CBT to in-person interventions, treatment groups, medications, or control groups, but none of the sort in this protocol, to the author's knowledge.

The limitations of this protocol include the lack of a control group. However, the e-CBT program used in this protocol has been previously clinically validated [11], and the main objective of this study is to uncover the differences between these 2 treatment arms. Furthermore, this protocol does not currently include a long-term follow-up, which is something that could be explored in the future.

These findings can provide valuable insight into the effectiveness of a weekly mental health check-in from a care provider versus a validated 12-week e-CBT intervention. If the check-in intervention proves to be a viable and effective option, it could be used as a less resource-intensive option, used in conjunction with e-CBT, or as an option for patients presenting with less severe symptoms. By providing a framework for future research to use these forms of check-in interventions, more work can be done investigating the effects in conjunction with other treatments as well. Electronically delivered mental health interventions are an ever-expanding area with a focus needed on how to continue growing the reach to more patients without sacrificing accessibility and quality of care.

Data Availability

The data sets generated during and/or analyzed during this study will be made available from the corresponding author on reasonable request.

Conflicts of Interest

NA and MO have cofounded the care delivery platform in use (ie, Online Psychotherapy Tool) and have ownership stakes in OPTT Inc.

Abstract

Background: Suicide attempts and suicide death disproportionately affect sexual and gender minority emerging adults (age 18-24 years). However, suicide prevention strategies tailored for emerging adult sexual and gender minority (EA-SGM) groups are not widely available. The Safety Planning Intervention (SPI) has strong evidence for reducing the risk for suicide in the general population, but it is unclear how best to support EA-SGM groups in their use of a safety plan. Our intervention (Supporting Transitions to Adulthood and Reducing Suicide [STARS]) builds on content from an existing life skills mobile app for adolescent men who have sex with men (iREACH) and seeks to target core risk factors for suicide among EA-SGM groups, namely, positive affect, discrimination, and social disconnection. The mobile app is delivered to participants randomized to STARS alongside 6 peer mentoring sessions to support the use of the safety plan and other life skills from the app to ultimately reduce suicide risk.

Objective: We will pilot-test the combination of peer mentoring alongside an app-based intervention (STARS) designed to reduce suicidal ideation and behaviors. STARS will include suicide prevention content and will target positive affect, discrimination, and social support. After an in-person SPI with a clinician, STARS users can access content and activities to increase their intention to use SPI and overcome obstacles to its use. EA-SGM groups will be randomized to receive either SPI alone or STARS and will be assessed for 6 months.

Methods: Guided by the RE-AIM (reach, efficacy, adoption, implementation, and maintenance) framework, we will recruit and enroll a racially and ethnically diverse sample of 60 EA-SGM individuals reporting past-month suicidal ideation. Using a type-1 effectiveness-implementation hybrid design, participants will be randomized to receive SPI (control arm) or to receive SPI alongside STARS (intervention arm). We will follow the participants for 6 months, with evaluations at 2, 4, and 6 months. Preliminary effectiveness outcomes (suicidal ideation and behavior) and hypothesized mechanisms of change (positive affect, coping with discrimination, and social support) will serve as our primary outcomes. Secondary outcomes include key implementation indicators, including participants' willingness and adoption of SPI and STARS and staff's experiences with delivering the program.

Results: Study activities began in September 2021 and are ongoing. The study was approved by the institutional review board of the University of Pennsylvania (protocol number 849500). Study recruitment began on October 14, 2022.

Conclusions: This project will be among the first tailored, mobile-based interventions for EA-SGM groups at risk for suicide. This project is responsive to the documented gaps for this population: approaches that address chosen family, focus on a life-course

XSL•FO

Introduction

Background

Suicidal behavior disproportionately affects sexual and gender minority youth [1] who are also at high risk for risk factors for suicide including harassment and trauma [2-4], yet few interventions address the specific needs of this population. In the United States, suicide rates increased for emerging adults (aged 18-24 years) in the past decade; suicide is now the second leading cause of death [5,6]. Youth who identify as sexual and gender minorities are >3 times more likely to have made a suicide attempt than those identifying as heterosexual [7]. Although sexual and gender minority individuals constitute only 4.5% of the general population (rates vary widely across studies), 10% of emerging adult (aged 18-24 years) suicide deaths occur among people who identify as sexual and gender minorities, representing a significant disparity [8]. Evidence-based suicide prevention programs tailored for emerging adult sexual and gender minority (EA-SGM) groups are not widely available.

Interventions to reduce suicidal ideation and behavior must address the unique risk factors that predict suicidal ideation and attempts in EA-SGM groups, including discrimination [9-11], family or friend rejection [9,12-16], and low positive affect [17]. Moreover, interventions promoting protective behaviors and social support may provide a complementary approach to traditional interventions to reduce risk in EA-SGM groups [18,19]. Developing youth's assets (eg, coping strategies and activity scheduling to promote positive affect) and linkage to health-promoting resources (eg, social support and access to safe spaces) may reduce suicidal ideation. EA-SGM people who can envision a healthy future in which they achieve their long-term goals have, on average, great psychological well-being [20], few risk behaviors [21,22], and improved use of health services [23]. These findings are consistent with the suicide prevention literature, in which goal-action consistency is targeted to reduce suicide risk [24-26] and improve mood regulation [27,28], and social connection is viewed as a factor that reduces the likelihood of developing suicidal ideation [29,30] or the intensity of suicidal ideation [31]. Studies are yet to evaluate the extent to which improving coping with discrimination, promoting positive affect, and improving social support are associated with reduced risk for suicide among EA-SGM groups.

Individuals at risk for suicide and clinicians alike perceive Safety Planning Intervention (SPI) as acceptable and useful [32,33]. SPI is a brief intervention that combines evidence-based strategies to reduce suicidal behavior by providing prioritized coping strategies, identifying sources of social and professional support, and providing lethal means counseling to reduce access to potential suicide methods. Several studies have demonstrated that SPI can be successfully implemented in a variety of contexts, including university counseling centers [34] and crises call centers [35]. However, this intervention has not been explicitly evaluated among sexual and gender minority youth. This is important because there are many unique circumstances in some sexual and gender minority youths' lives that may require adaptation of SPI, including reduced family support [36], experiences of discrimination [37], and low positive affect in general [38], each of which is a unique risk factor for suicide.

SPI and follow-up contact is associated with a significantly reduced risk of suicide attempts [39]; however, some studies indicate that individuals struggle to use the safety plan in suicidal crises. Patients reported barriers to using their safety plan after they generate it, which include the following: difficulty in finding the paper form; not thinking about or being motivated to use the plan during crises; and struggling with social isolation, which reduces the ability to enact safety plan steps to connect with one's support network [40]. Recent studies have found that mobile apps, such as BeyondNow, Safety Net, and MYPLAN, show promise for implementing safety plans [41]. However, patients tend to discontinue using mobile apps in general, and among sexual and gender minority communities, a common sentiment is that apps are initially engaging but not necessarily effective [42]. To address this issue, we propose to bolster app engagement by providing users with weekly peer mentor sessions. The potential of this peer mentor care navigator approach in reducing suicide risk among lesbian, gay, bisexual, transgender, queer, plus (LGBTQ+) youth has not been evaluated.

EA-SGM people are early adopters of technology and rely heavily on e-delivered information [43,44], often ranking the web as their top resource to explore their sexuality and to access social support [45-49]. Our proposed intervention takes advantage of this phenomenon by examining whether a web intervention, Supporting Transitions to Adulthood and Reducing Suicide (STARS), reduces suicidal ideation among EA-SGM groups. We propose to examine a mobile app, STARS, which leverages peer mentoring and support to ensure that EA-SGM groups can implement their safety plan in times of suicidal crises. STARS will provide users with web opportunities to receive goal-related feedback and social support from clinically supervised peer mentors, who will function as care navigators.

XSL•FO
RenderX

This peer-to-peer approach offers a confidential and user-controlled opportunity to support EA-SGM groups. We will assess whether the peer mentor model to provide social support reduces the impact of discrimination, promotes positive affect, overcomes barriers to SPI use, and decreases suicidal ideation.

Objectives

STARS was developed based on the Integrated Behavior Model [50] and will include both the app and peer mentor access. Consistent with type-1 hybrid effectiveness randomized controlled trial design, our pilot study examines preliminary efficacy end points alongside implementation targets. We use the RE-AIM (reach, efficacy, adoption, implementation, and maintenance) framework [51] to guide the assessment of these concurrent end points. If successful, this pilot study will identify the potential clinical utility of STARS for suicide prevention in a vulnerable, often marginalized population based on key parameters needed to inform a future clinical trial.

Our study goals are (1) to develop STARS through a systematic adaptation of an existing web intervention (iREACH [52]) using the assessment, decision, administration, production, topical experts–integration, training, and testing (ADAPT-ITT) [53] framework; (2) to examine the preliminary efficacy (suicidal ideation and behaviors) and mechanisms of action of STARS, relative to our control condition (SPI only); and (3) to examine STARS' implementation outcomes when compared with the control arm using RE-AIM [51,54] metrics. This exploratory project will identify the potential clinical utility of STARS for suicide prevention in a vulnerable, often marginalized population based on key parameters needed to inform a future efficacy trial.

Methods

Study Design

We will use the RE-AIM implementation science framework [51] to guide the assessment of the program's RE-AIM. We will pilot-test STARS using a type-1 effectiveness-implementation hybrid design in a racially and ethnically diverse sample of 60 EA-SGM individuals living in Philadelphia, PA, who report past-month suicidal ideation. Participants will be randomized to receive an in-person SPI (control arm) or to receive in-person SPI alongside STARS (intervention arm). After the baseline evaluation, we will follow participants for 6 months, evaluating them at 2, 4, and 6 months.

Consistent with our type-1 design, we will prioritize the preliminary effectiveness outcomes (suicidal ideation and behavior) and hypothesized mechanisms of change (coping with discrimination, social support, and positive affect). These measures will help us estimate critical parameters for a future trial as our *primary outcomes*. We will also monitor implementation targets related to reach, adoption, implementation, and maintenance as *secondary outcomes*.

This study is registered on ClinicalTrials.gov (NCT03678181).

Participants and Enrollment Procedures

Eligibility Criteria

Participants will (1) be aged between 18 and 24 years, (2) live in the Philadelphia Metropolitan Area (given that we are most familiar with those emergency service options) and plan to live in the area for the next 6 months, (3) report past-month suicidal ideation, (4) identify as a sexual minority (ie, identify with a sexual identity other than heterosexual) or gender minority (ie, sex assigned at birth is different from gender identity), and (5) report owning and having regular access to a smartphone that they can use to participate in study activities. Those with symptoms of psychosis that are not adequately treated will be excluded.

Recruitment, Screening, and Enrollment

With increasing use of the internet, there exists a great opportunity for reaching traditionally hard-to-reach and vulnerable populations, including EA-SGM groups and racially diverse groups. We will reach the population using recruitment advertisements on social media platforms (eg, Facebook, Instagram, Reddit, and Twitter). We developed advertisements that promote our target population's interest by including diverse images of youth (ie, images of different ages and portraying diverse races and ethnicities) and using advertisement-targeting specific to sociodemographic characteristics (eg, youth living in our region and who meet our age range) and interests (eg, youth following media with LGBTQ+ themes). Materials avoid identifying candidates as EA-SGM groups in the recruitment text to prevent unintended disclosure. Advertisements will link interested individuals to the study survey in REDCap (Vanderbilt University), where they may verify their eligibility, email the team, or locate a toll-free number if they want to learn about the study. We have recruited through these platforms for more than a decade with a significant track record of demonstrated success [55] and plan to use lessons learned from these efforts to guide the implementation of our proposed recruitment strategy.

We anticipate reaching our recruitment goal within 9 months of beginning enrollment. In previous trials in Philadelphia with sexual and gender minorities in this age group, we have found that >40% of individuals who clicked on our web advertisements through social media screen were eligible. Of those, 80% provided full contact information, and approximately 40% scheduled and attended an in-person enrollment visit. We expect that most (approximately 85%) will consent and enroll in the trial. Thus, for the proposed study, we expect to screen approximately 550 individuals, conduct full eligibility evaluations with approximately 70 (12.7%) EA-SGM individuals in person over the 9-month period, and obtain consent from and randomize 60 (10.9%) for our study. On the basis of these estimates, we will randomize 5 to 7 participants per month over the course of 9 months. As an enrollment strategy, we will provide complimentary rideshare to and from the baseline visit site as needed.

The web screener survey (through REDCap) will include initial consent to be screened, followed by questions that relate to eligibility based on our inclusion and exclusion criteria.

XSL•FO
RenderX

Participants will be screened for self-reported psychosis using 2 questions taken from the Diagnostic Interview for Anxiety, Mood, and OCD and Related Neuropsychiatric Disorders screener [56]. Participants who report no active psychosis and meet all other criteria for eligibility will be asked the final eligibility question of whether they have had suicidal ideation in the past month. Participants who meet all the preliminary eligibility requirements will be asked to provide contact information and preferred mode of contact.

Phone Screening

Participants who are found to be preliminarily eligible via the web screening process will be contacted via phone. During phone screening, information about the potential participants' physical location will be collected (if emergency services are needed) and a brief safety check will be conducted. Then, potential participants will be scheduled for their baseline evaluation.

Baseline Evaluation

If preliminarily eligible, participants will be scheduled for an in-person visit where they will complete the informed consent process and be evaluated by a licensed clinician for suicidal ideation and attempts using the Columbia–Suicide Severity Rating Scale (C-SSRS) [57]. Ineligible participants will be provided with referrals to mental health services based on their insurance. Enrolled participants will receive SPI, complete the baseline survey, and then be randomized. EA-SGM participants randomized to STARS will have immediate access to the app, be scheduled for their 6 peer mentor check-ins, and learn how they can reschedule future peer mentor sessions.

Randomization

Enrolled participants will be randomized during the baseline visit through REDCap's randomization module. A statistician created a block randomized list to ensure that there is an equal number of control and STARS participants, with a total of 102 assignments in blocks of size 4 or 6. Participants randomized to the control condition will complete follow-up assessments over 6 months. Although providing the gold-standard SPI to participants in the control condition may result in a floor effect, withholding this protocol would be unethical, given the participants' vulnerability to suicide. This design will allow for a preliminary evaluation of whether the incorporation of STARS improves the use of SPI among EA-SGM groups.

Control Arm

SPI [58] involves a collaborative and personalized conversation between the intervention facilitator and a person who is at high risk for suicide. SPI reduces the likelihood of future suicide attempts by collaboratively developing a written safety plan that consists of six steps (Table 1): (1) identifying warning signs, (2) implementing internal coping strategies, (3) using social interactions for distraction, (4) using one's social network (family and friends) for help, (5) using professional resources for help, and (6) making the environment safe by reducing access to lethal means.

XSL•FO
RenderX

Table 1. Core components, scientific rationale, and measurement metrics.

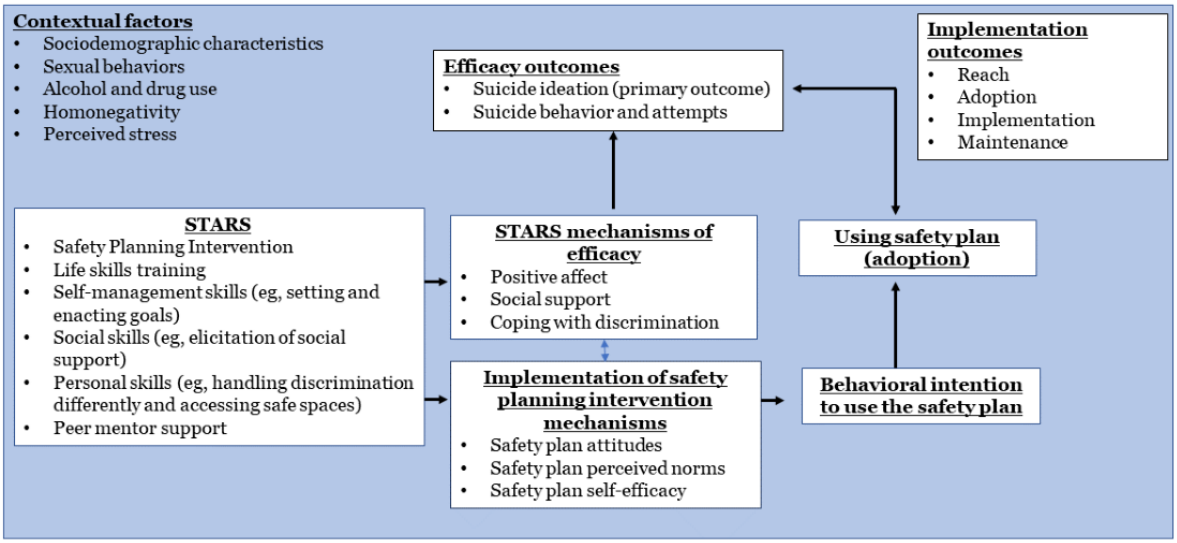
Features	Description	Scientific rationale (measurement metrics)
Safety plan	• Readable and editable digital version of the six-step Safety Planning Intervention, which includes: (1) warning signs, (2) internal coping strategies, (3) using social people and situations for distraction, (4) using one's social network (family and friends) for help, (5) using professional resources for help, and (6) making the environment safe • Phone numbers are tappable to facilitate calling • Call 911 button	• Increase the use of the Safety Planning Intervention [58] during times of crises by pairing the safety plan app content with peer mentor care navigator support (number of times accessed, number of times edited, and total time spent)
Resources and activities	• Multimedia resources and information about relationships, support, identity, stress, emotional well-being, safety planning and suicide, discrimination, drugs and alcohol, and life skills—tailored for emerging adult sexual and gender minorities, inclusive learning styles and health literacy • Robust management system to create new content and activities • Activity types include quizzes, self-assessments, goal setting, choose-your-own-adventure, sorting (eg, sort activities into healthy or unhealthy coping), and matching formatted to promote skills acquisition (eg, match the emotion to a typical behavior)	• Content corresponds to and aligns with the Integrated Behavior Model [50] (number of articles read and total time spent) • Interactive activities to address suicide prevention and reinforce emerging adult sexual and gender minorities' social support, coping with discrimination, and positive affect (number of activities completed and total time spent)
Peer mentor appointments	• Schedule of upcoming peer mentor appointments with links to web-based meeting room • List of completed peer mentor appointments	• Provide social support, reduce the impact of discrimination, promote positive affect, and reduce barriers for emerging adult sexual and gender minorities to enact their Safety Plans (number of sessions attended)
Profile	• Personalized username, customizable avatar, brief bio, badges earned, list of forum posts, and comments	• Personalization, gamification, and cues to incentivize engagement (number of times visited)
Goals	• Select from researcher-created goals or create new goals with milestones, tasks, and a journal feature	• Goals feature builds on self-management skills (number of goals set and milestones and tasks completed)
Forum	• Start or add to existing discussions; upload images, videos, memes; and so on • Favorite posts and follow others • Staff monitor and add to forum posts and include polls to encourage dialogue	• Peer support for resilience and behavior change (number of posts, comments, and likes; total time; and content of posts)
Gamification	• Sophisticated tracking of app use to trigger behavior-specific rewards • Badges awarded for tracked events	• Gamification [59] features incentivize continued engagement (number of log-ins and badges earned)

Intervention Arm

In the STARS intervention, our transdisciplinary team will develop and pilot-test an intervention to reduce suicidal ideation and behaviors among EA-SGM groups. STARS will include content about suicide prevention, including safety planning and targeting positive affect, and discrimination and social support. STARS will consider the unique cultural factors that may influence the efficacy of safety planning for EA-SGM groups (eg, access to LGBTQ+ resources) and include supports that promote the use of a suicide safety plan constructed with a licensed clinician.

Theoretical Foundation

The Integrated Behavior Model informs STARS in that the intervention acknowledges that EA-SGM groups' attitudes, norms, self-efficacy, and intentions are key constructs to target to effect behavior change (Figure 1). For STARS, we will adapt the Integrated Behavior Model–informed intervention messaging to promote EA-SGM groups' use of the safety plan during times of crisis by improving participants' attitudes toward, intention to use, and self-efficacy in using their safety plan (Multimedia Appendix 1). By enlisting peer mentor support, STARS will also target perceived norms about the frequency of safety plan use among their peer group. In addition, STARS will include a copy of the participant's safety plan and have topics to facilitate using the plan, with special attention dedicated to differences in social networks and previous negative experiences with health care to improve the impact of SPI among EA-SGM groups [11,60]. STARS provides life skills training (eg, building affirming relationships, applying to schools, study skills,



XSL•FO
RenderX

resume-writing skills, and emotion management skills; Table 1) and peer-delivered motivational interviewing (to support the use of the safety plan), through which, EA-SGM groups will learn about suicide prevention, set goals to shift their attitudes toward their safety plan, increase their intention to use their safety plan, and engage with a community that understands their needs and norms. This will help participants to manage their suicidal thoughts without engaging in suicidal behavior.

Consistent with the Integrated Behavioral Model, we recognize the importance of bolstering the linkage between intention and behavior to use their safety plan. To support this linkage, STARS will focus on three major skill sets: (1) self-management skills (eg, setting and enacting goals to promote positive affect), (2) social skills (eg, elicitation of social support), and (3) personal skills (eg, coping with discrimination more effectively and seeking safe spaces). With the support of peer mentors, EA-SGM groups can set goals to shift their sense of mastery (to improve positive affect), engage with a community that understands their needs (to improve social connection), and identify local resources that support their well-being (to improve coping and reduce the impact of discrimination on their well-being). Finally, STARS will promote the use of the safety plan by equipping peer mentors to discuss barriers to enacting the safety plan.

STARS will address theoretical mechanisms that can reduce the severity of suicidal ideation, including coping with discrimination and improving social support. STARS additions will include a module about promoting positive affect through behavioral activation, pleasant events scheduling, and safety plan content. STARS will address constructs of self-efficacy, knowledge, and attitudes about safety planning.

Figure 1. Conceptual model. STARS: Supporting Transitions to Adulthood and Reducing Suicide.

Intervention Components

STARS uses traditional multitier architecture in which the concerns are separated into presentation, service, and database *layers*. The administrative portal was written in React (Meta Platforms), whereas the mobile app is written in React Native, which allows us to build native apps for both Android and iPhone, reusing approximately 90% of the code between the 2 operating systems. Table 1 presents brief descriptions of the core components of STARS, aligned with the theoretical underpinnings for addressing stigma and changing behavior.

The adaptation of the existing iREACH content was guided by ADAPT-ITT (Table 2). The ADAPT-ITT model was developed to adapt evidence-based practices for circumstances or populations outside those included in the evidence base. The ADAPT-ITT model includes 8 phases. These include assessment, decision, adaptation, production, topical experts, integration, training, and testing. This framework is useful because implementation of evidence-based practices often requires modification to the innovation [53]. Following a framework such as ADAPT-ITT can speed the process of adaptation, while incorporating feedback from peer mentors and a technical expertise group (TEG) with expertise in LGBTQ+ health, youth development, and suicide prevention.

From September 2021 to September 2022, the team met weekly to review the existing content and features on the platform to identify the required modifications, to ensure readiness for the implementation of the pilot test (*assessment*). During the *decision* stage, we reviewed evidence-based practices and identified the components that were ready for adoption and those that needed to be adapted. For example, although SPI did not require adaptation, the research team built SPI into the app for STARS. We revised the iREACH content and interactive activities to address suicide prevention and reinforce EA-SGM groups' social support, coping with discrimination, and positive affect. Our review included both text and imagery and video content within the platform to ensure developmentally appropriate, contextually relevant, and culturally sensitive alignment with EA-SGM groups. Over the following months, the research team met weekly to discuss the features, design, and engagement desired within STARS *(administration)*. During these discussions, we reflected about whether the platform met the desired expectations for design and ease of use and

XSL•FO
RenderX

incorporated feedback regarding its content and layout accordingly (Multimedia Appendices 2-6).

Table 2. Modifications to the intervention content using the assessment, decision, administration, production, topical experts–integration, training, and testing framework (8 steps).

Phase	Procedures
Assessment (months 1-8)	• Obtain iterative feedback about content adaptation from the research team and technical expertise group
Decision (months 2-8)	• Review the information obtained from the assessment and draft the revised intervention content (text, video, and activities) and measures
Administration (month 9)	• Elicit feedback through iterative testing and feedback cycles • Address reactions and make modifications
Production (months 2-12)	• Balance priorities while maintaining fidelity to core elements and underlying theoretical framework
Topical experts (month 10)	• Elicit expert review of the final curriculum and activities
Integration (months 11-12)	• Integrate content from experts and conduct readability tests • Translate curricula into a mobile platform
Training (months 11-12)	• Beta test the study procedures, recruit peer mentors, and train the staff • Begin recruitment for pilot testing
Testing (months 18-36)	• Pilot-test the intervention with 60 emerging adult sexual and gender minority individuals • Collect implementation and preliminary efficacy data • Analyze the data

During the *production* phase, our technical partner produced instances of the app based on the elicited feedback and began to iteratively test for platform stability, identification of bugs requiring modification, and ability to track engagement metrics. The test environment looked as similar to production as possible, so that changes and bug fixes could be tested and reliably expected to work when promoted to the production environment. The research team used the beta versions of STARS for internal usability testing. We worked with our technology partner to finalize the app and ensure its security using industry best practices.

Our TEG served as *topical experts*, offering their subject matter expertise on the content and activities incorporated into the app. After the TEG provided written comments, we integrated their comments and tested the readability of the finalized content using the Flesch-Kincaid Readability Test (average score 6.98, SD 1.8) [61].

During the *integration* stage, the research team worked with the technical partner to make the final refinements and modifications before launching the production server. We reviewed the production server instance to ensure that the layout works with different mobile devices and browser platforms as intended and that all data are captured and saved in the server as planned.

During the *training* stage, the research team worked on reviewing the study-related procedures and finalizing the protocols' operations manual. The recruiters were trained to fidelity in the process of describing the study to EA-SGM individuals who call to inquire about participation and suicide risk assessment as potential participants will indicate previous suicidal ideation in the past month. Research team members were trained in data management, which includes securely storing data, data protection, and proper data collection. All staff were trained in accordance with National Institutes of Health standards on recognizing and reporting adverse events.

The research team also finalized the peer mentor modules and began the recruitment and training of peer mentors using the existing training and fidelity protocols (Multimedia Appendix 1). STARS relies on peer mentors as care navigators to provide social support, reduce the impact of discrimination, connect youth to safe spaces, remind them to use their safety plan at the beginning and end of every session, and brainstorm and implement solutions to overcome obstacles to its use. For example, at each session, the peer mentor will check in on whether the participant used their safety plan and inquire about how it went, about barriers to its use or efficacy, and about whether any changes are needed to the safety plan. This approach offers a confidential and user-controlled opportunity to support EA-SGM groups in their transition to adulthood.

Peer mentor positions were posted on the web; applicants were asked to provide their curriculum vitae and a 1-paragraph description of any previous experiences with or interest in working with LGBTQ+ emerging adults (aged 18-24 years). This allowed for the selection of candidates who would be suitable as peers for the project. Once selected, peer mentors completed 12 hours of training with a licensed clinical psychologist, which included didactics, modeling, role-plays with feedback, and discussions about difficult topics that might emerge outside the planned content. Following training, they attended weekly group supervision for 1 hour. Peer mentors were trained to conduct 6 sessions (which were audio recorded) with participants to provide social support, reduce the impact of discrimination, promote positive affect, and reduce barriers to enacting the safety plans (refer to the peer mentor manual in

XSL•FO
RenderX

Multimedia Appendix 1 for additional details). Staff identified measures of fidelity specific to each peer mentoring session that were assessed for each audio-recorded session. Peer mentors were paid on an hourly basis.

The peer mentors do not conduct SPI, but they help participants brainstorm ways to overcome obstacles to using SPI. Peer mentors receive booster trainings every 2 months to reinforce their skills and respond to emerging challenges [62]. Peer mentors' proficiency is monitored via audio-recorded role-plays using standard coding protocols. Peer mentor sessions occur on a Health Insurance Portability and Accountability Act–compliant telehealth platform.

Testing

The final ADAPT-ITT phase evaluates the intervention in a pilot trial described in the following section. A randomized clinical trial (N=60) is recruiting individuals aged 18 to 24 years who identify as sexual or gender minorities and who report past-month suicidal ideation. After completion of an interest survey and phone screening, participants complete a comprehensive eligibility assessment in person with a licensed clinician. All eligible participants complete SPI in an original, unadapted format. Then, participants are randomized to either the STARS or control group. The control group completes assessments, which include a survey and an interview, every 2 months (2-, 4-, and 6-month follow-up). Participants in STARS meet with a research assistant to download and complete an orientation to the STARS app and to schedule the peer mentoring sessions, conducted virtually. The STARS participants then complete the same assessment as the control group (at 2, 4, and 6 months). User data are collected from the STARS app, as is feedback from the peer mentors about the way that time was spent in their sessions.

Sample Size and Power Analysis

We plan to recruit 60 EA-SGM participants. A power analysis in Repeated Measures with Attrition: Sample Sizes for 2 Groups (5% attrition at each time point; 2-sided test; r=0.50 between tests; Cronbach α=.05; power=0.80) suggested that we would need 29 participants per group to detect a medium between-group effect size on suicidal ideation (Cohen d=0.60). Previous studies found that crisis response planning (a type of safety planning) had a between-group effect size ranging from 0.0 to 0.7 (at the 1-, 3-, and 6-month follow-up) compared with contracting for safety [39]. We anticipate that with the addition of important skills (coping with discrimination, social support, and positive affect) and peer support, a medium effect size improvement in suicidal ideation over safety planning alone is realistic and clinically meaningful.

There is controversy regarding the use of "pilot data" to estimate actual effect sizes [63]. The primary goal of this project is to determine our intervention's reach, feasibility, acceptability, and its implementation fidelity. Our secondary goal is to ensure that the critical parameters required to plan efficacy targets within a large trial are estimated. We seek to estimate key study parameters with sample means and proportions together with 2-sided 95% CIs and test the primary null hypotheses at the traditional 2-sided level α=.05. These data can help rule out unusually large or small effects by confirming that extrinsic effect sizes are contained within our CIs and help inform a future efficacy trial.

Engagement and Retention

Retention

We will make all efforts to retain consented participants. Our study retention plan draws on previously successful retention protocols to achieve at least an 80% retention rate. It is critical to obtain accurate follow-up contact information. We will use best practices to retain participants (eg, comprehensive locator information that includes participants' mobile phone number, email, Facebook and Twitter username, and contact information about 2 peers who could help us contact them), while being sensitive to undue disclosure of EA-SGM individuals participating in the study.

We also have a planned schedule of follow-up that consists of a variety of follow-up methods. Short time (2 months) between assessments will help us quickly address retention issues. A study-specific home page allows study staff to monitor participant progress at a glance, viewing steps or phases in the dashboard filtered by conditions such as record status, intervention arm, last log-in to the app, and so on. This dashboard facilitates participant retention via prompts to study staff to reach out to participants who have missed a specified number of study activities and by providing a secure platform to communicate with staff and deliver participant incentives. At each follow-up assessment, participants can update their contact information. This allows us to remain connected with participants and facilitates the delivery of reminders regarding upcoming study procedures.

Initially, a participant who does not respond to an electronic notification that a survey is due will automatically receive additional notifications 36 hours after the initial notification. If the participant has still not completed the assessment 24 hours after the third electronic notification, a research staff member will escalate contact intensity. Depending on the participant's preferences provided upon registration, they will be contacted initially through the preferred mode of recontact (eg, via SMS text message); if still unresponsive, other available modes (eg, phone call) will be used. Each contact is logged in an electronic retention system.

Incentives

Participants will be followed for 6 months after enrollment. We have designed our incentive schedule to encourage the completion of study assessments, in that after the baseline assessment, which is in person and for which participants are compensated US $50, each of the subsequent assessments pays the participant at an increasing rate to encourage them to complete future assessments. They will be compensated US $30 for completing the 2-month assessment, US $40 for the 4-month assessment, and US $50 for the 6-month assessment. This incremental compensation has proven highly effective in our previous cohorts. Neither our institutional review board (IRB) nor previous advisory boards have found this amount of incentive to be coercive. Rather, they have found it commensurate with what would be expected to compensate

XSL•FO
RenderX

participants if they were engaged in face-to-face and web assessments that are similar in duration.

Outcomes

Overview

Assessments will be conducted on the web using REDCap (Table 3). All participants will complete web surveys every 2 months (2-, 4-, and 6-month follow-up surveys), which are similar to the baseline survey they completed in person.

Table 3. Measures for primary and secondary outcomes.

Outcome	Measures
Recruitment	
Recruitment and enrollment (Reach)	Advertisement and screening metrics
Primary outcomes	
Suicidal ideation (efficacy)	Columbia–Suicide Severity Rating Scale; Severity of Suicidal Ideation Subscale [57] (primary outcome); Intensity of Ideation Subscale (secondary outcome); Suicidal Behavior Subscale (secondary outcome); at baseline, we will assess lifetime and past-month suicidal thoughts and behaviors; and at follow-up assessments, we will assess suicidal thoughts and behaviors in the past 2 months
Secondary outcomes	
Safety Planning Intervention and STARS[a] app willingness (adoption)	Self-report of willingness to use and satisfaction with the Safety Planning Intervention and the STARS app and Short Intervention Evaluation Form [64]
Safety plan and STARS app use (participant implementation)	Self-reported use of the safety plan, STARS app log-in sessions, app session length, pages visited, and activities completed
STARS fidelity (peer mentor implementation)	Peer mentor session adherence and competence
Retention (maintenance)	Completion of evaluations
Expert and peer mentor perceptions (maintenance)	Qualitative interviews with the youth action group and technical expertise group
Mechanisms of action	
Social support and isolation	5-Item Scale of Parental and Peer Support [65], Interpersonal Needs Questionnaire–Reduced [66], and UCLA Loneliness Scale [67]
Positive affect	PANAS[b]-positive [68,69]
IBM[c] targets	Attitudes, norms, self-efficacy, and intentions to use safety planning [70]
Coping with discrimination	Coping with Discrimination Scale [71,72] and sexuality-related stressors [73]
Covariates	
Sociodemographics	Demographics and technology use [74]
Sexual behavior	Sexual Practices Assessment Schedule [21,75]
Alcohol and drugs	Alcohol Use Disorder Identification Test [76] and Alcohol, Smoking, and Substance Involvement Screening Test [77]
Homonegativity	Internalized homonegativity scale [78]
Gender-related stigma	Gender minority stress and resilience rejection subscale [79]
Perceived stress	Daily hassles over the past month [80]
Discrimination	Everyday Discrimination Scale [81,82]

[a]STARS: Supporting Transitions to Adulthood and Reducing Suicide.

[b]PANAS: Positive and Negative Affect Schedule.

[c]IBM: Integrated Behavioral Model.

Primary Outcomes

The RE-AIM framework guides our selection of efficacy and implementation indicators. Consistent with the type-1 hybrid design, the primary goal of our pilot study is to identify key indicators of preliminary efficacy, with a secondary goal of describing the implementation context.

Reach

We will track advertisement impressions (clicks, cost/click, and click-through rate), screening (number of participants who were

XSL•FO
RenderX

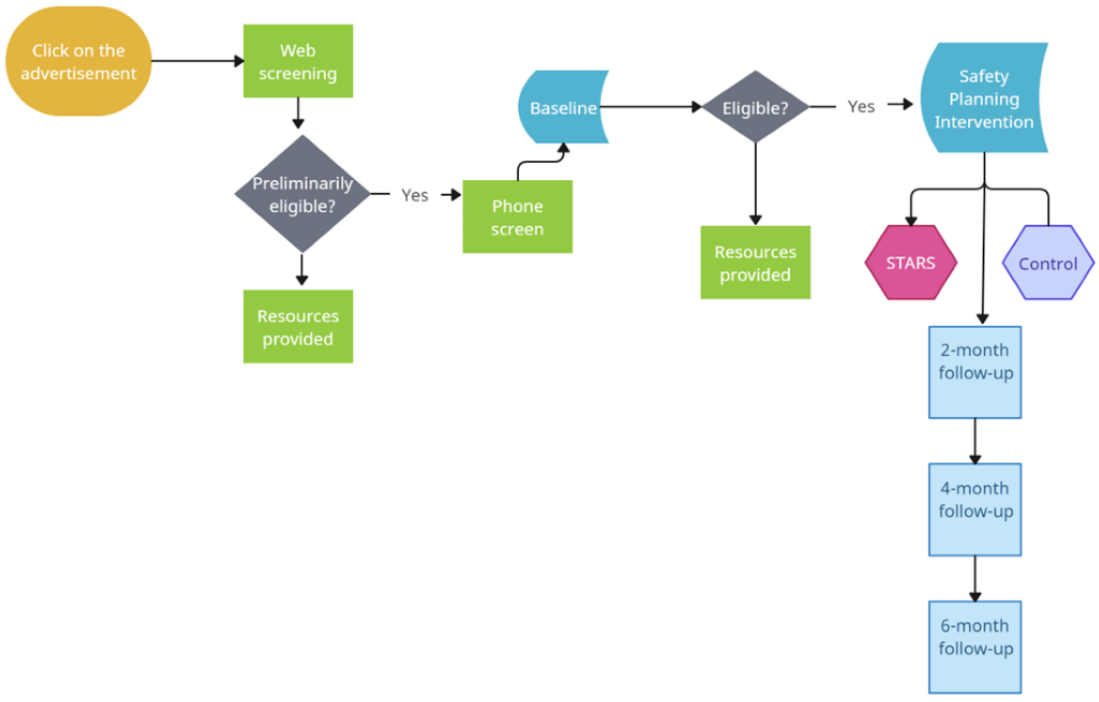
screened, were eligible, and provided contact information and cost/eligible contact), and enrollment metrics (number of eligible participants who attend in-person visits and enroll). We will document the reasons for refusal among eligible individuals. We will compare reach across social media platforms.

Efficacy

The C-SSRS is a clinician-rated interview measure of the severity of suicidal ideation (primary outcome), intensity of ideation (secondary outcome), and suicidal behavior (secondary outcome) with strong psychometric properties that will be our primary efficacy indicators [57].

Adoption

We will evaluate changes in the intention to use the safety plan from baseline through all follow-up assessments. We also will examine satisfaction with and perceived usefulness of the components in their assigned arm. Participants will also complete the Short Intervention Evaluation Form [64] to elicit information about their experience (ie, was the intervention interesting, was it relevant, or did they learn from the intervention). For STARS participants, we will evaluate self-reported intention to use the STARS app and satisfaction with the app.



Implementation

To assess intervention engagement by *participants*, we will measure counts of log-in sessions to the app, app session length, pages visited, activities completed, and other functions used within the app, which can indicate intervention dosage. We will also collect the number, frequency, and duration of peer mentor sessions that participants requested and attended and assess self-reported frequency of use of the safety plan in both conditions. *Peer mentors* will complete a case report form after each session to document the topics discussed. Procedures for monitoring intervention adherence and competence include audio recording all sessions and coding for clinical skill or competence. We will interview the *youth advisory group, TEG, and peer mentor members* for their reflections about lessons learned, insights into potential modifications, and experienced challenges and opportunities gleaned during implementation. Semistructured interviews will ask about the intervention adaptation process and perceived impact of the intervention. Interviews will last 30 minutes, will be audio recorded, and transcribed. We will create a codebook of a priori and emergent themes including operational definitions of all codes and sample quotations. Then, 2 study team members will independently code the data; a third team member will review the coded sections and resolve discrepancies.

Maintenance

We will monitor retention over time as a marker of maintenance, with a criterion of ≥80% retention at the 6-month follow-up (refer to Figure 2 for the timeline). We will compare those who are lost to follow-up with study completers across baseline scores based on our key efficacy indicators and sociodemographic characteristics.

Figure 2. Timeline for participation. STARS: Supporting Transitions to Adulthood and Reducing Suicide.

Mediators of Intervention Effects

We will also measure mechanisms of action (Integrative Behavioral Model targets [70], social support, positive affect, and coping with discrimination) and key demographic and behavioral covariates.

Social Support

Social support from parents and friends will be measured separately using a 5-item emotional support scale, with items rated on a 5-point scale. The measure has strong convergent and divergent validity, test-retest reliability, and internal

XSL•FO
RenderX

consistency. Participants will complete the UCLA Loneliness Scale [67], a 20-item measure of subjective experiences of loneliness, with items rated on a 4-point scale, reflecting the frequency with which a participant feels a particular way (often, sometimes, rarely, or never). The measure has strong convergent and divergent validity, test-retest reliability, and internal consistency. The Interpersonal Needs Questionnaire–Reduced [66] is a 15-item measure of perceived burdensomeness and thwarted belongingness. The measure has strong psychometric properties, including measurement invariance, divergent and convergent validity, and ability to predict future suicidal ideation.

Positive Affect

The Positive and Negative Affect Schedule–Positive Affect subscale [68] is a 10-item measure of positive affect over the past week, including enthusiasm, interest, determination, excitement, inspiration, alertness, activity, strength, pride, and attentiveness. Each item is rated on a Likert scale ranging from 1 (very slightly or not at all) to 5 (extremely). The Positive and Negative Affect Schedule has strong internal consistency and convergent and divergent validity.

Integrative Behavioral Model Questionnaire for Safety Planning

We will measure attitudes, norms, self-efficacy, and intentions regarding adoption of the safety plan using an adapted version of the Theory of Planned Behavior Questionnaire [83]. The measure has strong psychometric properties, including high reliability and validity.

Coping With Discrimination

The Coping with Discrimination Scale [71] is a 41-item measure assessing internalization (10 items), disengagement (5 items), drug and alcohol use (5 items), support seeking (5 items), resistance (6 items), resilience (6 items), and education or advocacy (8 items). Participants respond to these items using 6 response options, ranging from 1 (never like me) to 6 (always like me). Instructions for the measure are as follows: “This is a list of strategies that some people use to deal with their experiences of discrimination. Please respond to the following items as honestly as possible to reflect how much each strategy best describes the ways you cope with discrimination. There are no right or wrong answers.”

Covariates

We will measure the following constructs as covariates: sociodemographics (age, race and ethnicity, education, employment, income, sexual orientation, sex assigned at birth, and gender identity), sexual behavior, alcohol and drug use, internalized homonegativity, experiences of everyday discrimination, and perceived stress. These measures are presented in Table 3.

Statistical Analysis

Before conducting our multivariate analyses, we will examine the study variables using descriptive statistics and test for differences across demographic characteristics (eg, race and ethnicity, age, and education) using 2-tailed *t* tests, ANOVAs, and chi-square tests, as appropriate. As participants will be randomized to the 2 treatment groups, systematic baseline differences are not expected; however, if some parameters differ across conditions at baseline, they will be included as covariates in subsequent multivariate models. We will calculate descriptive summary statistics corresponding to the study variables at each visit to understand any temporal patterns and compare the 2 treatment groups in terms of average change from baseline after intervention (averaged across all 3 follow-up times).

In its simplest form, under the assumption of equivalence between the 2 randomized groups, we will compare differences from baseline to the 6-month outcomes across our outcome measures using 2-tailed *t* tests, ANOVAs, and chi-square tests, as appropriate. For repeated measures analyses, we will use the general framework of generalized linear mixed models to model the longitudinal outcomes. We will compare differences across the groups over time based on the C-SSRS suicidal ideation subscale, social support (a composite measure of the 5-Item Scale of Parental and Peer Support, Interpersonal Needs Questionnaire, and University of California, Los Angeles Loneliness Scale), coping with discrimination (a composite measure of Coping with Discrimination Scale and a measure of sexuality-related stressors), and positive affect (Positive and Negative Affect Schedule–Positive), noting that we will not be powered to detect differences in suicidal behavior; however, we will have sufficient power to detect changes in the severity of suicidal ideation. We will evaluate the preliminary evidence for associations between change in intervention targets, mechanisms, and suicidal ideation or behavior. We will examine differences in the rate of use of the safety plan and in retention by condition, and we will examine whether paradata from STARS (ie, frequency of peer mentoring sessions and using the app) correlate with safety plan use.

Missing Data

We will compare those who are lost to follow-up with study completers across baseline scores based on our key efficacy indicators (C-SSRS suicidal ideation and suicidal behavior subscales, social support, coping with discrimination, and positive affect) and on sociodemographic characteristics using linear regression. Web-based entry for all measures will help reduce missing data. We will manage missing data by applying likelihood-based methods that include partial information about participants who drop out prematurely and develop nonresponse adjustment and poststratification weights to account for survey nonparticipation. The use of expectation-maximization algorithm and multiple imputation approach in longitudinal analyses will help overcome missing data concerns when appropriate. When the missing-at-random assumption is not supported, we will not replace missing data to avoid bias.

Ethics Approval

The human participants’ considerations presented in this protocol are approved by the IRB of the University of Pennsylvania (protocol number 849500).

Results

This project began in September 2021. Preliminary study activities (eg, obtaining IRB approvals, hiring and training staff,

XSL•FO
RenderX

and developing the study protocol and study-specific procedures) were completed in September 2022. During this period, we also worked with our technology partner (One Cow Standing), our youth advisory group, and a TEG to update and expand the intervention content related to suicide ideation; finalized and programmed all study tools; and established robust recruitment, retention, and engagement plans. Recruitment began in October 2022; we anticipate completing recruitment by September 2023. Final participant follow-up will be completed by February 2024, followed by data analysis. Study results will be disseminated in 2024.

Discussion

Summary

The proposed project is innovative in 3 ways. First, although evidence-based life skills programs target diverse racial and ethnic and urban or rural youth [84,85], to the best of our knowledge, ours will be the first life skills intervention designed to reduce suicide risk among a diverse sample of EA-SGM groups who are at risk for suicide by promoting positive affect, coping with discrimination, and improving social support. Although a study found that interventions targeting positive affect reduced suicidal ideation to a greater extent than those targeting negative affect [86], this has not been demonstrated among EA-SGM groups. Second, we will be among the first to tailor and study the effects of an e-delivered life skills intervention to reduce EA-SGM groups' suicidal ideation and behavior among sexual minorities. The life skills app will deliver tailored and interactive content and reinforce it with peer mentor support. Third, our intervention acknowledges that EA-SGM groups might require ongoing support in enacting their safety plan and leverages our previous success in teaching motivational interviewing to young lay workers to facilitate care navigation and support of vulnerable youth. The peer mentors' ongoing support in problem-solving obstacles to the use of the safety plan and reminding EA-SGM individuals to use their safety plan will serve as key implementation strategies to enhance the impact of this intervention.

Principal Contributions to the Field

In light of the difficulty in using "pilot data" to estimate effect sizes [63], the primary goal of this project is to determine STARS' reach, acceptability, and implementation fidelity. Our secondary goal is to estimate the critical parameters required to plan efficacy targets within a large trial. Although we anticipate having adequate power to determine the effects on suicidal ideation, we will not be powered to determine the effects on suicidal behavior, which will be the goal of a fully powered future R01. These data can help rule out unusually large or small effects by confirming that extrinsic effect sizes are contained within our CIs [63] and help inform a large-scale version of the intervention to test its efficacy in reducing suicidal ideation and behavior among EA-SGM groups.

Acknowledgments

The authors would like to acknowledge the members of their Community Advisory Board. The authors would also like to acknowledge the members of their technical expertise group. This project was supported by the National Institutes of Health (P50 MH127511; multiple principal investigators: GKB and MO).

Data Availability

Data will be deposited in the National Institutes of Health data repository.

Conflicts of Interest

GKB and MO receive royalties for the commercial use of the Columbia–Suicide Severity Rating Scale from the Research Foundation of Mental Hygiene Inc. MO serves as an advisor to Alkermes, Mind Medicine, Sage Therapeutics, St George's University, and Fundación Jimenez Díaz. Her family owns stock in Bristol Myers Squibb.

Abstract

Background: Achieving the weekly physical activity recommendations of at least 150-300 minutes of moderate-intensity or 75-150 minutes of vigorous-intensity aerobic exercise is important for reducing cardiometabolic risk, but evidence shows that most people struggle to meet these goals, particularly in the mid to long term.

Objective: The Messages Improving Resting Heart Health (MIRTH) study aims to determine if (1) sending daily motivational messages through a research app is effective in improving motivation and in promoting adherence to physical activity recommendations in men and women with coronary heart disease randomized to a 12-month intensive lifestyle intervention, and (2) the time of the day when the message is delivered impacts compliance with exercise training.

Methods: We will conduct a single-center, microrandomized trial. Participants will be randomized daily to either receive or not receive motivational messages over two 90-day periods at the beginning (phase 1: months 4-6) and at the end (phase 2: months 10-12) of the Lifestyle Vulnerable Plaque Study. Wrist-worn devices (Fitbit Inspire 2) and Bluetooth pairing with smartphones will be used to passively collect data for proximal (ie, physical activity duration, steps walked, and heart rate within 180 minutes of receiving messages) and distal (ie, change values for resting heart rate and total steps walked within and across both phases 1 and 2 of the trial) outcomes. Participants will be recruited from a large academic cardiology office practice (Central Sydney

XSL•FO
RenderX

Cardiology) and the Royal Prince Alfred Hospital Departments of Cardiology and Radiology. All clinical investigations will be undertaken at the Charles Perkins Centre Royal Prince Alfred clinic. Individuals aged 18-80 years (n=58) with stable coronary heart disease who have low attenuation plaques based on a coronary computed tomography angiography within the past 3 months and have been randomized to an intensive lifestyle intervention program will be included in MIRTH.

Results: The Lifestyle Vulnerable Plaque Study was funded in 2020 and started enrolling participants in February 2022. Recruitment for MIRTH commenced in November 2022. As of September 2023, 2 participants were enrolled in the MIRTH study and provided baseline data.

Conclusions: This MIRTH microrandomized trial will represent the single most detailed and integrated analysis of the effects of a comprehensive lifestyle intervention delivered through a customized mobile health app on smart devices on time-based motivational messaging for patients with coronary heart disease. This study will also help inform future studies optimizing for just-in-time adaptive interventions.

Introduction

Background and Rationale

Physical activity has been widely recognized as an effective intervention for improving cardiometabolic health [1,2]. Regular endurance exercise has been shown to reduce body weight and visceral adiposity, improve insulin sensitivity and glucose tolerance, lower blood pressure, and enhance lipid metabolism, all of which contribute to the prevention and management of atherosclerotic cardiovascular disease [3-6]. However, achieving sufficient compliance with physical activity recommendations poses a significant challenge, which can be attributed to various factors, including lack of motivation, skills, resources, and limited access to exercise facilities, among others [7].

The emergence of new technologies and digital products such as wearable devices, mobile apps, and mobile health (mHealth) platforms offers the potential for the delivery of customized educational and motivational material, which may increase compliance with physical activity interventions [8]. Smartphones and mobile apps are the first and second most frequently used digital products in clinical research [9], and with other sensors connected to digital platforms, are increasingly becoming an integral part of daily health care routine [10].

Passive monitoring of health parameters can be accomplished using wearable devices, which allow for nonintrusive data collection [11]. These technologies allow for the gathering of real-time data, the tracking of progress, and the delivery of messages that are timed to align with a person's daily routines and patterns of activity. This can provide a personalized and targeted approach to physical activity, which can help individuals be more motivated and engaged in regular physical activity [12,13]. To explore this further, we have designed a microrandomized trial (MRT) to investigate the impact of delivering motivational messages at different times of the day targeting physical activity compliance, duration, and intensity.

An MRT is a cutting-edge trial design for mHealth research. A unique feature of an MRT is that an individual can be repeatedly randomized multiple times throughout the duration of the study [14,15]. The overall aim is to fine-tune the mHealth intervention by analyzing the effects of the different intervention components (eg, behavioral prompts) on the activities of the participant (eg, physical activity compliance; Textbox 1). This random sequence within and between participants constitutes an MRT [16,17], with most MRTs contributing to the development of just-in-time adaptive interventions (JITAIs). JITAIs aim to deliver appropriate support tailored to individuals' needs at the precise moment it is needed [18,19].

RenderX

Textbox 1. What are the benefits of randomizing a participant multiple times over the duration of this trial?

Microrandomized trials (MRTs) are unique clinical trial designs suitable for studying interventions using mobile health technologies. They randomize interventions at multiple time points, allowing for dynamic treatment investigation. Key features include fine-grained granularity, personalization, and sequential decision-making. MRTs provide additional information such as temporal dynamics, contextual effects, individual response patterns, and treatment adaptation. These trials offer insights into personalized and effective interventions in the mobile health context.

The unique experimental design of an MRT allows for capturing data with the aim of developing sharp decision-making tools or rules for fine-tuning the sending of messages as notifications. The ability to randomize a participant multiple times in an MRT gives it its distinctive characteristic, which is not present in a traditional parallel-group randomized control trial, thereby allowing us to study:

- the effects of the intervention multiple times over a given time period;
- if the motivational messages sent as notifications have any near-term effect on engagement with the intervention components over the duration of the study;
- if this near-term effect changes over the two 90-day study periods; and
- if the effects of the motivational messages in phase 1 are similar to those in phase 2, thereby having a long-term effect.

Through analyzing the data from above, researchers will be able to optimize just-in-time adaptive interventions more effectively for notification delivery through apps encouraging physical activity in patients with coronary heart disease.

The main purpose of the Messages Improving Resting Heart Health (MIRTH) study is to determine if (1) sending daily customized motivational messages through a research app improves motivation and engagement with physical activity recommendations in men and women with coronary heart disease randomized to a 12-month intensive lifestyle intervention, and (2) the time of the day when the message is delivered impacts compliance with exercise training. This trial will be a crucial step in determining the potential of technology to support people in their efforts to maintain a physically active lifestyle, which can have a significant impact on the prevention and management of cardiometabolic abnormalities and atherosclerotic cardiovascular disease.

The primary objective of this study is to evaluate the immediate effectiveness of motivational messages aimed at promoting physical activity in adults with stable atherosclerotic cardiovascular disease. The secondary objectives include assessing the impact of message delivery time (ie, 6 AM, 11 AM, or 3 PM) on the immediate effectiveness of the intervention and investigating its long-term effectiveness over a 12-month period by comparing results at the midpoint and end of the study.

The primary hypothesis is (1) that participants will demonstrate an increase in steps taken within 180 minutes of receiving motivational messages compared to those who do not receive the messages. The secondary hypotheses are (2) that participants will exhibit an increase in physical activity duration and heart rate within 180 minutes of receiving motivational messages compared to those who do not receive the messages; (3) the proximal effect sizes of message are different at different times of a day (ie, 6 AM, 11 AM, or 3 PM); and (4) that there will be no difference in long-term outcomes between phase 1 (months 4-6 of the Lifestyle Vulnerable Plaque Study [LIVEPLUS]) and phase 2 (months 10-12 of the LIVEPLUS) of the study.

Previous Work

In the HeartSteps MRT study, research volunteers randomly received, through an app, contextually tailored physical activity notifications delivered up to 5 times per day at user-selected times [20]. During the 6-week trial, the implementation of a physical activity notification resulted in a significant 24% increase in average step count compared to no suggestion. However, the effect was not consistently maintained throughout the study, with higher compliance observed primarily at the beginning. Similarly, the 6-week DIAMANTE student study [21] demonstrated that motivational text messages based on a cognitive-behavioral approach led to a significant increase in daily step count, although the effect diminished over time. These findings highlight the need for further research to investigate the potential advantages of incorporating personalization and contextualization in text-messaging interventions, aiming to enhance the effectiveness of physical activity promotion [21]. Aguilera et al [22] explored the effects of text messages in alleviating depression and anxiety symptoms during the COVID-19 lockdowns in the United States in the StayWell at Home study. The study revealed a positive association between engagement in a text-messaging program rooted in cognitive-behavioral principles and the amelioration of depression and anxiety symptoms associated with the COVID-19 pandemic. The program involved the delivery of 2 messages per day over a period of 60 days and demonstrated significant engagement and effectiveness in enhancing mental well-being. These findings suggest that text-messaging interventions, when used as a standalone component of a comprehensive program, have the potential to serve as a valuable tool in public health initiatives targeting mental health concerns, facilitating improved health outcomes through increased engagement with the intervention.

Methods

Study Design

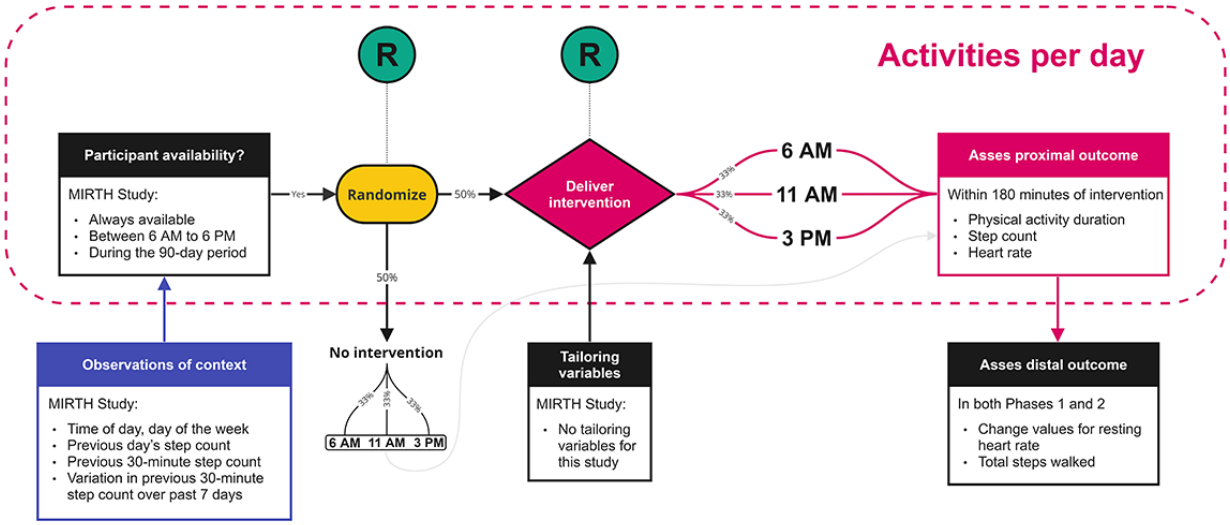
Overview

Figure 1 [23] provides an overview of the study design for the MIRTH MRT study. The intervention period consists of two 90-day periods, which are condensed into phases for the purposes of this protocol. Phase 1 corresponds to months 4-6 of the LIVEPLUS program, while phase 2 corresponds to months 10-12 (Figure 2). Throughout the study, participants are randomly selected at decision time points, which occur at 3 different times of the day: early morning (6 AM), late morning

XSL•FO
RenderX

(11 AM), and early afternoon (3 PM). At the designated time point, each participant is randomly assigned to either receive or not receive the intervention component (motivational message) using a simple randomization method (Multimedia Appendix 1). The randomization process is independent of the participant's allocation from the previous day. To ensure allocation concealment, a central randomization algorithm is used. Computerized sequence generation will be used to conduct participant randomization. Given the nature of the intervention, participants will be aware of the messages they receive. Subsequently, the duration and type of physical activity performed will be evaluated. A research personnel will assist participants in downloading the study app, creating a profile, and providing a brief demonstration of the app's various functionalities. Detailed written instructions, along with a video tour of the app, can be accessed in the app's help section. Screenshots of the app are available in Multimedia Appendix 2.

Figure 1. Microrandomized trial design for the Messages Improving Resting Heart Health (MIRTH) study. Intervention randomization is followed by time randomization, as shown by R. Figure adapted from Golbus et al [23].



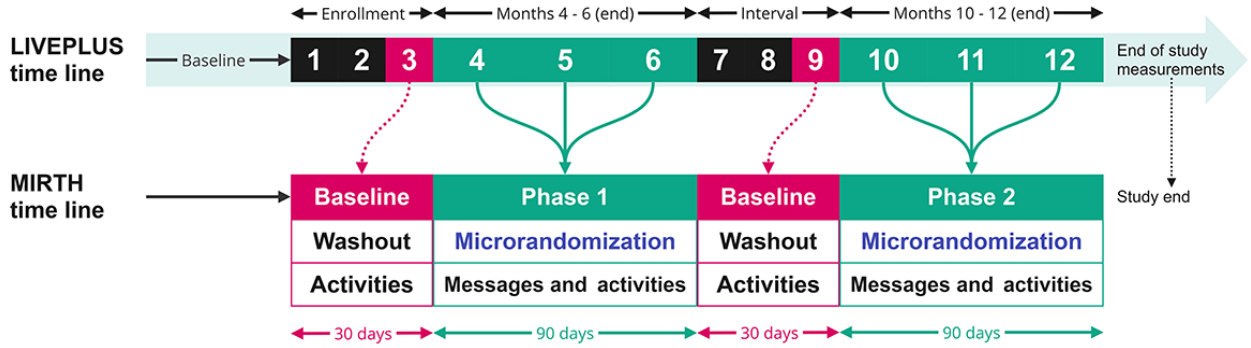


Figure 2. Time line of the Messages Improving Resting Heart Health (MIRTH) study, illustrating the participant flow and duration for each phase aligned with the Lifestyle Vulnerable Plaque Study (LIVEPLUS) time line. Baseline data collection for the MIRTH study will occur over a period of 1 month (30 days) at the ends of months 3 and 9 of the LIVEPLUS intervention. The collected data will include various metrics such as the average daily step count, duration, and heart rate from 6 AM to 6 PM. Additionally, we will also collect the average weekly physical activity duration. Activities refer to the LIVEPLUS component of the intervention (end-of-study measurements assessed at the end of month 12).

Study Population

The study will recruit adults aged 18-80 years with stable heart disease who have undergone a clinically indicated coronary computed tomography angiography scan at Royal Prince Alfred Hospital in Sydney, New South Wales, Australia, as previously described [24]. Only individuals with a confirmed positive diagnosis of a low attenuation plaque (quantifiable plaque within the –30 to 150 HU range) by 2 independent clinicians or researchers will be contacted for potential participation. Before collecting any participant data, informed written consent will be obtained. Volunteer self–opt-in will not be considered eligible for participation in the study.

Key Inclusion and Exclusion Criteria

The criteria listed in Textbox 2 were followed in selecting participants for the study.

XSL•FO
RenderX

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria:

- Intervention group participants from the Lifestyle Vulnerable Plaque Study (Australian New Zealand Clinical Trials Registry ACTRN12620001151921)
- Adults who have access to and can competently use a smartphone (running iOS or Android)
- Presence of low-attenuation plaque on coronary computed tomography angiography
- aged 18-80 years
- BMI≥22.0 kg/m^2
- Have no contraindications for the Lifestyle Vulnerable Plaque Study
- Able to provide full, informed consent

Exclusion criteria:

- History or clinical manifestation of any other significant metabolic, hematologic, pulmonary, cardiovascular, gastrointestinal, neurologic, immune, hepatic, renal, or urologic disorders, or cancer that, in the opinion of the investigator, would make the candidate ineligible for the study
- Non–magnetic resonance imaging–compatible implanted devices or implants
- Estimated glomerular filtration rate less than 30 mL/kg/1.73 m^2
- Inability to exercise through a supine ergometer
- Claustrophobia
- Contraindications for adenosine: sinus node disease (eg, sick sinus syndrome and symptomatic sinus bradycardia), second- or third-degree heart blocks, unstable angina, bronchospasm (eg, asthma), heart transplant recipient, and history of seizure disorder
- Contraindications for glyceryl trinitrate: known nitrate hypersensitivity, severe anemia, severe aortic or mitral stenosis, and hypotension defined as resting systolic blood pressure equal to 89 mm Hg
- Not suitable for computerized tomography coronary angiography due to contraindications
- Psychiatric or behavioral problems (history of drug and alcohol abuse, eating disorder, etc)
- Breastfeeding or pregnant women, or those intending to become pregnant before the scheduled end of the intervention
- Concurrent participation in any other interventional study

Recruitment

The subsample for this study will be recruited from the intervention group of the LIVEPLUS (Australian New Zealand Clinical Trials Registry ACTRN12620001151921). Participants will be recruited from Central Sydney Cardiology and the Departments of Cardiology and Radiology at the Royal Prince Alfred Hospital in Camperdown, New South Wales, Australia. Eligible patients will be introduced to the study by their cardiologist. The research team will conduct a 30-minute informal web-based (Zoom) call to illustrate the study, which will include a presentation and an opportunity for participants to ask questions.

Baseline Assessment

The collection of participants' physical activity data will occur in a free-living setting, reflecting their daily life activities. The baseline assessment for enrollment into the MIRTH study will be conducted based on the baseline assessment previously described for the LIVEPLUS [24].

Trial Arms

In contrast to traditional randomized controlled trials, the MRT approach in this study enables each participant to serve as their own control. As a result, there is a single group of research participants who are randomly assigned on a daily basis to either the intervention group (receive message) or the control group (no message) in order to provide data.

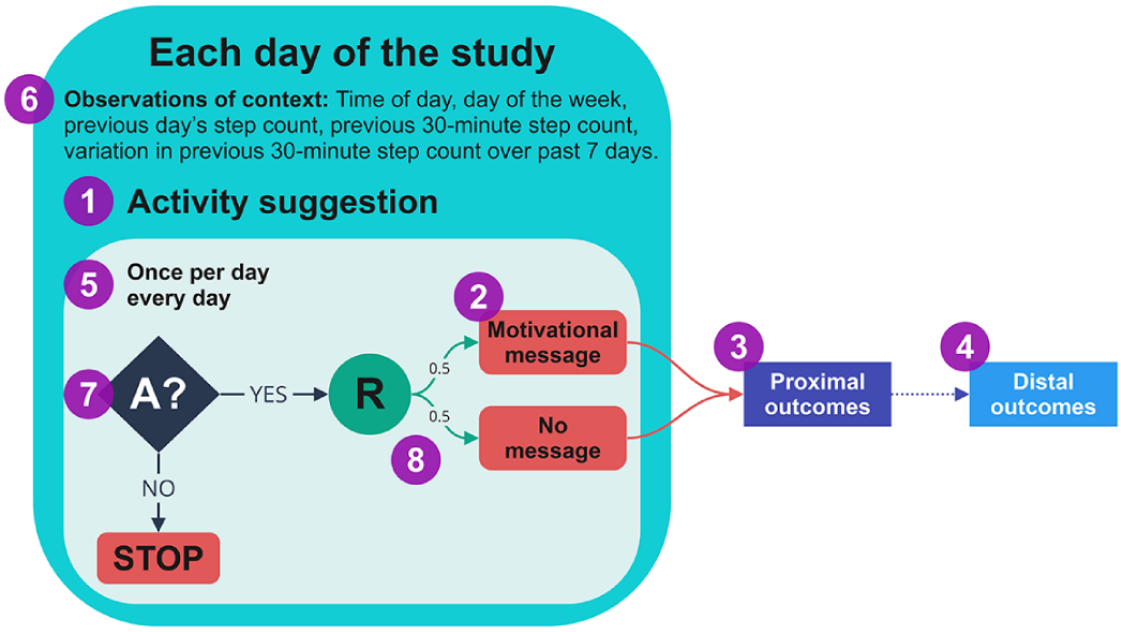
Intervention

Participants in the study will receive messages as app notifications based on a random schedule. Each day during the intervention period, participants will be randomized to either receive or not receive the messages at a designated time point. Some of the messages included in the intervention have been previously used in the DIAMANTE study [25]. Additional messages were created in collaboration with a health psychologist (LA) who specializes in health behavior change. These messages were designed to incorporate various behavior change techniques (BCTs) based on established theories, such as providing information about health consequences, using cues and prompts, and encouraging problem-solving. The selection of BCT was guided by a validated and reliable BCT taxonomy to ensure their effectiveness [26]. Multimedia Appendix 3 provides a comprehensive list of the current messages, along with the BCT they incorporate and whether they target motivation or volition. Moving forward, we intend to expand this message bank using the same principles and guidelines that were used to develop the existing messages.

Examples of MIRTH messages include the following:

XSL•FO
RenderX

1. "Physical activity is a great way to feel better overall, improve your cardiometabolic health, and lift your mood. Aim for at least 30 minutes of walking each day at a medium pace to see the benefits."
2. "Going for a walk can improve your mood and clear your mind."
3. "Can you find 30 minutes in your day to go for a walk? That is less time than it takes to watch one episode of a TV show."
4. "Do not worry if you are not as physically active as others. Focus on you and your own goals. Everyone is different."



We will track participants' activity using the Fitbit Inspire 2 wrist-worn device, which connects to a smartphone through Bluetooth and collect the data using our custom-built LivePulse research app, available only in Australia on the App Store [27] (Apple) and Play Store [28] (Google).

Study Duration

The participant time line consists of 2 intervention periods lasting for 90 continuous days, spanning 4-6 months and 10-12 months (Figure 2). Throughout these intervention periods, participants will be required to wear Fitbit Inspire 2 wrist-worn devices continuously. Baseline data collection will take place for 1 month at month 3 before initiating the intervention for the 4-6–month study period. Another baseline data collection will occur at month 9 (natural baseline) for the 10-12–month study period.

Motivational messages will be randomly delivered to participants allocated to receive the intervention for that day at 3 different time points: 6 AM, 11 AM, or 3 PM (Figure 1). In the MIRTH study, specific exercises will not be prescribed through these messages. Participants have the freedom to choose the type, duration, and intensity of their physical activity. However, through the LIVEPLUS program, participants will receive a home-based program that aligns with the guidelines provided by the American College of Cardiology Foundation and the American Heart Association [29]. The following recommendations will be emphasized: (1) engaging in 30-60 minutes of moderate-intensity aerobic exercise, such as brisk walking, for at least five days, ideally 7 days per week; (2) enhancing daily physical activity through lifestyle activities (eg, taking walks during work, gardening, or household chores); and (3) incorporating resistance training into their routine at least two days per week. The delivery of messages will be monitored using app analytics to ensure successful delivery to participants (Figure 3).

Figure 3. Each day of the Messages Improving Resting Heart Health trial. Please follow the numbers in the figure caption to guide you: (1) intervention component: activity suggestion sent as push notifications to participants' smartphones as motivational messages. (2) Intervention options: motivational message (encouraging physical activity) or no message. (3) Proximal outcomes: physical activity duration, total step count, and heart rate, in the 180 minutes following a decision time point. (4) Distal outcomes: total step count and the change of resting heart rate during each 90-day study period. (5) Decision points: 6 AM, 11 AM, or 3 PM. (6) Observations of context: time of the day, day of the week, previous day's step count, previous 30-minute step count, variation in previous 30-minute step count over past 7 days. (7) Availability: participants are deemed to be always available between 6 AM and 6 PM during the 90-day period. (8) Randomization probabilities: participants who are available at a decision point are randomized with a 0.5 probability to (a) receive or (b) not receive a motivational message.

Outcome Measures

Primary Outcome

The number of steps walked within 180 minutes after either the message or no-message intervention is sent randomly at each decision-making time point (proximal).

Secondary Outcomes

The secondary outcomes are as follows: (1) the duration of time spent engaged in physical activity within 180 minutes after randomization at each decision-making time point (proximal short-term effect); (2) the change in heart rate within the next 180 minutes after receiving either the intervention or no intervention randomly (proximal short-term effect); (3) the

XSL•FO
RenderX

average change values of resting heart rate within and across both phases 1 and 2 (distal long-term effect); and (4) the total number of steps walked within and across both phases 1 and 2 periods (distal long-term effect).

For the proximal analysis, which is based on an MRT design where each participant receives either control or intervention randomly at each selected decision time point over the study period, the proximal effect size of intervention (with-intervention vs without-intervention) is estimated. For the distal analysis, there is no control group; we only observe the total step count (total step counts accumulated over each phase) difference between phases 1 and 2 for each participant.

Statistical Analysis

The effect sizes of the proximal outcome variables will be determined based on improvements in the number of steps (hypothesis 1), physical activity duration, and heart rate (hypothesis 2) observed within 180 minutes following the randomization of messages at each decision time point. To estimate these effect sizes, we will use the weighted and centered least-squares method as proposed by Boruvka et al [30]. This approach is specifically designed for analyzing longitudinal data within the context of an MRT design [20]. The weighted and centered least-squares method used in this study is similar to multilevel models, which account for the nested structure of the data, with daily time points nested within participants. It also shares similarities with the generalized estimating equation method. While there is a within-participant correlation across time in the outcome, the independent working correlation matrix is considered, as the message intervention is a time-dependent factor. This approach leverages sequential randomization to estimate the causal effects of the intervention. The estimated intervention effects are robust and not biased, even when covariates are included to reduce the variance of the estimates.

The regression model used in this study includes several covariates: days in study (ranging from 1 to 90 days), message type (intervention messages versus control), and an interaction term between days and message type. The message variable will be converted into a binary variable (0 for control and 1 for intervention), and it will be centered using the corresponding randomization probabilities (eg, A-0.5, where A represents the binary message variable, with A=1 for intervention and A=0 for control). Different trends over days, such as constant, linear, or quadratic, can be considered to assess the proximal effect of intervention messages in the regression models.

To estimate the proximal effect sizes of messages at different time points (hypothesis 3), we will replace (A-0.5) by $(A-0.5)I_{6AM}$, $(A-0.5)I_{11AM}$, and $(A-0.5)I_{3PM}$ in the regression model. Here, $I_{6AM}=1$ indicates that the participant is randomized to the 6 AM time point, and 0 indicates otherwise.

Our goal is to examine the effect of messages at these specific time points (6 AM, 11 AM, or 3 PM), considering that messages are only received at 1 of the 3 time points. Therefore, assuming a constant trend, we can model the daily steps using the following equation:

$$Y = \beta_0 + \beta_1(A-0.5)I_{6AM} + \beta_2(A-0.5)I_{11AM} + \beta_3(A-0.5)I_{3PM}$$

Where Y=steps; β_0 is the expected number of steps; and β_1, β_2, and β_3 are the proximal effects of messages on steps at 6 AM, 11 AM, and 3 PM, respectively.

The effect size of the distal outcome variables will be assessed using a 2-tailed paired *t* test, assuming that there will be no significant difference in the long-term outcomes between phase 1 and phase 2 of the study (hypothesis 4).

Sensitivity Analyses

Sensitivity analyses will be conducted for hypotheses 1-3, considering the following factors:

1. The intervention's proximal effect size will be estimated by adjusting for additional baseline characteristics such as age, gender, and physical activity history. These characteristics can be included as covariates in the regression models.
2. The regression model estimating the proximal effect of the intervention will be based on participants who have at least 45 (50%) out of 90 days of data available.

In the case of positively skewed distributions of the primary outcome variables, the data will be transformed using logarithm or square root transformations. Before the transformations, a small decimal number (eg, 0.5) will be added to the zero values. This is done to address the issue of zero values in the data [20]. Missing data will be addressed using the full-information maximum likelihood approach [31].

Power

Sample size calculations were conducted using Liao et al [32] as a reference, and an R-shiny app [33] was used for this purpose. Based on the calculations, a sample size of 58 participants was determined for randomization over a 90-day period (Multimedia Appendix 4). The calculations were performed with 80% power and a significance level of 5%. For the proximal outcomes, which involve 1 decision time point per day over the 90-day study duration and a randomization probability of 0.5, it is anticipated that participants will have an average availability rate of 0.8 at each decision time point, following a constant trend. The proximal effect size is expected to follow a quadratic trend, with an initial value of 0 and an average value of 0.1. The maximum value is anticipated to occur on the 45th day. For the distal outcome, such as the change in resting heart rate within either phase 1 or phase 2, the sample size of 58 participants can detect a standardized effect size of 0.374 (small to medium effect size) based on a paired *t* test.

Data Exclusion

For activity suggestions, the interventional messages aim to promote physical activity, that is, walking. The primary outcome measure for each participant at each decision-making time point is the step count recorded within the subsequent 180 minutes after receiving a message. With 1 decision-making time point per day, this step count serves as the key data point for analysis. Detailed data management procedures have been outlined in

XSL•FO
RenderX

the study's protocol to ensure proper handling, processing, and analysis of the collected data [24].

User Statistics

Fitbit data will be collected during participant visits, specifically scheduled to align with the 6th and 12th months of the LIVEPLUS. During these visits, the data from Fitbit devices will be downloaded and collated for further analysis (the time line described in Figure 2).

Ethical Considerations

In Australia, all human research is reviewed by an independent human research ethics committee. MIRTH's parent study LIVEPLUS received approval from the ethics review committee of the Royal Prince Alfred Hospital (RPAH) Zone of the Sydney Local Health District (protocol X20-0229 & 2020/ETH01273 on July 22, 2020). The original informed consent allows for secondary data analysis without additional consent. Before baseline testing, the research team will conduct a video call with potential participants to provide an overview of the study and address any questions or concerns. Any identifiable data obtained will remain confidential and encrypted on secure RPAH servers. Participants will be assigned a unique study ID number, and nonidentifiable data will be stored for at least 15 years. All deidentified data will be stored on university servers and only accessible by research staff through password-protected computers. The mobile app backs up data on both the smartphone and a web-based cloud server based in Sydney. While the app does not have a delete function, participants may request to have their data deleted from the cloud server. Access to mobile app data is restricted to the research team. There is no monetary compensation or amount for LIVEPLUS participants; however, participants who complete the 12-month period get to keep the Fitbit device used for physical activity monitoring.

Results

The LIVEPLUS trial received funding in 2020 and initiated participant enrollment in February 2022. Recruitment for the MIRTH trial began in November 2022. As of September 2023, two participants have been enrolled in the MIRTH study and provided baseline data.

Discussion

Overview

The MIRTH trial aims to conduct a comprehensive analysis of the impact of a customized mHealth app on smart devices, delivering a lifestyle intervention to patients with coronary heart disease. This intervention includes time-based motivational messaging, which can be used to develop a JITAI. The goal of this approach is to provide prompts and cues at the optimal time to enhance motivation and promote increased physical activity behavior among participants. Through this study, we aim to gain insights into the effectiveness of this intervention in improving motivation and achieving the desired objectives of the study.

During the 90-day study duration, participants may receive randomized physical activity suggestions at up to 90 time points. Considering both phase 1 and phase 2 of the trial, there is a maximum potential for 180 time points in total (90 days for each phase). Since we anticipate an equal distribution of intervention and control messages among participants (with a randomization probability of 0.5), it is statistically unlikely for any participant to receive the intervention at all 180 time points. However, we can use the two 90-day study phases to examine improvements in distal outcomes. Our analysis will involve comparing resting heart rate and step counts from baseline (months 3 and 9) to the end of each phase. Furthermore, we will assess distal outcomes by comparing monthly changes within a study phase and between the 2 phases. Based on our hypothesis, we anticipate that participants who receive the intervention messages will demonstrate an increase in physical activity behavior aligned with the recommended guidelines. Additionally, we expect to observe improvements in resting heart rate and overall cardiometabolic health at the 12-month time point. This study will serve as a foundation for integrating an MRT design into routine clinical digital health prescriptions, especially for populations where lifestyle behavior change facilitated by digital health interventions can improve or potentially reverse disease states. The physical activity data collected during the baseline time points are more likely to reflect habitual physical activity behavior. In future studies, the incorporation of a reinforcement learning algorithm can consider additional factors such as user location, local weather conditions, and undisclosed calendar information to deliver a personalized and gamified JITAI.

Strengths

This study introduces an innovative strategy to address physical activity behavior in patients diagnosed with coronary heart disease. It examines the timing of messages within each individual and their impact on outcomes. The study implements a layered digital intervention with minimal participant burden. It spans a longer duration of 180 days, divided into two 90-day periods. Furthermore, to our knowledge, this is the first MRT study to use incremental recruitment specifically for this population.

Limitations

The findings of this study may have limited generalizability to the broader population with cardiovascular disease due to the specific characteristics of the study participants. It is important to note that this study is not designed as a double-blind study, as both participants and researchers are aware of the content and frequency of the messages being delivered. However, the lack of blinding does not pose a significant disadvantage since the outcomes are objectively assessed through Fitbit data, minimizing potential bias in outcome evaluation. It should be noted that this study does not incorporate reinforcement learning in the algorithm, which limits our ability to examine time-varying states for potential moderation effects, such as participant activity levels on the intervention day or the preceding day. Given that the intervention component is delivered through personal electronic devices such as smartphones and Fitbit, it is important to acknowledge the

XSL•FO
RenderX

potential for technical issues that could impact the reliability of step count records. These challenges may include supporting participants in resolving technical issues with limited in-person assistance. It is worth noting that, in certain instances, Fitbit devices have been known to register hand movements as step counts, which could introduce some measurement inaccuracies [34]. To address potential data collection issues, the research team and technical support will closely monitor and cross-validate the data collection process, ensuring any troubleshooting is promptly addressed. Participants will be informed if any data collection issues occur. The incremental recruitment approach used in this study limits the ability to make adaptive changes based on preliminary results from phase 1 to inform and improve the intervention in phase 2. This may impact the optimization of the intervention based on real-time feedback. The 180-minute window for assessing the effect of messages may not capture the true change in motivation. There could be delayed effects observed weeks after receiving the messages, such as lag effects. Finally, the lack of message sequencing or tailored content may result in participants who are already making progress receiving messages that target earlier stages of motivation.

Conclusions

The outcome of this study will provide preliminary insights into the value and efficacy of motivational messages in promoting physical activity behavior among patients with coronary heart disease in a community setting. The results will provide important data on the effectiveness of delivering physical activity motivational messages through a research study app. If proven effective, this approach could be implemented to enhance personalized care strategies, including the use of digital health interventions, for patients with coronary heart disease.

Acknowledgments

The authors would like to thank the study sponsors for their support. The authors would also like to extend thanks in advance to all participants who volunteered their time to be part of this and the parent study.

Data Availability

The data sets generated during and/or analyzed during this study will be made available from the corresponding author on reasonable request.

Authors' Contributions

SM, JX, BC, and LF conceptualized the study. SM, JX, BC, CMK, AM, and LF further built on the initial study plan. SM, CMK, and LA prepared the message bank, with LA verifying and amending the messages to suit the study cohort. SM drafted the study protocol and submitted it to Australian New Zealand Clinical Trials Registry for registration, with the draft reviewed by CMK, JX, and LF. SM drafted the protocol manuscript for publication, with all authors contributing to the draft. JX prepared the statistical analysis and power sections. RH contributed by adding the randomization sequence and inserting the message bank into the study app. IH and IW recruited participants. SM, CK, SAC, AM, TW, RH, LA, JX, BC, and LF reviewed the manuscript before submission. All authors revised the manuscript for relevant scientific content and approved the final version of the manuscript.

Abstract

Background: Management of severe symptomatic immune-related adverse events (IrAEs) related to immune checkpoint inhibitors (ICIs) can be facilitated by timely detection. As patients face a heterogeneous set of symptoms outside the clinical setting, remotely monitoring and assessing symptoms by using patient-reported outcomes (PROs) may result in shorter delays between symptom onset and clinician detection.

Objective: We assess the effect of a model of care for remote patient monitoring and symptom management based on PRO data on the time to detection of symptomatic IrAEs from symptom onset. The secondary objectives are to assess its effects on the time between symptomatic IrAE detection and intervention, IrAE grade (severity), health-related quality of life, self-efficacy, and overall survival at 6 months.

Methods: For this study, 198 patients with cancer receiving systemic treatment comprising ICIs exclusively will be recruited from 2 Swiss university hospitals. Patients are randomized (1:1) to a digital model of care (intervention) or usual care (control group). Patients are enrolled for 6 months, and they use an electronic app to complete weekly Functional Assessment of Cancer Therapy-General questionnaire and PROMIS (PROs Measurement Information System) Self-Efficacy to Manage Symptoms questionnaires. The intervention patient group completes a standard set of 37 items in a weekly PROs version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE) questionnaire, and active symptoms are reassessed daily for the first 3 months by using a modified 24-hour recall period. Patients can add items from the full PRO-CTCAE item library to their questionnaire. Nurses call patients in the event of new or worsening symptoms and manage them by using a standardized triage algorithm based on the United Kingdom Oncology Nursing Society 24-hour triage tool. This algorithm provides guidance on deciding if patients should receive in-person care, if monitoring should be increased, or if self-management education should be reinforced.

XSL•FO
RenderX

Results: The Institut Suisse de Recherche Expérimentale sur le Cancer Foundation and Kaiku Health Ltd funded this study. Active recruitment began since November 2021 and is projected to conclude in November 2023. Trial results are expected to be published in the first quarter of 2024 and will be disseminated through publications submitted at international scientific conferences.

Conclusions: This trial is among the first trials to use PRO data to directly influence routine care of patients treated with ICIs and addresses some limitations in previous studies. This trial collects a wider spectrum of self-reported symptom data daily. There are some methodological limitations brought by changes in evolving treatment standards for patients with cancer. This trial's results could entail further academic discussions on the challenges of diagnosing and managing symptoms associated with treatment remotely by providing further insights into the burden symptoms represent to patients and highlight the complexity of care procedures involved in managing symptomatic IrAEs.

Introduction

Immune checkpoint inhibitors (ICIs) have increasingly become part of the standard treatment for multiple cancer types and stages, with the main benefits including superior overall survival rates [1-14]. Although ICIs are generally considered as well-tolerated, they may trigger immune-related adverse events (IrAEs), which can be severe and result in debilitating or fatal outcomes [15,16]. Treatment modality, cancer type, and patient characteristics appear to influence the likelihood of symptomatic IrAEs, which generally occur in 40%-80% of patients [10,15]. Combinations of ICI agents generally result in a higher incidence and severity of symptoms, with 55% of IrAEs being severe (grade 3 or higher) [15,17]. Even though the incidence of IrAEs appears to be positively correlated with superior objective response rates to ICIs, the occurrence of severe events may lower overall survival rates [2,18]. It is posited that solid tumors that exhibit high mutational burden elicit a stronger immune response, which may trigger more IrAEs [19,20]. Limited evidence suggests that skin, respiratory, renal, and hepatic IrAEs also appear to be correlated with melanoma, lung cancer, kidney cancer, and hepatocellular cancers, respectively, suggesting that different tumor types may increase the likelihood of specific IrAEs [21-23]. In addition, genetic risk factors such as allelic variations of *HLA-B* and mutations in the *TMEM162* gene are correlated with higher or lower likelihood of IrAEs [24]. Recent studies have highlighted that the potential chronicity of IrAEs could further burden patients and contribute to lower overall quality of life [16,25-27]. The timing of detection and intervention of IrAEs appears to play a key role in limiting their progression and outcome [10,15,28].

Although most IrAEs occur within the first 3-6 months of the start of treatment, some may develop after a year even when treatment has been discontinued [15,29,30]. In addition to the uncertainty of when they may manifest, IrAEs are heterogenous in their symptomatic presentation and are usually related to the affected tissue or organ [15]. Therefore, patients need to be ready to engage in self-care activities to self-monitor and self-manage symptoms they confront outside of the clinical environment during the multiple weeks between treatments [31].

As clinicians rely on patient recall to assess symptomatic adverse events, the time between visits and the clinician's own judgement may inadvertently contribute to an underestimation of their severity, frequency, and burden [32,33]. Collecting patient-reported outcomes (PROs) has become a standard to accurately describe symptomatic adverse events by avoiding some of the biases of clinician reporting, thus contributing evidence on safety, tolerability, and efficacy of cancer treatments [34,35]. Recent studies show that PRO data collected electronically can enable more timely interventions to support patients in managing symptoms, resulting in improvements in overall survival, health-related quality of life (HRQoL), symptom control, and patients' perceived self-efficacy [34,36,37]. Improvements and smaller declines in HRQoL have been observed when actionable PRO data are available to clinicians [38]. PROs can improve communication between patients and health care professionals by increasing the scope of symptoms addressed and how often they are discussed [34].

Clinical trials using electronic PROs (ePROs) in remote symptom management have noted how these data enable interventions that prevent complications related to cancer treatment, leading to similar or lower rates of hospital admissions and emergency care admissions than the current standard of care [36,37]. These models of care generally interpret ePRO symptom data that nurses use to provide personalized remote symptom management support to patients or that activate automated feedback through custom algorithms [36,37,39]. These interventions have seldom been detailed on the procedures put in place to monitor and manage ePRO symptom data. We thus hypothesized that a structured and standardized ePRO-based model of care, including remote monitoring and symptom management, using real-time data may reduce the time to detection of symptomatic IrAEs. This would, in turn, facilitate timely intervention and limit worsening of patients' HRQoL and perceived self-efficacy to manage their conditions. This randomized controlled trial (RCT), the IePRO

XSL•FO
RenderX

(IrAEs monitoring through electronic PROs) trial, aims to verify the effect of an ePRO-based model of care on the time to detection of symptomatic IrAEs.

Methods

Project Context

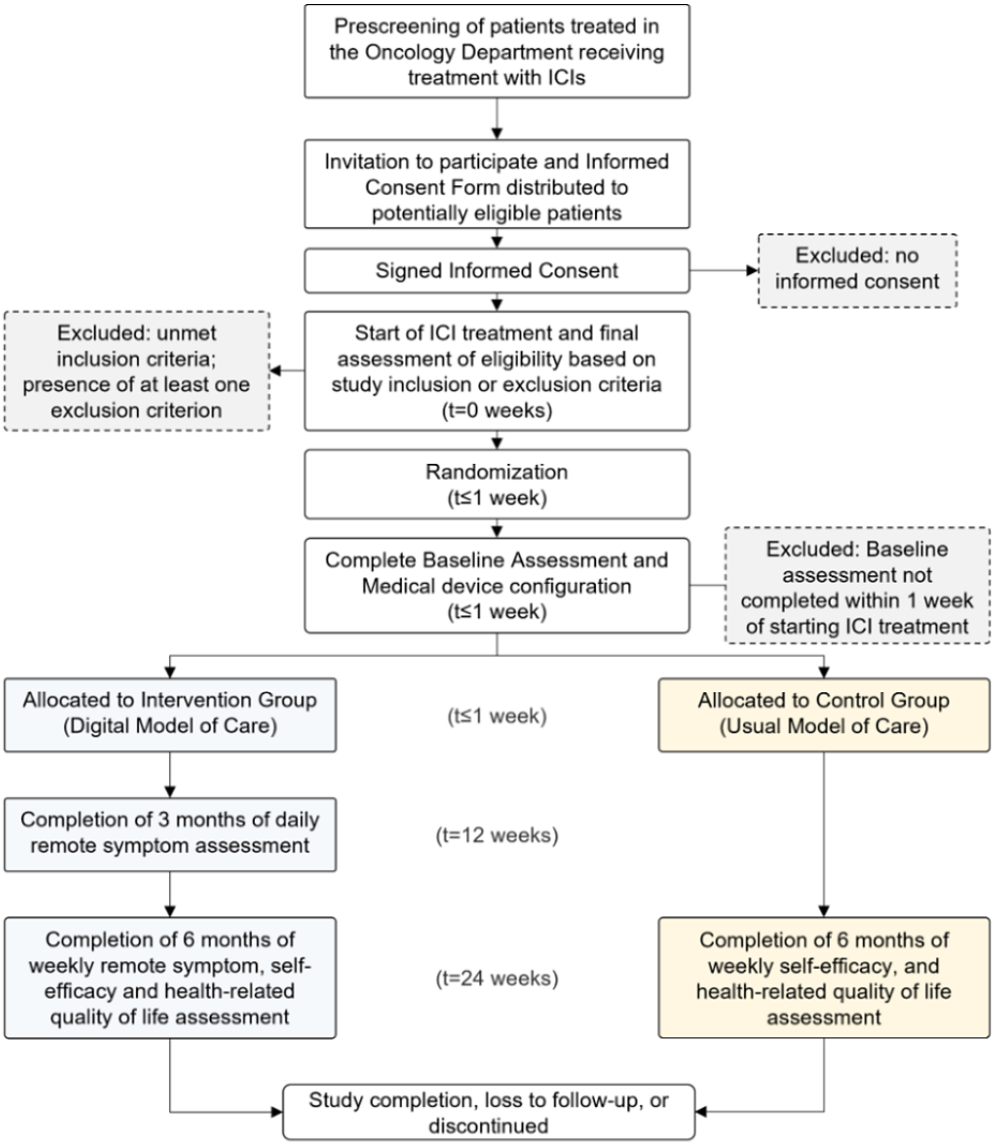
The RCT described in this protocol is the third phase of the IePRO project, which began in the year 2020. The first phase focused on the development of a PRO measure based on the PRO version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE) [40]. The development of this measure has been detailed in a previously published Delphi study [41]. The second phase was concerned with the development of the ePRO-based model of care being tested in the RCT [42]. This is a 2-arm RCT taking place in the ambulatory care oncology units of 2 university hospitals in French-speaking Switzerland since 2 years. Its overall aim is to compare an ePRO-based model of care that enables remote monitoring and management of symptoms to usual care for patients with cancer receiving ICIs exclusively for up to 6 months.

Study Population

Setting

Patients are being recruited in the Department of Oncology of the 2 university hospitals. They receive treatment and have same-day follow-up appointments at the hospitals' outpatient clinics. Both sites include tumor type–oriented clinical oncology teams with treatment strategies dictated by multidisciplinary tumor boards.

Eligibility Criteria



Participants fulfilling all the following inclusion criteria are eligible for this study: (1) patients 18 years old or older, (2) diagnosed with cancer, (3) starting or restarting systemic single- or dual-agent ICI monotherapy in neoadjuvant, adjuvant, consolidation, or palliative settings, and (4) providing informed consent as documented by the signature on the informed consent form. The presence of any of the following exclusion criteria will lead to participant exclusion: (1) patients self-declaring not being able to use the electronic app and complete the questionnaire in French, (2) patients with any psychological, familial, or sociological condition and linguistic limitation, potentially hampering compliance with the study protocol requirements or follow-up procedures, (3) patients restarting ICI therapy who have previously participated in this study, (4) patients with cognitive impairment, as declared in the patient record, and (5) patients participating in other interventional clinical studies.

Screening and Enrollment

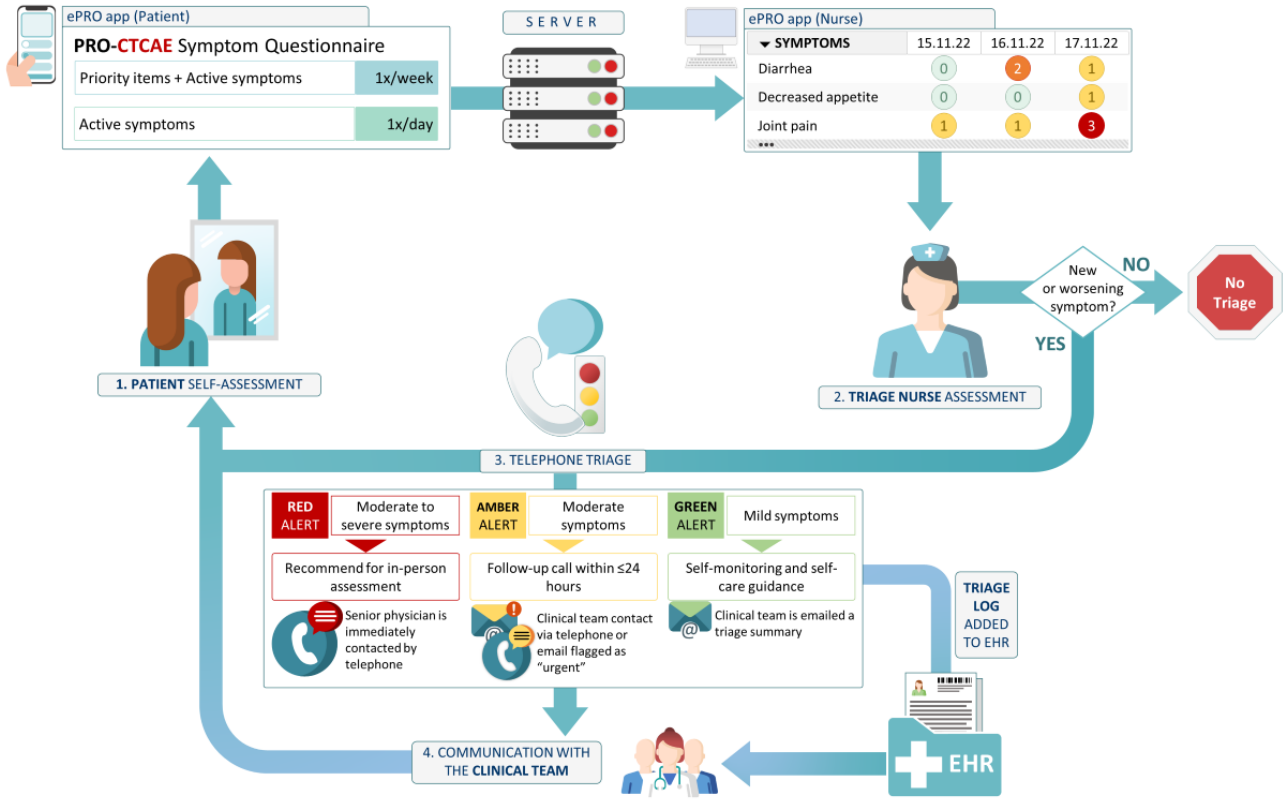
Patients are identified by the local principal investigator and a team of sub investigators. Potentially eligible patients are approached after clinician appointments or during treatment. They are given the informed consent form (Multimedia Appendix 1), and a telephone call with a subinvestigator is scheduled within the following week to answer any questions or concerns. Patients are given at least 48 hours to consider participating in the study. Figure 1 shows the flowchart for patient enrollment in this study. Informed consent forms are collected during the patients' next hospital appointment. Patients can be enrolled in the study up to a week after ICI treatment has started. When eligible patients refuse to participate, their reason for refusal is anonymously recorded with their consent.

XSL•FO
RenderX

Figure 1. Flowchart of the enrollment of the patients in this study. ICI: immune checkpoint inhibitor.

Study Design

Prior to randomization, subinvestigators collect demographic, medical history, and active treatment data from eligible consenting patients. Participants are randomized by subinvestigators using a web-based REDCap (Research Electronic Data Capture) form (version 12.4.21) [43]. The form has a randomization table (1 per site) using permuted block 1:1 randomization (block size of 4), independently prepared by the study biostatistician. Initially, the IePRO RCT was open to patients with melanoma and patients with lung cancer exclusively, and randomization was stratified by cancer type. Due to challenges in recruitment and following a protocol amendment in April 2022, this study was open to patients with all cancer types, and the stratification criteria were dropped. Blinding was not possible due to the nature of the intervention. Patients are informed that they will be randomly allocated to 1 of the 2 models of care: the standard model (control group) or the digital model (intervention group). The informed consent form and support documentation for the electronic app used to deliver the PRO questionnaires include these same conventions to further mitigate the adverse effects of the lack of blinding toward participants. Data collection instructions and reminders sent to clinicians caring for participants do not indicate which group the participant belongs to.



Patients in both groups obtain access to an electronic mobile app, which contains weekly questionnaires for HRQoL and self-efficacy to manage symptoms. An information sheet detailing how to navigate the app is also provided. Nurses and subinvestigators are available to assist patients in installing the app, registering and signing into an account, and replying to the baseline questionnaires in-person or over the phone. Patients in the intervention group have access to a symptoms questionnaire that is part of the intervention being tested. Automated reminders via emails or push notifications are sent to patients when a new questionnaire is available. Patients in both groups have the same number of scheduled clinician appointments—usually the same day and frequency of the ICI treatment—and are followed up for up to 6 months of ICI treatment.

XSL•FO
RenderX

Intervention

The intervention of this RCT consists of a complementary model of care that uses ePROs to facilitate remote symptom management [42]. This model is represented in Figure 2. Patients in the intervention arm have access to a weekly PRO-CTCAE questionnaire through an electronic mobile app. Patients receive an email invitation to access the app and an information sheet explaining its interface. Once patients access the app, they are required to complete a questionnaire of predefined symptoms. During the first 3 months of the intervention, active symptoms are reassessed daily. When replying to a questionnaire, patients can add any other item of the full PRO-CTCAE item library, which are automatically added to the following daily or weekly questionnaires as well (see Multimedia Appendix 2). The rapid and sudden onset of IrAE and ICI's interference with pre-existing conditions and symptoms drove the decision to collect symptom data daily [10,28]. Due to the potential burden this sustained frequency could represent to patients, this was restricted to the first 3 months of the intervention. Patient replies are available in real time to the triage nurses. Two triage nurses at each site are notified via email when patients submit new replies or report severe symptoms, and they contact patients by telephone in the event of new or worsening symptoms. The nurses review patients' answers every working day from 8 AM to noon. Outside of these hours, usual care procedures apply.

Figure 2. IePRO (immune-related adverse events monitoring through electronic patient-reported outcomes) Model of Care: (1) When prompted by the mobile app, patients reply to a Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events symptom questionnaire via their own computer or mobile device. Data collected through the questionnaire are stored in a server controlled by the study sites. (2) Triage nurses are notified when patients have declared symptoms. (3) In the event of new or worsening symptoms, nurses initiate a telephone triage call with the patient. (4) Using the United Kingdom Oncology Nursing Society 24-hour triage tool, nurses determine the adequate course of action according to symptom severity and communicate the outcome of their assessments with the clinical team. The triage nurse's detailed assessment is recorded in a triage log stored in the electronic health record. EHR: electronic health record; ePRO: electronic patient-reported outcome; PRO-CTCAE: Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events.

Triage nurses perform an assessment of the reported symptoms with the United Kingdom Oncology Nursing Society 24-hour triage tool [44], which are graded on a CTCAE-based scale [45]. If patients report symptoms not covered by the PRO-CTCAE questionnaire, they are also addressed during these calls. The combination of symptoms may result in different types of color-coded alerts that tie into different recommendations. Mild symptoms generally result in green alerts, where self-care and self-monitoring instructions are warranted. Moderate symptoms requiring remote follow-up within the next 24 hours correspond to an amber alert. The presence of 2 or more amber alerts or of severe symptoms results in a red alert, where urgent in-person assessment is recommended. Triage nurses communicate with physicians via email or telephone according to the type of alert. A triage log detailing the symptom assessment, recommendations to the clinical team, and the actions taken to manage patient care is added to the electronic health record (EHR).

Patients are informed that this model of care is complementary to the usual care model. They are instructed by the triage nurses and subinvestigators in the clinical team that in the event of a symptom that causes them any level of concern and would lead them to seek medical assistance, they must contact their reference clinician or the on-call oncologist as usual. It is also

XSL•FO
RenderX

clarified that the likelihood of being called by the triage nurse should never delay them from seeking medical assistance. In this sense, patients are reminded of these procedures at every telephone interaction with the triage nurses.

Electronic App (Medical Device)

This study is categorized as a clinical trial with medical device of risk category A1. It uses a web-based and mobile CE-marked app (Kaiku Health app) containing the PRO measures. The app is classed as a medical device that allows patients to submit their answers and access previous replies. Patients receive a summary of the reported symptoms detailing which of those improved, remained stable, or worsened. The app's security features were assessed and validated by the participating hospitals' information technology departments. Web-based and mobile versions of the app are identical in content and functionality. Patient data collected through the medical device are encrypted at rest and in transit and are subject to regular backups. Security updates are ensured by the app developer (Elekta AB). Two-factor authentication is activated for all patients.

Study Objectives and Outcomes

Primary Objective and Primary Outcome

The primary objective of the IePRO RCT is to compare the effect of an ePRO-based model of care to the current standard model of care on the delay between symptomatic IrAE onset and its detection by health care providers in patients with cancer treated with ICIs. The ePRO-based model of care complements the standard model of care with remote symptom monitoring via ePROs and remote symptom management via telephone triage calls done by oncology nurses. The primary outcome is the time-to-detection of IrAEs, as evidenced by a statistically significantly lower length of time when compared to that in usual care. Time to detection is the difference expressed in days between the IrAE detection date by the clinical team and the associated symptom's onset date according to the patient's self-report.

Secondary Objectives and Secondary Outcomes

The secondary objectives of this trial include assessing the effect of the ePRO-based model of care on the following secondary outcomes: (1) the delay between symptom onset and deployment of pharmacological interventions to manage symptomatic IrAEs by a statistically significant shorter or longer average time delay, (2) the type and amount of pharmacological interventions to manage symptomatic IrAEs by a statistically significant lower average dose, (3) the average maximum symptomatic IrAE grade by a statistically lower or higher average score, (4) the HRQoL through a statistically significant higher or lower overall score of the Functional Assessment of Cancer Therapy-General (FACT-G) questionnaire [46], (5) the perceived self-efficacy to manage symptoms through a statistically significant higher or lower score of the PROMIS (PRO Measurement Information System) Self-Efficacy for Managing Chronic Conditions–Managing Symptoms (short form 8a) [47], (6) overall survival at 6 months plotted using Kaplan-Meier estimates, using routine data collected in the EHR, and (7) description of the symptomatic IrAEs experienced by patients by type and grade according to version 5.0 of the National Cancer Institute's CTCAE [48]. Remote symptom management processes recorded by nurses will be described using (1) patient-reported symptoms triggering remote symptom management procedures using the composite grading algorithm for the PRO-CTCAE questionnaire [49] and (2) the type of issued triage alerts following triage procedures according to the United Kingdom Oncology Nursing Society 24-hour triage tool [44] and associated symptoms reported using the PRO-CTCAE questionnaire.

Exploratory Objectives

As exploratory objectives, the RCT will also describe the following in the intervention group: (1) symptoms reported via the PRO-CTCAE questionnaire that suggested the need for in-person intervention and patients received the intervention (true positives), (2) symptoms reported via the PRO-CTCAE questionnaire that suggested the need for in-person intervention but patients did not receive the intervention (false positives), (3) type of interventions required and provided for symptoms as reported in the triage log and the EHR, (4) symptoms reported via the PRO-CTCAE questionnaire that require an intervention beyond remote symptom management, (5) usability of the electronic app used to collect PRO symptom data and acceptability of the ePRO-based model of care, assessed through semistructured patient interviews, and (6) acceptability of the ePRO-based model of care assessed via semistructured individual interviews and focus groups with clinical nurse specialists, nurses, and physicians.

Sample Size Calculation

A sample of 29 health records of previously treated patients with melanoma who experienced IrAEs was used to estimate the required sample size. Patients with lung cancer were not considered for this calculation due to the lack of accessibility to symptomatic IrAE data in that population. Only records where the symptom onset was reported were included for this sample size calculation. In that record sample, the time interval between symptom onset and clinician detection of symptomatic IrAEs was estimated at 4.43 days, with an SD of 3.65 days. A 2-sample *t* test with a statistical power of 90% and significance level set at .05 determined that 138 participants would be required to detect a 2-day difference, assuming the same SD of 3.65 days. Given that similar studies have reported an attrition rate of 30%, the target sample size was adjusted to 198 patients [36,50].

Data Collection Methods

Demographic data and data relating to symptomatic IrAEs and their management for both control and intervention groups are collected through EHR review of the clinical oncologist's follow-up notes at each scheduled appointment with participants. Data from the EHR are recorded in REDCap electronic case report forms hosted in the server of the study sponsor's Clinical Research Center [51]. PRO data are collected through the Kaiku Health electronic app, which contains 3 questionnaires. The questionnaires were selected by the study's subinvestigator team, including a patient advocate (GS-B), by discussing matters of burden and of pertinence of the collected data to patients, and what data were actionable for the model of care.

XSL•FO
RenderX

HRQoL data are collected via version 4 of FACT-G questionnaire, translated in French [46,52]. The questionnaire targets 4 domains: physical well-being, social or family well-being, emotional well-being, and functional well-being. Recall period, instrument scaling, scoring, and methods to handle missing data do not differ from the official administration and scoring guidelines [53]. The self-efficacy for managing symptoms is assessed weekly using the 8-item short-form French version of the PROMIS Self-Efficacy for Managing Chronic Conditions–Manage Symptoms measure [54]. Instrument scaling, scoring, and missing data handling also do not differ from the official scoring manual [55].

Symptom data in the intervention group are collected using a weekly PRO-CTCAE that includes symptom terms categorized as of the highest importance to monitor during ICI treatment. Thirty of the 37 symptom terms were identified through the Delphi study conducted in the first phase of the IePRO project [41]. The remaining 7 were selected by the IePRO project's clinical team and principal investigators. All PRO-CTCAE items were translated in French. Currently, no official guidelines exist on how to best analyze PRO-CTCAE data longitudinally [56]. In this RCT, we will follow guidance provided by Basch et al [49] to calculate a single composite numerical grade for PRO-CTCAE symptom terms to facilitate longitudinal analysis.

As previously stated, active symptoms are reassessed daily during the first 3 months of the RCT. This is done by modifying the standard PRO-CTCAE recall period from 7 days to 24 hours. Although modifications to the recall period of PRO-CTCAE items are not encouraged, this is specifically due to potential considerable measurement errors, as that period is extended [57]. Recent studies [58,59] have highlighted how PRO measures using 24-hour recall periods more accurately convey symptom burden and variability over a short period of time, particularly for symptoms such as constipation, diarrhea, nausea, and those related to the patient's emotional state. In patients treated with chemotherapy, shortened recall periods across different symptom PRO measures have enabled detection of clinically meaningful changes and were shown to be capable of detecting severe symptoms earlier [58,59]. Because some IrAEs can be fulminant and evolve in severity very quickly, daily reassessment of active symptoms could also support early detection and management. Although there is concern that the inclusion of all PRO-CTCAE items for daily assessment can be burdensome to patients, this concern addressed static questionnaires. In this intervention, questionnaires are dynamic and only active symptoms are reassessed daily to avoid overburdening patients.

To minimize missing data, the app requires respondents to provide a response before they are able to progress within the questionnaire. Patients receive automated reminders to reply to the questionnaires via email. In the event of early study discontinuation or withdrawal, all data collections, including PRO data, are halted. A semistructured interview guide based on the mHealth App Usability Questionnaire by Zhou et al [60] was developed to assess the usability of the ePRO app. Acceptability of the model of care will be assessed using an interview guide developed around the 7 constructs of acceptability of health care interventions as described by Sekhon et al [61]. Patient and individual staff interview data will be collected via audio recordings. Recordings will be transferred from the recording device's secure digital card to be stored in the corresponding site's local secured servers. Transcriptions of the recordings will be independently analyzed by 2 subinvestigators by using thematic analysis.

Statistical Methods

In this RCT, the null hypothesis postulates that there is no difference in the primary end point (delay between symptom onset and detection be clinical team) between the intervention and control groups. The primary outcome will be analyzed comparing groups by means of multivariable regressions, adjusting for cancer type, age, and treatment regimen, against a 1-sided hypothesis. Secondary outcomes will be analyzed using multivariate regression analysis, controlled for cancer type, treatment regimen, and age. All statistical analyses will be presented as effect measure plus 95% CI, using a significance level of 5%. Variations in HRQoL and self-efficacy scores will be assessed by adjusting to baseline measure. Overall survival at 6 months will be controlled for cancer type and stage. All data processing and statistical analyses will be performed in R statistical software (v4.2.2; R Core Team 2023) and Microsoft Excel for Microsoft 365 MSO (version 2302, 2023). In-questionnaire data completeness is compulsory, though potential errors in the app may nevertheless occur. In addition, data such as time points may prove difficult to collect. According to the type and amount of missing data, strategies including imputation methods, deletions, or dismissals will be considered. For the HRQoL and self-efficacy for managing symptoms questionnaires, missing data will be handled according to official guidelines [53,55]. For exploratory outcomes, descriptive statistics will be applied. Qualitative data of semistructured interviews will be analyzed by the subinvestigators. Interviews will be transcribed verbatim and analyzed through thematic analysis.

Patient and Public Involvement

A patient expert (GS-B) was involved from the initial stages of the design of this study. The patients helped define the outcomes of interest of the study; gave their feedback on its design, choice of instruments for PRO data collection, and choice of medical device; assisted in the creation of documents targeting patients such as the informed consent form and the information sheet for the medical device; and participated in the study's dissemination. Ten patients gave feedback on the medical device interface during its development phase.

Safety Reporting

The university hospitals participating in this study have signed a research agreement detailing each site's responsibilities and data access and management procedures to ensure compliance with the research protocol and data monitoring plan. All information related to the trial will be stored securely at the corresponding study site. Documents containing participant data will be identified by a coded identification number only to maintain patient confidentiality. The sponsor and medical device developer have entered a written data processing agreement that outlines the extent in which data processing can be handled by

XSL•FO
RenderX

the developer. Upon trial completion or early withdrawal, patients' login credentials are deactivated, and PRO data are archived. The data archive is stored by the data manager and the sponsor of the study. Accessing encrypted data logs requires prior authorization from the sponsor-investigator. Trial monitoring activities are ensured by a data monitor for each site, following a clinical monitoring plan submitted alongside the research protocol to the competent ethics committee. Monitoring visits are scheduled to occur at 6, 12, 18, and 24 months (end of trial). Any study-related incidents are reported to the sponsor representative. Serious adverse events are reported to the competent ethics committee of the trial. Patients enrolled in the trial are covered by indemnity for negligent harm through the sponsor.

Ethics Approval

This study has been approved by the ethics committee of the Canton of Vaud, Switzerland (approval 2021-00301) and is conducted according to local regulations and the Declaration of Helsinki [62]. This trial is sponsored and led by the Lausanne University Hospital in Switzerland and registered at ClinicalTrials.gov (NCT05530187). Informed consent is obtained from all participants. Due to the nature of the intervention, this study is unblinded. Data are deidentified for data analysis purposes. No compensation was provided to patients participating in this study. In addition to the major amendment to the eligibility criteria, challenges brought by the COVID-19 pandemic (including site-imposed restrictions to conducting research not related to the pandemic) and resulting uncertainty on whether all the components of this trial could be deployed and thus its original outcomes assessed, further prevented this trial from being registered prospectively. Trial registration preceded any interim data analysis, and the original outcomes have been preserved.

Results

The first version of the research protocol of the IePRO RCT was approved in September 2021. In addition to 2 minor amendments, the latest version of the protocol contained a major amendment to the inclusion criteria, which was modified to include patients with any cancer type. This version was submitted and approved by the responsible ethics committee in April 2022. The current version of the protocol includes minor amendments that were approved in March 2023 (version 3.1 on September 22, 2022). All trial documents, including the protocol, site-specific informed consent form, and participant education materials, have been approved by the competent ethics committee. Patients have been actively recruited to this trial since November 2021, and this trial is projected to close by November 2023. The results of this trial will be published through abstracts, posters, presentations, and publications in peer-reviewed journals, when agreed to and reviewed by the principal investigators and the sponsor representative of the trial.

Discussion

The IePRO RCT is, to our knowledge, among the first trials to use PRO data to directly influence the routine care of patients treated with ICIs. Current guidelines argue that PRO measures can guide clinicians in monitoring patients at home, optimize patient interactions when the patients come to the hospital, and highlight symptoms that could improve or resolve through supportive care interventions [32]. Crucially, PROs can help identify active treatment-associated toxicities that, if unmanaged, may worsen and require complex care, impact quality of life, lead to treatment interruptions, and thus, ultimately, decrease survival [32,34].

Recent studies have shown the feasibility and acceptability of ePRO symptom monitoring systems to monitor IrAEs but have provided limited evidence of their impact on patient care and clinical outcomes [63]. IrAE investigation and management algorithms and the lack of integration and adaptability to routine care are among the key areas requiring improvement for the success of these interventions. The triage process in the IePRO model is a potential strength, as it provides nurses with a standardized procedure to investigate and manage symptoms, potentially decreasing variations in how care and information are provided, facilitating more consistent outcomes. In addition, the model of care was conceived with adaptability in mind, to be able to accommodate 2 tertiary hospitals. The adaptive structure of the PRO-CTCAE questionnaire focuses on active symptoms and enables patients with the choice of adding self-detected symptoms, while limiting the risk of increased burden, particularly due to more frequent data collection. It is possible that its weekly data collection may more accurately portray changes throughout treatment, as opposed to multiple-month intervals of measures of HRQoL and self-efficacy for managing symptoms.

Other limitations of this study are that the broad triggers for a telephone triage call (new or worsening symptom) may lead to a significant number of calls that may not always result in meaningful changes to how care is provided. A recent publication by Msaouel et al [64] has described adaptive and more granular alert thresholds that could prevent and alleviate clinician burden. Clinicians in similar studies have noted the time-consuming nature of ePRO data review, and these broad triggers may compound that burden further and limit clinician compliance to study procedures [65]. Tolstrup et al [66] attempted to empower patients with the decision to contact the hospital, though this may have discouraged computer-naïve patients from doing so even when symptoms were concerning, leading the authors to consider a proactive approach for future iterations of remote PRO monitoring. Integration with the EHR was complicated by the differences in EHR platforms across study sites and the short time interval between the finalized code for the mobile app and the start of the study. EHR integration is a major factor for ensuring successful implementation of ePRO monitoring [63], and it remains unclear if the measures implemented to mitigate the lack thereof will be successful.

Dropping tumor type and excluding ICI agents as stratification criteria constitute a major limitation of this study, as patient groups could present important differences that could influence the type, severity, and frequency of IrAEs. This consideration should guide future analysis of the data, and its impact will be addressed in future publications. More frequent measuring and

XSL•FO
RenderX

the reactive nature of the intervention increase the risk of surveillance bias, as clinicians will be more aware of the challenges patients are experiencing. The intervention also does not allow blinding of patients who may alter their usual self-monitoring and self-care behaviors due to their awareness of the triage nurse's monitoring [66]. As this study is being deployed in 2 sites, tracking hospitalization and emergency room admissions for patients in the control group was outside the resources available to the study team. As a consequence, they were not included as secondary end points for this study, limiting insight on its efficiency to improved care. Overall survival measures were capped at 6 months due to limited resources to pursue a longer target, which could hinder the visibility of long-term effects of the model of care. Lastly, excluding patients who self-declare unable to use the electronic app and the lack of alternative means to self-report symptoms limit the comparability of this sample to the general population [36,67]. Despite these limitations, the IePRO RCT takes a pragmatic approach to symptom monitoring with ePRO data by not insulating its model of care from the existing resources the sites use to assist patients. Importantly, the IePRO RCT may further highlight the challenges patients treated with ICIs face outside the clinical setting, particularly as more data revealing the true burden of treatment-associated toxicities continue to emerge.

Acknowledgments

The authors are grateful to the clinicians, patients, patient-experts, and collaborators in the participating sites who have facilitated the development of this study and to Dr Sandra A Mitchell for her guidance in using the Patient-Reported Outcome version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE).

Data Availability

The data sets generated during or analyzed during this study are not publicly available due to its sensitive nature but are available from the corresponding author on reasonable request.

Authors' Contributions

ME and OM conceived the study's original concept and design. AMdSL, SC-L, CD, VA-L, SL, NM, GS-B, and AA later contributed to refining the design, instruments, and methods. The first draft of the manuscript was written by AMdSL, and all authors commented on the previous versions of the manuscript. Analyses will be conducted by the study biostatistician MC and AMdSL. ME is the sponsor representative of the Lausanne University Hospital for this study. All authors read and approved the final manuscript.

Conflicts of Interest

SC-L reports grants from Institut Suisse de Recherche Expérimentale sur le Cancer Foundation. GS-B reports grants from MSD France, grants from Novartis, and personal fees from Bayer, Melanoma Patient Network Europe, and Working Group of European Cancer Advocacy Networks outside the submitted work. Abstract

Background: An estimated 40% of people living with HIV smoke cigarettes. Although smoking rates in the United States have been declining in recent years, people living with HIV continue to smoke cigarettes at twice the rate of the general population. Mobile health (mHealth) technology is an effective tool for people living with a chronic illness, such as HIV, as currently 84% of households in the United States report that they have a smartphone. Although many studies have used mHealth interventions for smoking cessation, few studies have recruited people living with HIV who smoke.

Objective: The objective of the pilot randomized controlled trial (RCT) is to examine the feasibility, acceptability, and preliminary efficacy of the Sense2Quit App as a tool for people living with HIV who are motivated to quit smoking.

Methods: The Sense2Quit study is a 2-arm RCT for people living with HIV who smoke cigarettes (n=60). Participants are randomized to either the active intervention condition, which consists of an 8-week supply of nicotine replacement therapy, standard smoking cessation counseling, and access to the Sense2Quit mobile app and smartwatch, or the control condition, which consists of standard smoking cessation counseling and a referral to the New York State Smokers' Quitline. The Sense2Quit app is a mobile app connected through Bluetooth to a smartwatch that tracks smoking gestures and distinguishes them from other everyday hand movements. In the Sense2Quit app, participants can view their smoking trends, which are recorded through their use of the smartwatch, including how often or how much they smoke and the amount of money that they are spending on cigarettes, watch videos with quitting tips, information, and distractions, play games, set reminders, and communicate with a study team member.

Results: Enrollment of study participants began in March 2023 and is expected to end in October 2023. All data collection is expected to be completed by the end of January 2024. This RCT will test the difference in outcomes between the control and intervention arms. The primary outcome will be the percentage of participants with biochemically verified 7-day point prevalence smoking or tobacco abstinence at their 12-week follow-up. Results from this pilot study will be disseminated to the research community following the completion of all data collection.

Conclusions: The Sense2Quit study leverages mHealth so that it can help smokers improve their efforts at smoking cessation. Our research has the potential to not only increase quitting rates among people living with HIV who may need a prolonged, tailored intervention but also inform further development of mHealth for people living with HIV. This mHealth study will contribute significant findings to the greater mHealth research community, providing evidence as to how mHealth should be developed and tested among the target population.

Introduction

Overview

An estimated 40% of people living with HIV smoke cigarettes [1]. Smoking leads to many health problems among people living with HIV, including cardiovascular disease, pulmonary infections, bacterial pneumonia, chronic obstructive pulmonary disease, and cancer [2]. Lung cancer is the leading cause of death among people living with HIV taking antiretroviral therapy (ART) in the United States [1,3]. Although smoking rates in the United States have been declining in recent years, people living with HIV continue to smoke at twice the rate of the general population [3,4]. Quitting smoking can significantly decrease the risk of acquiring serious illnesses [2].

Mobile health (mHealth) technology is an effective tool for people living with a chronic illness, such as HIV. Currently, 84% of households in the United States report that they have a smartphone [5]. Due to the high rate of smartphone ownership and associated tech literacy, mHealth apps are an accessible and affordable means of delivering health care [6].

Although many studies have used mHealth interventions for smoking cessation [7-9], few studies have recruited people living with HIV [10-12]. As such, this study's team created the Sense2Quit app, using the Information Systems Research (ISR) framework [13], for people living with HIV who want to quit smoking. Through an iterative process with people living with HIV who were current or former smokers, as well as usability experts, we identified major themes associated with quitting smoking and developed and evaluated the Sense2Quit app to be used in our randomized controlled trial (RCT) starting in March 2023 [14,15].

Study Objective

The objective of this pilot RCT is to examine the feasibility, acceptability, and preliminary efficacy of the Sense2Quit app as a tool for people living with HIV who are motivated to quit smoking. This paper details the procedures that will take place during the Sense2Quit RCT.

Methods

Ethical Considerations

All study procedures were reviewed and approved by the Columbia University institutional review board (protocol number AAAT7031). Study participants will provide written informed consent and HIPAA (Health Insurance Portability and Accountability Act) authorization before enrolling in the study. Consent forms inform participants about (1) why the study is being carried out, (2) the things they will be asked to do if they are part of the study, (3) any known risks involved, (4) any potential benefit, (5) options other than taking part in this study that they have, and (6) the way their health information will be used and shared for research purposes. The study staff explains all procedures that will occur throughout the study and answers any participant questions before obtaining the participant's informed consent.

Confidential participant information will be assigned a code number and separated from any name or information that is identifiable. The research file that links a participant name to the code number will be kept on a password-protected computer, and only the investigator and authorized study staff will have access to the file. Any results disseminated from the study will be deidentified.

All participants will receive US $40 after completing baseline procedures, US $50 after completing their 4-week follow-up, and US $60 after completing their 12-week follow-up. All tokens of appreciation will be presented in the form of a Bank of America pay card.

Design

The Sense2Quit study is a 2-arm RCT among people living with HIV who are motivated to quit smoking. Sense2Quit is a 12-week pilot study to determine the feasibility and acceptability of the intervention. This study duration is comparable to other small pilot feasibility and acceptability studies [16-21]. Participants are randomized to either the active intervention condition, which consists of an 8-week supply of nicotine replacement therapy (NRT), standard smoking cessation counseling, and access to the Sense2Quit mobile app and smartwatch, or the control condition, which consists of standard smoking cessation counseling and a discussion about enrolling in the New York State (NYS) Smokers' Quitline, whereby the study team encourages the participant to contact the Quitline. Those who contact the NYS Quitline are eligible to receive an NRT supply, smoking cessation counseling, and other benefits, depending on their zip code [22]. Participants in the control arm do not receive NRT as part of the study because the study team determined that offering NRT would not be considered a true standard of care. Intervention participants will self-report NRT use on the follow-up visit surveys. Control participants will receive a sheet with information about the NYS Quitline and will self-report whether or not they contacted the Quitline during check-in calls with the study team. Participants in both conditions are scheduled for a baseline visit, a 4-week follow-up, and a 12-week follow-up. Participants are informed that the day of their baseline visit is their quit date; however, they are given the option to set their quit date on an established date within 1 week following their baseline appointment. Study team members will call participants in both arms to check in on a weekly or biweekly basis about their quitting process. The differences in study arms are presented in Table 1.

[c]NYS: New York State.

Recruitment and Eligibility

Targeted recruitment occurs through the posting of flyers in community-based organizations and the submission of web-based advertisements (ie, Craigslist and RecruitMe), as well as through snowball sampling [23] of study participants. Potential participants are instructed to call our office line or contact the study email to participate in screening procedures over the phone with a study team member. The eligibility criteria for this study are presented in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- People living with HIV confirmed through medical records or pill bottles for antiretroviral therapy (ART) medications.
- Aged 18 years or older.
- Able to understand and read English.
- Current smoker (smokes at least five cigarettes per day for the past 30 days).
- Owns an Android smartphone.
- Not pregnant or breastfeeding (due to contraindications for nicotine replacement therapy [NRT]).
- Permanent contact information.
- Interested in quitting smoking within 30 days.
- Exhaled carbon monoxide (eCO) ≥5 ppm (parts per million) at baseline.

Exclusion criteria

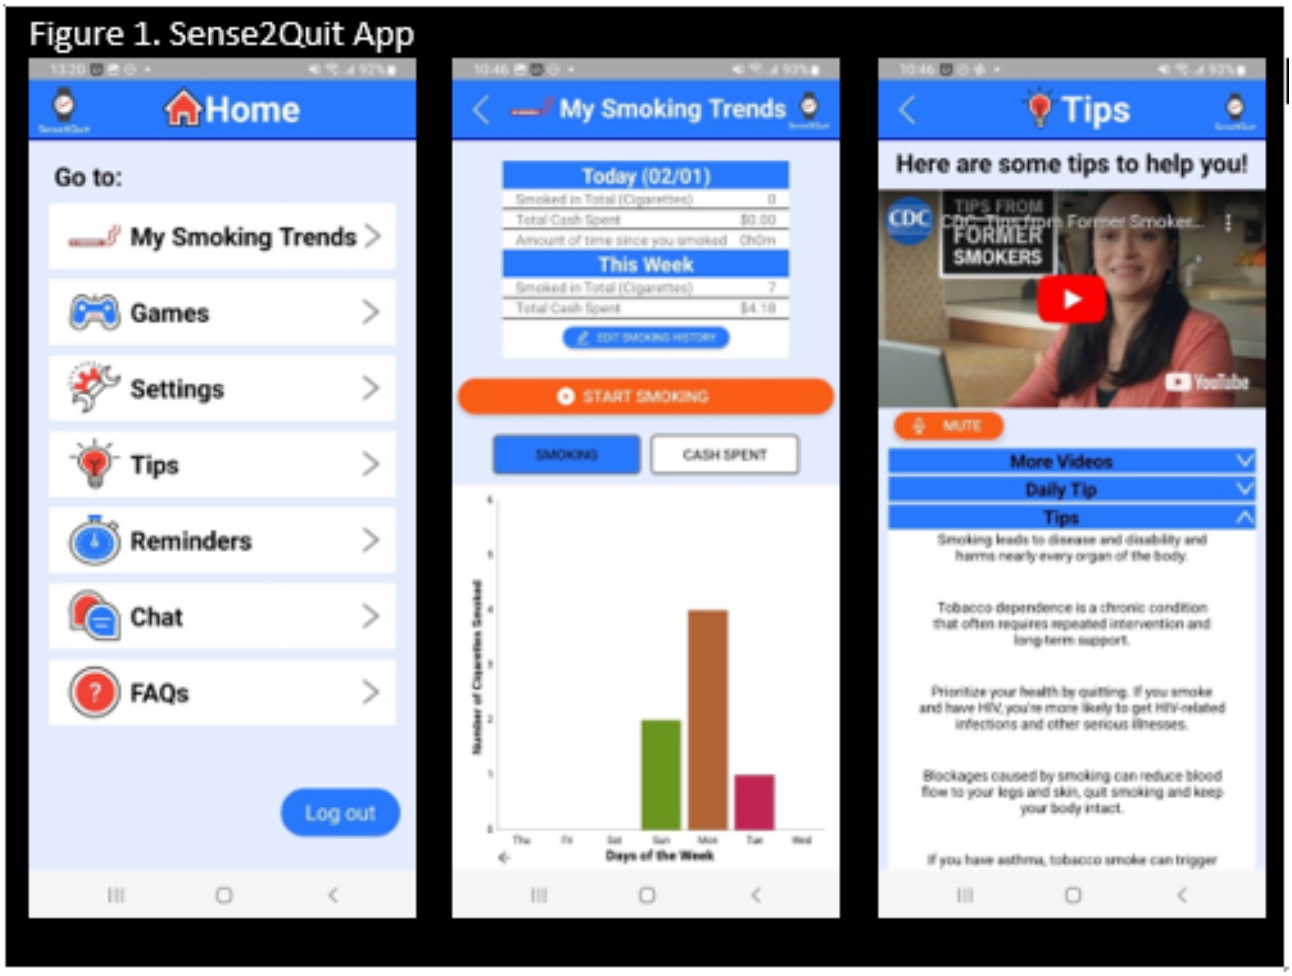
- Use of tobacco products other than cigarettes (ie, vapes, electronic cigarettes [e-cigarettes], cigars, piped tobacco, chew, and snuff).
- Planning to move within 3 months of enrollment.
- Alcohol dependence as measured through the Alcohol Use Disorders Identification Test-Concise (AUDIT-C).
- Positive history of a medical condition that precludes nicotine patch use.
- Current use of NRT or other smoking cessation medications (eg, Chantix or Zyban).
- Current enrollment in another smoking cessation program
- A household member is also participating in the Sense2Quit study, as it can lead to study contamination [24].

Sample Size Calculation

This study is a pilot study, and therefore it is not powered to detect efficacy. In this pilot study, we propose a total sample of 60 (30 per arm group) with a 20% expected attrition rate. Therefore, this study is not powered to detect a significant difference between study arms. Instead, we estimated the precision of proportion estimates (cessation rates) for the given

XSL•FO
RenderX

sample size (30 per arm). For the proposed sample size of 30 per group, we will have at least an 80% probability that the SE of the cessation rate estimates are ≤7%.



Randomization

Eligibility is confirmed at the in-person baseline visit. Participants confirm their HIV status by showing the study team their ART prescription or other medical records that provide HIV status. Smoking status is confirmed by the participant having an exhaled carbon monoxide (eCO) level of ≥5 ppm (parts per million). Upon confirmation of eligibility, participants complete the informed consent process and are randomized to the study group using a computer random number generator in Research Electronic Data Capture (REDCap). Study personnel are blinded to randomization before enrollment. Sex (assigned at birth)-stratified randomization is achieved through random-permuted blocks.

Description of the Intervention: Sense2Quit App

The Sense2Quit app (Figure 1) is a mobile app connected through Bluetooth to a smartwatch that tracks smoking gestures and distinguishes them from other everyday movements such as eating, drinking, etc. The ISR framework guided the development of the app and included an iterative process [14,15] where both people living with HIV, who were current or former smokers, and usability experts helped design, evaluate, and refine the Sense2Quit app. Findings from the formative work were used to inform the final Sense2Quit app, which was used in the RCT [14,15].

Figure 1. Sense2Quit app.

In the Sense2Quit app, participants can view their smoking trends, which are recorded through their use of the smartwatch, including how often or how much they smoke and the amount of money that they are spending on cigarettes, watch videos with quitting tips, information, and distractions, play Pac-Man and Tedroid (a game similar to Tetris [25]), set reminders, and communicate with a study team member.

Following enrollment in the study, participants who are randomized to the intervention arm receive a smartwatch and access to the Sense2Quit app. Participants are assigned a username (their study ID, SQ, followed by a number assigned chronologically) and can create a password for themselves. A study team member familiarizes the participant with the app, highlighting each component and feature. Participants can send a chat or call the study office whenever they have a question about the app or watch.

Study staff will encourage participants to wear their smartwatch on a daily basis so that it accurately captures smoking data. All smoking data will be displayed on the "My Smoking Trends" page of the app in the form of a graph. If the smartwatch incorrectly detects smoking, participants can click "Edit Smoking History" to update their smoking data for the previous

XSL•FO
RenderX

week. Participants will be informed of the potential benefits of using the "Games," "Tips," and "Reminders" pages of the app, such as distracting themselves to overcome an urge to smoke by playing Pac-Man or Tetroid or watching a video. Additionally, tailored reminders can be set to overcome daily urges such as those surrounding morning coffee or a meal. Study staff will check in with participants throughout the study about any issues that arise while using the app, and participants will come into the office for a tech appointment when necessary.

Study Assessments

Participants are enrolled in person at the research office. After enrollment, participants in both arms complete study assessments at their baseline, 4-week, and 12-week follow-up visits, for a total of 3 study visits. Surveys are administered through Qualtrics (Qualtrics Experience Management [XM]) and gather information about participant demographics [26], tobacco use history, tobacco cessation (primary outcome: self-report of whether or not they have smoked or used other tobacco products in the last 7 days; number of quit attempts), illicit substance and alcohol use [27,28], predictors of tobacco cessation [29,30], cravings and withdrawal [31], psychosocial factors [32-34], markers of HIV/AIDS immune status [35], and pharmacotherapy use. All instruments used in the surveys have consistently demonstrated high reliability and validity [26-37]. The Health Information Technology Usability Evaluation Scale (Health-ITUES) and Post-Study System Usability Questionnaire (PSSUQ) will be used on the 12-week follow-up assessment to help us determine the acceptability of the intervention. We will ask participants in both arms how useful each of the intervention components was using the PSSUQ with a 7-point Likert scale (1=strongly agree to 7=strongly disagree) [37] and Health-ITUES with a 5-point Likert scale (1=strongly disagree to 5=strongly agree) [38].

Primary Outcome

The primary outcome is the percentage of participants with a biochemically verified 7-day point prevalence of smoking or tobacco abstinence. The 7-day point prevalence of abstinence is calculated as the percentage of participants who reported no smoking or tobacco use in the 7 days before their 12-week follow-up visits (self-report on survey whether or not they have smoked cigarettes, even just a puff, or used other forms of tobacco in the past 7 days), which is then biochemically verified by eCO collected at 12 weeks through a breathalyzer (Micro+TM basic Smokerlyzer, coVita). Participants with eCO levels <5 ppm will be classified as abstinent, while participants with eCO levels ≥5 ppm will be classified as not abstinent. Although we exclude participants who report use of tobacco products other than cigarettes at baseline, we anticipate that some participants may use other tobacco products during the study period. Thus, abstinence will be defined as having refrained from using not only cigarettes but also all tobacco products.

Statistical Analysis

This is a pilot study to assess feasibility, acceptability, and preliminary efficacy. To determine feasibility, we will examine retention rates, eligibility criteria, recruitment and enrollment rates, missing data, and study measures. Descriptive statistics will be used for the analysis of demographic characteristics. The rate of quit attempts will be calculated as the proportion of smokers who made a quit attempt (defined as no smoking for at least a 24-hour period); 7-day point prevalence abstinence will be calculated as the proportion of smokers who have not smoked or used tobacco products in the 7 days before the study visit (as reported in the 4- and 12-week follow-up surveys) and verified by an eCO level of <5 ppm. We will provide point estimates and corresponding CIs of these measures for each arm. Because of the small sample sizes, we will obtain Clopper-Pearson exact CIs based on the binomial distribution. Given the small sample size, the purpose of the arms is to monitor for unexpected, gross differences between the 2 groups. The preliminary efficacy of the intervention will be based on 7-day point prevalence abstinence at the 12-week follow-up survey. Participants lost to follow-up will be included as smokers because we will be missing follow-up data and cannot determine whether or not the intervention was effective. Since this is a pilot study, we will be focusing on the acceptability, demand, and limited efficacy testing of the intervention. Acceptability will be assessed by evaluating how the participants react to the intervention (using PSSUQ and Health-ITUES). The demand for the intervention will be assessed by gathering data on estimated use. The limited-**efficacy testing** will be conducted on a convenience sample with a short follow-up period and limited statistical power [39].

Results

Enrollment of study participants began in March 2023 and is expected to end in October 2023. All data collection is expected to be completed by the end of January 2024. Results from this pilot study will be disseminated to the research community following the completion of all data collection.

Discussion

Overview

Our planned study will test the effectiveness of the Sense2Quit app for smoking cessation among people living with HIV in New York City. This RCT will assess the difference in outcomes between the control arm, receiving smoking cessation counseling and Quitline referral, and the intervention arm, receiving smoking cessation counseling, an 8-week supply of combination NRT, and a smartwatch linked to the Sense2Quit app. This study plans to address a gap in the literature surrounding mHealth for people living with HIV who smoke.

Smartwatch technology has been developed and tested in interventional smoking cessation studies within the past decade, yet study samples have been small, and more testing is required to improve the accuracy of smoking detection [40-43]. Similarly, mHealth has been used for smoking cessation and has been found to be effective in the short term [44-51], with little evidence of efficacy in the long term [52]. A systematic review of quit-smoking apps in Android's Play Store and Apple's App Store found high rates of existing irrelevant or nonfunctioning apps and few apps with evidence-based support [53]. Thus,

XSL•FO
RenderX

despite the large volume of apps to help users quit smoking that are currently on the market, few are likely to be effective.

Smoking cessation mHealth studies among people living with HIV are limited [12]. Tobacco cessation studies targeting people living with HIV have mostly consisted of automated messaging systems to intervene with smoking habits, motivational interviewing, and provision of pharmacotherapy [11,54-56]. In most cases, mHealth interventions for people living with HIV who smoke have been found to be more effective than face-to-face interventions [11], yet there is a need for more research on mHealth interventions which include interactive components such as communication with the study team or smoking cessation counseling [57]. Because people living with HIV are likely to have a shorter life span if they are chronic smokers [3], further research on effective quitting tools for people living with HIV is needed.

Although we found that people living with HIV in our focus groups were highly motivated to quit smoking due to health concerns, they identified needing additional interventions and support to successfully quit smoking amid everyday challenges and struggles [14]. With more than 350,000 apps currently on the market, mHealth technology is becoming widely known and used among people of all ages, races, and ethnicities [58,59]. mHealth technology is a promising tool across socioeconomic groups, as roughly 76% of low-income households (earning US $30,000 or less yearly) in the United States own a smartphone and indicate that their smartphone is their primary source of internet access [60,61]. Consequently, mHealth technology is a tool that is used in people's everyday lives and therefore can help with promoting health behavior change. This study will help us determine the potential of the Sense2Quit app to help people living with HIV quit smoking cigarettes. To our knowledge, the Sense2Quit study is the only existing study to use mHealth combined with a smartwatch to guide people living with HIV through their quitting process in New York City.

Limitations

This pilot study plans to recruit 60 people living with HIV in New York City who smoke cigarettes. As a result, the population may be too small to make generalizations about effective tobacco cessation techniques among people living with HIV in the short or long term. A second limitation is that although we will exclude people who use other tobacco products, such as cigars and vapes, we do not exclude people who may smoke other drugs, such as marijuana. This may result in incorrect smoking data for some participants. Participants will be instructed, however, on how to edit their smoking log in the app if incorrect data is shown.

Conclusions

The Sense2Quit study leverages mHealth so that it can help smokers improve their efforts at smoking cessation. Our research has the potential to not only increase quitting rates among people living with HIV who may need a prolonged, tailored intervention but also inform further development of mHealth for people living with HIV. This mHealth intervention also has the potential to address health inequities among people of different socioeconomic groups, as the majority of people in the United States own a smartphone and have access to apps. Finally, this study will contribute significant findings to the greater mHealth research community, providing evidence as to how mHealth should be developed and tested among the target population.

Abstract

Background: The integration of artificial intelligence (AI) into clinical practice is transforming both clinical practice and medical education. AI-based systems aim to improve the efficacy of clinical tasks, enhancing diagnostic accuracy and tailoring treatment delivery. As it becomes increasingly prevalent in health care for high-quality patient care, it is critical for health care providers to use the systems responsibly to mitigate bias, ensure effective outcomes, and provide safe clinical practices. In this study, the clinical task is the identification of heart failure (HF) prior to surgery with the intention of enhancing clinical decision-making skills. HF is a common and severe disease, but detection remains challenging due to its subtle manifestation, often concurrent with other medical conditions, and the absence of a simple and effective diagnostic test. While advanced HF algorithms have been developed, the use of these AI-based systems to enhance clinical decision-making in medical education remains understudied.

Objective: This research protocol is to demonstrate our study design, systematic procedures for selecting surgical cases from electronic health records, and interventions. The primary objective of this study is to measure the effectiveness of interventions aimed at improving HF recognition before surgery, the second objective is to evaluate the impact of inaccurate AI recommendations, and the third objective is to explore the relationship between the inclination to accept AI recommendations and their accuracy.

Methods: Our study used a 3 × 2 factorial design (intervention type × order of prepost sets) for this randomized trial with medical students. The student participants are asked to complete a 30-minute e-learning module that includes key information about the intervention and a 5-question quiz, and a 60-minute review of 20 surgical cases to determine the presence of HF. To mitigate selection bias in the pre- and posttests, we adopted a feature-based systematic sampling procedure. From a pool of 703 expert-reviewed surgical cases, 20 were selected based on features such as case complexity, model performance, and positive and negative labels. This study comprises three interventions: (1) a direct AI-based recommendation with a predicted HF score, (2) an indirect AI-based recommendation gauged through the area under the curve metric, and (3) an HF guideline-based intervention.

Results: As of July 2023, 62 of the enrolled medical students have fulfilled this study's participation, including the completion of a short quiz and the review of 20 surgical cases. The subject enrollment commenced in August 2022 and will end in December 2023, with the goal of recruiting 75 medical students in years 3 and 4 with clinical experience.

XSL•FO
RenderX

Conclusions: We demonstrated a study protocol for the randomized trial, measuring the effectiveness of interventions using AI and HF guidelines among medical students to enhance HF recognition in preoperative care with electronic health record data.

Introduction

Computer-based diagnostic systems have played a critical role in both clinical practice and medical education, enhancing diagnostic accuracy and fostering the development of necessary knowledge and skills [1]. According to the Institute of Medicine's report [2], the use of informatics for clinical decision-making is an essential educational competency required for all health care professionals. However, the informatics landscape has undergone rapid advancement with the advent of deep learning in artificial intelligence (AI) and has revolutionized disease diagnosis, treatment delivery, and patient care [3-5]. Subsequently, AI-based tools become increasingly prevalent in health care, allowing health care providers to make informed clinical decisions for high-quality care and optimal patient outcomes [6-8].

As AI continues to be integrated into medical practice, it becomes inevitable for medical students, residents, and professionals to acquire the necessary skills for effective medical practice [9]. In 2021, Lomis et al [10] highlighted the importance of incorporating AI training across health care professions to maximize its benefits while mitigating the potential drawbacks in routine patient care. Mckinsey's report [11], titled "Transforming Healthcare with AI," emphasizes the need to implement this transformation within the realm of education and training. Moreover, AI training within the medical school curriculum is an active area of discussion and investigation [10,12,13]. With AI in the medical program, students have the opportunity to learn about the use of apps and limitations of AI in clinical practice and improve their ability to use AI-based tools to enhance patient care and decision-making.

In 1989, Iliad [14,15], a computer-aided diagnosis, was introduced to enhance diagnostic abilities, encompassing over 6300 disease manifestations and addressing 1300 diseases related to internal medicine. Iliad offered a unique diagnostic learning experience by simulating cases and guiding users through a series of decision-making processes encountered in clinical workups. It also provided tailored feedback at each decision-making of the clinical workups based on the user's performance. Lincoln et al [16] and Lange et al [17] demonstrated the improvement of diagnostic reasoning and a diagnostic error reduction among medical students and nurse practitioner students. Similarly, Friedman et al [18] confirmed enhanced diagnostic accuracy before and after using diagnostic consultation systems among medical students, residents, and physicians.

Despite the benefits of diagnostic systems, their integration into educational programs has been limited and has insufficient results [19,20]. Berner and McGowan [1] also pointed out that 1 contributing factor to limited educational usage is the stand-alone nature of these systems, which needs to be better integrated into existing clinical workflows. Conversely, Tolsgaard et al [21] observed that commercially available AI systems used in clinical settings are predominantly tailored to address specialized clinical challenges rather than assisting health care providers in skill enhancement. As a result, there is a gap in the development of health care professionals' ability to use such decision support systems to use algorithmically generated recommendations in their clinical decision-making responsibly.

Moreover, an overreliance on AI systems can lead to unintended errors due to automation bias [22], which refers to the tendency for individuals to place excessive trust in automated systems and disregard their own judgment, such as the failure of autopilot technology [23]. Without proper training on the responsible use of AI, health care professionals may unknowingly commit mistakes by relying too heavily on AI-based systems [24,25]. The lack of understanding and awareness of AI's limitations and potential biases can lead to errors in decision-making and patient care [26]. Health care professionals need the knowledge and skills to critically evaluate and interpret AI-generated recommendations, taking into account contextual factors and individual patient needs [27].

To mitigate the adverse effects and ensure the responsible use of AI, Tolsgaard et al [21] emphasized the importance of integrating learning sciences with clinical science and data science while developing new AI systems. This interdisciplinary approach aims to combine insights from educational research, clinical practice, and data analysis to design AI systems [28]. This approach enhances performance and fosters continuous learning and professional development. By integrating these disciplines, AI systems can be designed to provide appropriate feedback, facilitate reflective practice, and support the acquisition of clinical reasoning skills, promoting a balance between clinical practice and education in health care.

This paper is centered on demonstrating a study protocol, including a study design, a systematic procedure for case selection from electronic health record (EHR) data, and intervention designs to improve the recognition of patients with heart failure (HF) before surgery in a preoperative care clinical setting. HF is a common and serious chronic condition characterized by an abnormality in the structure and function of the heart, leading to reduced blood circulation throughout

XSL•FO
RenderX

the body [29,30]. However, identifying patients with HF remains challenging due to its subtle and concurrent progression with other conditions and the lack of a single gold standard diagnostic test for HF [31,32]. Several algorithmic approaches have been recently published to improve HF detection, such as convolutional neural network with ECG [33-35], logistic regression [36], recurrent neural network [37], and transformer [38] models with EHR data.

The primary objective of this study is to measure the effectiveness of interventions aimed at improving HF recognition in preoperative care through a web-based clinical decision support (CDS) tool. The interventions are grounded in our previous research using traditional machine learning (ML) algorithms [39] and guideline-based diagnostic factors reviewed by clinical experts [40,41]. These interventions are algorithmically and manually synthesized from a large amount of EHR data for identifying HF. The secondary objective is to evaluate the impact of inaccurate ML recommendations in recognizing patients with HF, as compared to HF guideline-based recommendations. The third objective is to explore the relationship between the inclination to accept AI recommendations and the ability to accurately recognize HF using ML-based interventions.

Methods

Study Setting and Participants

Participants in this study are medical students to simulate the clinical task of preoperative surgical screening, targeting the recognition of HF as a specific educational objective using surgical cases performed at a tertiary hospital. This study's participants review surgical cases on our internally developed web-based CDS educational tool that displays deidentified EHR data, including clinical visits, diagnoses, procedures, vitals, laboratory, medications, imaging or studies, and clinical notes up to the day of surgery. To maximize the efficiency of case reviews, clinical data included in the CDS tool was tailored to preoperative care and cardiovascular diseases for screening HF. Irrelevant EHR data to this study (eg, administrative data, non-HF-related imaging) was excluded. This CDS tool was developed and deployed in a secure internal environment where study participants can access and review surgical cases.

The eligible students for participation in this study are medical students in their third (M3) or fourth (M4) year of medical school, who completed some coursework requirements and underwent clinical rotations. In addition, medical school graduates who have not yet started their residency program are eligible for inclusion. The rationale behind including senior medical students in this study is that accurate identification of HF using real-world EHR data needs a comprehensive understanding of clinical knowledge and skills acquired through coursework and clinical rotations.

This study is entirely on the internet and comprises two components as follows:

1. The first component entails an e-learning module, including an instructional video about the intervention and a short quiz, with an estimated completion time of 30 minutes.
2. The second component involves reviewing 20 surgical cases to evaluate the presence or absence of HF using EHR data, with an estimated completion time of 90 minutes.

Prior to reviewing the surgical cases, participants are required to complete a 5-question short quiz with all correct answers. They have the option to attempt the quiz multiple times if necessary. As this study is conducted on the internet, participants can complete this study at their own pace and at their own convenient time. Upon successful completion of this study, participants receive US $50 as a gift of appreciation.

Ethics Approval

This research study involving human subjects has received ethical approval from the institutional review board at the University of Michigan (HUM00207646). This approval indicates that this study's protocol, including research design, data collection methods, and informed consent, has been reviewed and considered to be in compliance with ethical standards for human subject research.

Study Design

The study design of this HF recognition study is a 3 × 2 factorial randomized trial that involves 3 intervention groups and the order exchange of 2 sets of surgical cases during the pre- and posttests. This study design allows us to measure the effectiveness of 3 interventions without introducing bias from surgical case selection in the pre- and posttests, summarized in Multimedia Appendix 1.

The rationale behind exchanging the order of 2 sets is to minimize the potential bias arising from differences in individual surgical cases. For example, if set A in the pretest contains 10 surgical cases that are more difficult than those in set B in the posttest, it would be challenging to attribute any improvements in accuracy solely to the interventions. Therefore, exchanging the order of the sets between the pre- and posttests ensures the measurement of unbiased interventions' effectiveness.

Furthermore, the use of random selection for the surgical cases is not suitable in this study due to the implementation of specific case selection criteria. The selection criteria aim to provide medical students with targeted learning opportunities to recognize HF through the review of surgical cases. The selection process is designed to ensure that the chosen cases offer valuable educational experiences and align with the intended learning objectives. Further details about the case selection are discussed in the later section dedicated to the systematic procedure for surgical case selection.

Prior to implementing the 3 × 2 factorial study design, a pilot study was conducted using a 3-arm study design. In this preliminary investigation, participants were asked to determine the presence or absence of HF before intervention access and then reassess the same surgical case after intervention access. However, this study design demonstrated an "anchoring effect," where participants tended to adhere to their initial clinical judgment. Therefore, it underestimated the effectiveness of the intervention. Consequently, the decision was made to adopt the 3 × 2 factorial design to overcome this limitation and provide a more accurate evaluation of the effectiveness of interventions.

XSL•FO

Interventions: ML_{DR}, ML_{IR}, and EB References

In order to measure the effectiveness of AI and guideline-based educational methods with 3 distinct interventions, the interventions need to provide essential information specific to the methods to enhance the ability to accurately recognize HF using patient data from the EHR.

The essential information is consolidated into a single *reference* page, which compiles risk factors associated with HF and method-specific recommendations (eg, HF yes or no, risk scores) to augment medical students' ability to recognize HF accurately. The risk factors are categorized into nine sections based on consultations with HF experts to improve the readability and comprehensibility of the interventions. These sections include (1) signs and symptoms, (2) past HF history, (3) past medical history, (4) surgical history, (5) medications, (6) physical exams, (7) test labs, (8) imaging or studies, and (9) ECG. A detailed description of the risk factors within each section can be found in Multimedia Appendix 2.

During the posttest phase, the intervention, represented by the reference page, is available to medical students who completed the first 10 surgical cases using only their clinical judgment during the pretest. In the posttest, the reference page is accessible through an ML or EB reference tab (6) in Figure 1 and can be accessed at any time while medical students review a surgical case. Further information about developing the ML model used in ML reference is included in Multimedia Appendix 3, and the details of the intervention differences are outlined as follows.

Figure 1. A web-based educational tool to review surgical cases, including (1) demographics (top left), (2) surgical case information (top middle), (3) preoperative vitals (top right), (4) subject domains (left side), (5) EHR data of a subject domain (center), (6) ML and EB intervention (left bottom). The intervention tab is only available during the posttest. After reviewing surgical cases, answer survey questions by clicking the (7) "TAKE QUIZ" button. EB: evidence based; EHR: electronic health record; ML: machine learning.

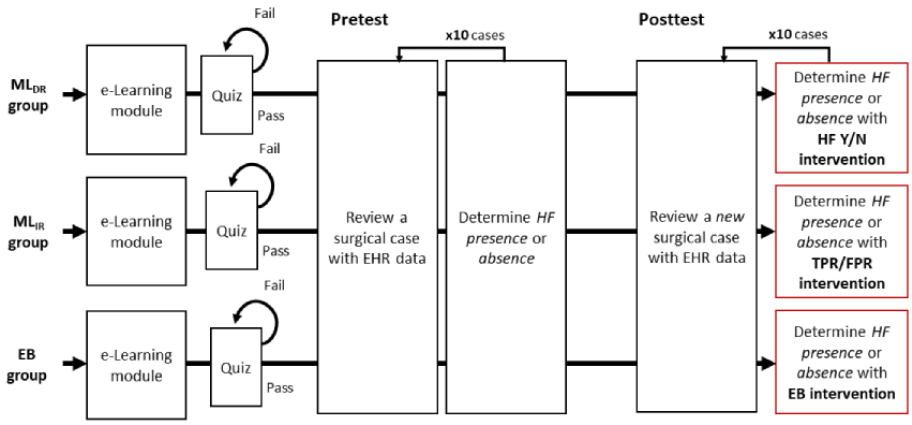
ML_{DR} Reference

The ML_{DR} reference provides a direct recommendation (DR), which is an output from the ML algorithm in the form of the presence or absence of HF, a dichotomous response. To achieve this, an optimal threshold is set to discriminate between positive and negative cases based on the estimated HF probability. The threshold configuration is critical in determining the sensitivity and specificity of the system. In this study, the optimal threshold was determined to be 38% based on the assumption that sensitivity and specificity are equally important. The ML_{DR} reference includes a brief explanation of the dichotomous recommendation, such as "this patient has a 98% chance of having HF, which is above the 38% threshold," to allow medical students to incorporate this into their clinical decision-making. It is important to note that the diagnosis of HF is a complex process that requires a thorough examination, and ML_{DR} reference offers a simple and efficient method to recommend the presence or absence of HF to medical students, along with a justification of the recommendation. The screenshot of ML_{DR} reference is in Multimedia Appendix 4.

ML_{IR} Reference

ML_{IR} reference offers an indirect recommendation (IR), which is a proxy of carrying HF risk, using the area under the receiver operating characteristic (AUROC), which comprises the true-positive rate (TPR) and false-positive rate (FPR). The AUROC plot, with TPR and FPR plotted along its axes, provides a comprehensive view of the model's performance across various thresholds. In contrast to ML_{DR} reference, which is limited to a single threshold, ML_{IR} reference shows the position of TPR and FPR on the AUROC plot when the threshold is defined as the predicted probability of HF for individual cases. For example, in the case of a surgical case with a high predicted

XSL•FO
RenderX



HF probability, ML_{IR} reference displays the corresponding TPR or FPR position on the AUROC plot, reflecting a high-level threshold equivalent to the predicted HF probability. This approach enables medical students to examine surgical cases with different TPR and FPR positions on the AUROC plot, thereby avoiding a *decision bias* toward a single threshold. The screenshot of ML_{IR} reference is in Multimedia Appendix 5. In short, ML_{DR} and ML_{IR} references adopt 2 distinct approaches to present direct and indirect recommendations to medical students while using the same underlying ML model.

EB Reference

The third intervention, *EB reference*, includes risk factors described in HF guidelines [42,43] and shows the presence or absence of these risk factors explicitly documented in EHR and clinical experts' impressions while reviewing the case from EHR. In our previous study [40], the 20 surgical cases were adjudicated by a consensus panel of HF experts (cardiologists, cardiac anesthesiologists, and critical care physicians) who indicated the explicit documentation of the risk factors in EHR as well as their impression of presence or absence of the risk factors. Unlike the risk factors from EHR data in ML references, this intervention uses the highest-quality evidence in the medical literature from various clinical studies and a consensus of domain experts to incorporate evidence-based practice into HF diagnostic recommendations. Further, because the HF recommendations in the guidelines [42,43] are intended to provide evidence-based recommendations for health care practitioners, they are presented in a way that is easy to *understand* and *acceptable* for clinicians. As such, the risk factors related to heart diseases are incorporated into medical education and training, resulting in less friction in clinical reasoning and decision-making. The screenshot of the EB reference is in Multimedia Appendix 6.

Each group in the HF recognition study is given access to one of the interventions during the posttest case reviews. After assignment to an intervention group, all participants reviewed the same 20 surgical cases, 10 surgical cases during the pretest phase, and then 10 new surgical cases during the posttest phase. The intervention is only accessible during the posttest. Figure 2 shows an overview of this study's participants for the three intervention groups: (1) ML_{DR} group, which receives direction recommendations indicating the presence or absence of HF; (2) ML_{IR} group, which receives indirect recommendations in the form of TPR, FPR, and AUROC plot; and (3) EB group, which receives expert-reviewed evidence-based risk factors from HF guidelines.

Figure 2. An overview of study participation using a 3 × 2 factorial study design. The participation includes an e-learning module, a short quiz, and 20 surgical case reviews. The order of 2 sets of 10 surgical cases is predetermined before the participant begins this study's activities. ML_{DR} group: a group of students who receive ML-generated risk factors and a direct recommendation of HF Y/N. ML_{IR} group: a group of students who receive ML-generated risk factors and an indirect recommendation of the likelihood of having HF from TPR, FPR, and AUROC. EB group: a group of students who receive HF expert-reviewed risk factors extracted from HF guidelines. AUROC: area under the receiver operating characteristic; EB: evidence based; EHR: electronic health record; FPR: false-positive rate; HF: heart failure; ML: machine learning; TPR: true-positive rate; Y/N: yes or no.

E-Learning Module

Prior to starting the surgical case review, participants are required to engage in a series of preparatory activities, including a web-based e-learning module that includes a 20-minute prerecorded instructional video, and a short quiz with 5 multiple-choice questions. The purpose of the e-learning module is to provide participants with the necessary knowledge and understanding to recognize patients with HF using the web-based tool. Given the diversity of participants' backgrounds and lack of familiarity with the new tool, this module offers educational materials and essential concepts that are fundamental to comprehending the interventions used to facilitate clinical decision-making.

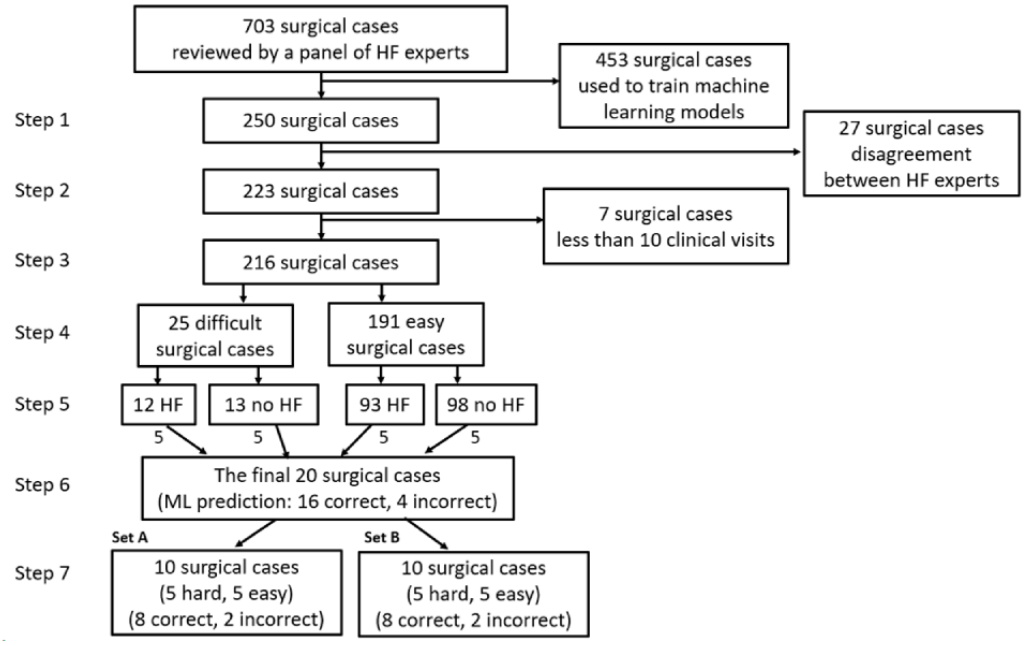
The e-learning module focuses explicitly on facilitating participants' comprehension of machine learning concepts, including predicted risk scores, important features, thresholds, and evaluation metrics (eg, sensitivity, specificity, TPR, and FPR) for ML intervention groups. Additionally, the module covers the identification of risk factors contributing to HF, as outlined in the American Heart Association [42,44] and the European Society of Cardiology [43] HF guidelines, and Framingham criteria [45] for the EB intervention group.

In an attempt to confirm that subjects have viewed and comprehended the material presented in the prerecorded video, participants are required to complete a short quiz, which must be completed with a score of 100% (5 out of 5 questions). When

XSL•FO
RenderX

questions are answered incorrectly, participants are instructed to review the material and revise their responses prior to proceeding to the next step. This e-learning module reduces variations in participants' prior knowledge and background to develop a standardized basis for evaluating surgical cases and measuring the effectiveness of interventions.

Surgical Case Selections



In our previous study [40,41], a consensus panel of HF experts, comprising cardiologists, cardiac anesthesiologists, and critical care physicians, assessed 1018 surgical cases, of which 703 were available during this study. These cases were part of a stratified subsample of 40,659 adult noncardiac surgical procedures between 2015 and 2019 at Michigan Medicine. Using a feature-based sampling process [46], 20 surgical cases were deliberately selected, considering factors, such as case complexity, expert consensus, ML performance, and HF outcomes. The 20 cases were divided into 2 sets, each consisting of 10 cases, for the use of pre- and posttests. Each set included an equal number of easy and difficult cases, as well as an equal representation of patients with and without HF.

The systematic sampling procedure for surgical case selection is illustrated in Figure 3. There are seven steps involved: (1) selecting cases from the holdout data set, (2) including cases that are consensus among expert reviewers, (3) including patients who had at least 10 clinical visits, (4) determining the level of difficulty from clinical diagnostic factors presented in EHR, (5) selection priority based on HF outcome, (6) consideration of ML performance (90% AUROC, 82% sensitivity, and 82% of specificity in our model), and (7) dividing cases into two sets for pre- and posttests. The more detailed descriptions of each step are included in Multimedia Appendix 7.

The implementation of a systematic methodology for case selection from EHR is critical, as the validation derived from this study could serve as a foundational cornerstone for scalability across diverse medical conditions. For example, diagnostic tasks using ML with expert-reviewed labels are potential candidates that could be integrated into this CDS tool by following the steps above, requiring only minor adjustments to accommodate unique clinical nuances. Thus, these ML-based tasks could be transformed into additional educational resources and presented to learners through this educational tool.

In the last step, surgical cases in set A and set B were presented to medical students in pre- and posttests to determine the presence or absence of HF. However, it does not guarantee equivalent difficulty levels, which is critical for evaluating intervention effectiveness. To mitigate the issue, we altered the order of sets in the pre- and posttests. Half of the participants received set A in the pretest and set B in the posttest, and vice versa for the rest of the participants, resulting in a 3 × 2 factorial design that ensured a balanced measurement of the interventions' effectiveness.

Figure 3. A systematic sampling procedure for the final 20 surgical cases with respect to the level of difficulty, positive and negative HF cases, and the ML performance from expert-reviewed surgical cases. HF: heart failure; ML: machine learning.

Sample Size and Recruitment Strategies

To assess the effectiveness of interventions with a power of 80% at a significant level of 5%, the total number of subjects needed is 75, with 25 subjects assigned to each group. This power analysis was conducted using a 1-sample *t* test using SPSS (version 28.0; IBM Corp), a statistical software package. The power analysis was based on our preliminary results, which indicated a mean difference of 0.08 and an SD of 0.13.

The recruitment for this study commenced in August 2022 and will continue until December 2023. The primary recruitment method involves sending a group email to year 3 and 4 medical students through faculty and academic curriculum coordinators, posting notices in various institutional newsletters and web-based bulletin boards, and distributing fliers. The recruitment started at a single institution and expanded to participants from other institutions.

XSL•FO
RenderX

Furthermore, snowball sampling has been used, which asks for referrals from enrolled study participants. To encourage referrals, a referral-based lottery has been implemented for individuals who refer their friends and colleagues in year 3 or 4 medical students. This lottery is recurring quarterly, and the winner will be drawn each term and awarded a US $100 prize. In addition, we have implemented a sweepstakes for study participants who will enter for a chance to win US $500 worth of prizes to recruit more students.

Assignment of Interventions

To participate in this study, subjects must first complete a survey form providing information about their school year, clinical experiences, and their level of acceptance toward clinical recommendations made by both clinical experts and AI algorithms. As an individual's behavior and willingness to accept recommendations can significantly impact this study's outcome [47], the level of acceptance was included in the survey form for use in the subject assignment.

Upon registration, subjects are allocated to one of the intervention groups using a permuted block and stratification method [48]. This method involves stratifying subjects based on key characteristics and randomly assigning them across groups within a fixed size of blocks. For this study, the acceptance level of AI recommendations (≥50%) and medical institutions serve as the stratification criteria, with subjects being randomly assigned to intervention groups within each block of size 6. As a result, each block consists of 2 occurrences of 3 distinct interventions.

Data Collection

Upon completing the e-learning module, medical students begin reviewing 20 surgical cases. To assess the accuracy of recognizing patients with HF, medical students respond to a set of 3 survey questions for each case review. This survey is embedded in the web-based tool, which is accessible after reviewing EHR data and intervention information. Medical students have the option to revisit data points if needed to address the survey questions. As shown in Multimedia Appendix 8, 3 survey questions are presented to evaluate the ability of medical students to accurately identify the presence or absence of HF. The first question pertains to the final decision of HF presence or absence at the start of surgery, followed by a question on their level of confidence in their clinical decision. Finally, medical students are requested to check the type of information they use to inform their clinical decision-making process.

Outcomes

The primary outcome of this study is to assess the effectiveness of interventions in improving the accuracy of recognizing patients with HF, by measuring the mean difference of recognition accuracy before and after intervention in pre- and posttests. Specifically, this study will demonstrate the mean difference in HF recognition accuracy before and after accessing ML_{DR} ML_{IR}, and EB reference interventions.

The second outcome of this study is to evaluate the impact of accurate or inaccurate ML recommendations on medical students' clinical judgment to recognize the presence or absence of HF, compared to the EB intervention group. In addition, this study explores the differential effects of direct and indirect ML recommendations on clinical decision-making among students.

Lastly, this study measures the effect of the acceptance level of AI reported in the prescreening survey on the accuracy of recognizing HF using ML references. This exploratory outcome will provide valuable insights for enhancing the acceptability of AI tools.

Results

As of July 2023, 62 of the enrolled medical students have fulfilled this study's participation, including the completion of a short quiz and the review of 20 surgical cases. The recruitment process for these study participants began in August 2022 and will end in December 2023.

Discussion

Principal Findings

In this study protocol paper, we outlined a methodological approach for measuring the effectiveness of ML-based interventions, both direct and indirect recommendations, and EB intervention. The interventions were integrated with EHR data within a web-based educational tool to enhance the recognition of HF before surgery. Specifically, we demonstrated a novel randomized trial using a 3 × 2 factorial design, systematic procedures for surgical case selection, and 3 interventions using ML algorithms and HF guidelines using EHR data.

The demonstration of 3 × 2 factorial design (intervention type × order of prepost sets) represents a unique methodological contribution, enabling the measurement of intervention effectiveness through enrolling students in pre- and posttests. Prior work such as Lincoln et al [16] with medical students and Lange et al [17] with nurse practitioner students adopted a 2 × 2 × 2 mixed factorial design (disease sets × trained or untrained groups × replication) to evaluate diagnostic errors and posterior probability pertaining to the comprehensiveness of clinical workups. In contrast to Iliad, which offers feedback during training via simulated cases, our study provides an e-learning module designed to impart and apply synthesized information, grounded in AI or HF guidelines, to enhance diagnostic accuracy. With our proposed factorial design, the effectiveness of the synthesized information was measured before and after reviewing surgical cases derived from EHR.

Furthermore, this study protocol paper articulates a systematic procedure of selecting HF cases from expert-reviewed surgical cases in EHR, incorporating the difficulty level and positive and negative outcomes. We believe that this systematic procedure of case selection not only mitigates selection bias for this study but also offers a replicable framework for other diseases when expert-reviewed labels and EHR data are available. In addition, our approach has the potential of scalability to present algorithmically or manually synthesized information, along with other data available in EHRs, on other

XSL•FO
RenderX

diseases. This is challenging for expert systems like Iliad, equipped with a knowledge base or inference engine [14,49].

Limitations

While this study provides a foundational approach to measure the effectiveness of enhancing HF recognition, it is important to note limitations with respect to a limited scope of findings and generalizability. Specifically, the target sample size of 75 participants (25 in each study arm) is adequate with a statistical power of 0.80 to measure the effectiveness of enhancing HF decision-making before and after intervention access. However, additional research questions, such as comparative effectiveness between ML and EB interventions, are limited in this study. Furthermore, this study was primarily conducted within an academic medical center that could be limited to a representative of medical schools in the United States. Despite this sample size constraint, our proposed study has the potential to inform future studies to broaden our understanding of how AI-based tools can be helpful for medical education and training.

Moreover, this study primarily focuses on intervention effectiveness, neglecting the essential facet of learner engagement and feedback mechanisms within the web-based tool. To enhance the effective learning outcomes in future iterations, the web-based decision support tool could incorporate real-time feedback upon each case completion, such as indicating the accuracy of case reviews and providing preannotated expert commentary on examined surgical cases. Additionally, offering structured guidance on interpreting AI-generated outputs is critical for accurately using predictive scores and in-depth analysis of misclassification instances. Integrating these postreview feedback mechanisms holds considerable promise for aiding learners in effectively leveraging AI-based tools for clinical decision-making.

The ML model used in this study was trained and evaluated on a stratified and manually reviewed data set, comprising patients who had developed HF and patients at high and low risk [40,41]. While stratification ensures the model learns various stages of HF progression, it may not accurately reflect the prevalence of HF estimated between 1.5% and 1.9% in the US population [50]. As a result, the model performance should be interpreted with caution when considering its use in a routine clinical setting and requires careful further examination. In this study, however, the deliberate inclusion of surgical cases for training the model with various complexities serves educational purposes effectively. This approach allows learners to gain experience in clear-cut positive or negative outcomes and also borderline cases, which are inherently challenging yet particularly informative.

Conclusions

In summary, this study protocol demonstrates a study design for measuring the effectiveness of interventions to enhance HF recognition among adult noncardiac surgical patients. Despite limitations of sample size and generalizability, this study serves as a foundational step toward a more comprehensive understanding of how AI techniques and evidence-based medicine can be synergistically used to advance both medical education and patient care outcomes.

Acknowledgments

The deployment of this study was possible with the extensive financial, infrastructure, and resource support provided by the University of Michigan. Several funding sources supported this study, including Research. Innovation. Scholarship. Education. (RISE) initiative, Michigan Institute for Computational Discovery and Engineering, Rackham Graduate Student Research Grant, and Aikens Innovation Academy from Frankel Cardiovascular Center. The Department of Learning Health Sciences offered unique opportunities to engage with professionals in health care, data, and implementation sciences. We thank Dr Karandeep Singh and Dr Zhenke Wu for their critical study reviews, and Dr Gretchen Piatt and Dr Anne Sales for their valuable insights in the realm of implementation science during this study's development. Additionally, during the RISE fellowship, the RISE team offered training sessions, ongoing support, and feedback to enhance my understanding of developing an AI-based tool for medical education. Notably, the core members of the RISE team, namely Dr Paula Thompson and Dr Nikki Bibler Zaidi, facilitated the training sessions and recommended developing relationships with relevant individuals for further guidance in order to obtain essential knowledge regarding the problem. With these supports, necessary connections were established with Dr Brian George, a surgeon whose insights into surgical consultation and workflow proved invaluable, and Dr James Woolliscroft, a professor of internal medicine and former dean of the medical school at Michigan Medicine, who provided valuable feedback on the overall study design and student recruitment processes. Lastly, the development and deployment of the web-based tool were feasible with the tremendous support from the Michigan Anesthesiology Informatics and Systems Improvement Exchange with the necessary IT infrastructure and resources to make this tool easily accessible to researchers and medical students. The use of ChatGPT (OpenAI, Microsoft Corporation) to improve the style of academic writing and grammar checking is disclosed in Multimedia Appendix 9.

Data Availability

Due to patient identification concerns and confidentiality, the data used for this study is not publicly available. Any request for data access may need additional approval from the institute review board at Michigan Medicine.

Abstract

Background: Depression is one of the most prevalent mental disorders and frequently co-occurs with other mental disorders. Despite the high direct and indirect costs to both individuals and society, more than 80% of those diagnosed with depression remain with their primary care physician and do not receive specialized treatment. Self-guided digital interventions have been shown to improve depression and, due to their scalability, have a large potential public health impact. Current digital interventions often focus on specific disorders, while recent research suggests that transdiagnostic approaches are more suitable.

Objective: This paper presents the protocol for a study that aims to assess the efficacy of a self-guided transdiagnostic app-based self-management intervention in patients with mild or moderate depression with and without comorbid mental disorders. Specifically, we are investigating the impact of the intervention on symptoms of depression, quality of life, anxiety symptoms, and mental health–related patient empowerment and self-management skills.

Methods: The intervention under investigation, MindDoc with Prescription, is a self-guided digital intervention aimed at supporting individuals with mild to moderate mental disorders from the internalizing spectrum, including depression. The app can be used as a low-threshold psychosocial intervention. Up to 570 adult patients will be randomized to either receive the intervention in addition to care as usual or only care as usual. We are including adults with a permanent residency in Germany and mild or moderate depression according to International Classification of Diseases, 10th Revision, criteria (F32.0, F32.1, F33.0, and F33.1). Clinical interviews will be conducted to confirm the diagnosis. Data will be collected at baseline as well as 8 weeks and 6 months after randomization. The primary outcome will be depression symptom severity after 8 weeks. Secondary outcomes will be quality of life, anxiety symptom severity, and patient empowerment and self-management behaviors. Data will be analyzed using multiple imputations, using the intention-to-treat principle, while sensitivity analyses will be based on additional imputation strategies and a per-protocol analysis.

Results: Recruitment for the trial started on February 7, 2023, and the first participant was randomized on February 14, 2023. As of September 5, 2023, 275 participants have been included in the trial and 176 have provided the primary outcome. The rate of missing values in the primary outcome is approximately 20%.

Conclusions: Data from this efficacy trial will be used to establish whether access to the intervention is associated with an improvement in depression symptoms in individuals diagnosed with mild or moderate depression. The study will contribute to expanding the evidence base on transdiagnostic digital interventions.

Introduction

In Germany, approximately 1 in 10 individuals experience depression in a given 12-month period [1]. Depression frequently co-occurs with other mental disorders; epidemiological data show that 61% of those with depression have at least 1 other mental illness [2]. This is supported by clinical evidence, where 69% of patients diagnosed with major depression also had at least 1 other Axis I diagnosis [3].

Health insurance billing data in Germany show a comorbidity rate of 50% within the group of mental disorders [4]. The most common combinations involve mood disorders (F3 group) and neurotic, stress, and somatoform disorders (F4 group) according to the International Classification of Diseases, 10th Revision (ICD-10), classification system [5].

The World Health Organization's World Mental Health Survey findings suggest that the majority of comorbid mental illnesses are a result of shared causal factors [6]. A study of the Dunedin Multidisciplinary Health and Development Study data also supports this conclusion [7], showing that across diagnostic categories mental illness can be broken down into 3 common higher-level factors (internalizing, externalizing, and thought disorders).

This finding may explain the transdiagnostic effects of many pharmaceutical and psychosocial treatments for a range of mental disorders [8,9]. As a result, mental health treatment approaches are shifting toward transdiagnostic interventions which are based on common underlying mechanisms of mental illness that have been proven to be effective across diagnoses [10]. Examples include the Unified Protocol [11] and the Common Elements Treatment Approach [12], which are increasingly replacing disorder-specific treatments.

Mental disorders are among the top 4 causes of healthy life years lost in Germany, with depression taking the first place within that group [13]. In 2015, the direct medical costs of depression in Germany were estimated at nearly €9 billion (US $8.4 billion) [14], while the loss of income due to depression throughout the European Union is approximately €176 billion (US $164 billion) per year [15].

Despite the high prevalence of depression and its significant direct and indirect costs, few receive specialized treatment. Health insurance billing data showed that while nearly 10% of insured individuals were diagnosed with an affective disorder at least once over a 3-year period, more than 80% of those affected remained with their primary care physician for the entire treatment [4]. On top, epidemiological data suggest that 3 out of 4 cases of major depression in Germany go undiagnosed and only 1 in 10 affected individuals receive evidence-based treatment as per national guidelines [16]. More recent data confirm this trend [17].

Treatment delay for depression can be attributed not only to limited resources among providers, but also to personal barriers such as low health literacy or negative attitudes toward seeking help. A desire to handle the issue alone and a low perceived need for treatment play a greater role in delaying treatment than structural barriers [18,19]. These factors hinder early detection, worsen the issue of underdiagnosis, and increase the risk of long-term symptom deterioration and chronicity [20].

Most people with depression in Germany receive treatment only from primary care physicians [4]. However, billing data from 2021 indicate that there are significant discrepancies between the frequency of mental illnesses in the general population as detected in epidemiological studies, and the diagnoses made by general practitioners [1,21,22]. While depression is diagnosed relatively in line with its frequency in the general population, anxiety disorders are underdiagnosed by as much as 75%. This suggests that comorbid disorders are likely not consistently recognized in primary care. This may be due to the difficulty of making a guideline-based diagnosis and differential diagnosis within the limited time frame of a general practitioner consultation, which typically lasts between 6 and 11 minutes [23,24].

Studies have found digital, cognitive-behavioral self-management programs to be effective for depression. Disorder-specific programs produce moderate to large effects on depression compared to waitlist controls [25-30]. Specifically, smartphone-based interventions have been shown to produce small to moderate effects [31]. The effect of self-guided transdiagnostic interventions on depression symptoms is comparable to the effect of disorder-specific interventions, with moderate to large effects on depression symptoms, and large effects on anxiety symptoms [32].

Interventions that include guidance by a mental health professional have larger effects [30,33-36], but there is also research showing no differences between guided and self-guided interventions [34,37-39]. Overall, self-guided interventions are more scalable due to lower costs and less human resources, making them more impactful for public health [40], especially when administered in primary care settings [41]. Other factors contributing to the variability in the results of self-guided interventions include study design characteristics including the use of clinical interviews [42], automated reminders [43], and the clinical setting [41], as well as participant characteristics like the severity of the disorder [34].

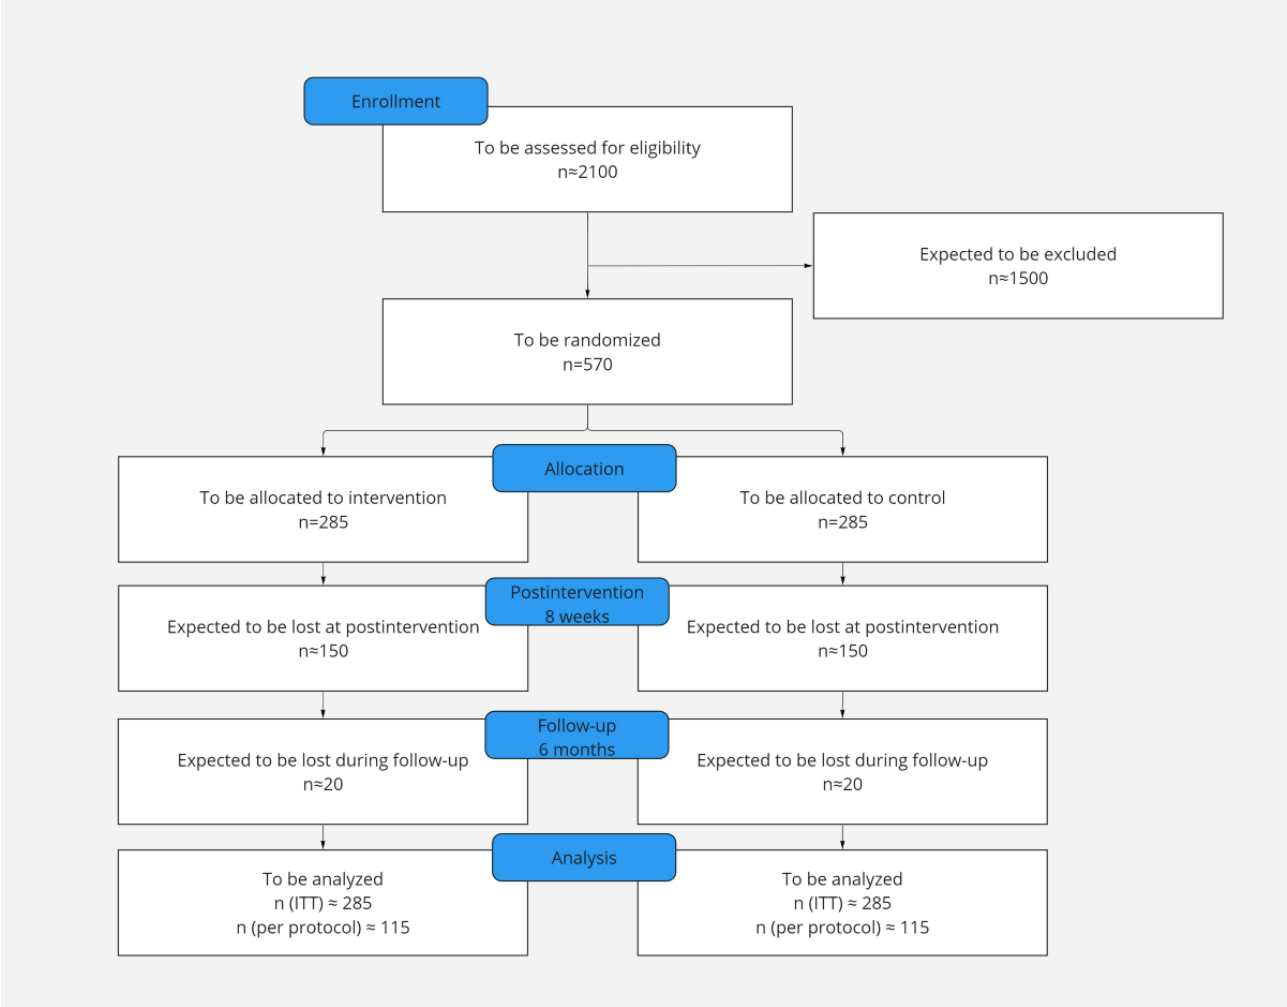
Meta-analyses confirm the effectiveness of digital interventions not only in reducing symptoms but also in improving quality of life [44] and there is also some evidence that such

XSL•FO
RenderX

interventions can reduce self-stigma [45-47] and improve health-promoting behaviors [48].

Overall, digital interventions can help close the treatment gap for mental disorders including depression. In primary care settings, low-threshold transdiagnostic interventions appear to be most suitable, particularly due to the opportunity to address comorbid disorders, which are often overlooked in the setting, with the same intervention.

In a previous study on such a transdiagnostic intervention (MindDoc App) in people with mild or moderate symptoms of mental disorders from the internalizing spectrum [49,50], we detected small effects on depression symptoms (d=0.34) in both the overall sample (d=0.34) and a subsample of participants with depression symptoms above the diagnostic threshold (d=0.43). Small effects were also detected on quality of life (overall sample: d=0.19; subsample: d=0.31), anxiety symptoms (overall sample: d=0.22; subsample: d=0.24), and mental health–related patient empowerment and self-management skills (overall sample: d=0.29; subsample: d=0.41). Patient empowerment and self-management behaviors encompass a range of attitudes and behaviors that individuals exhibit in relation to taking control of their health and well-being, including seeking support, actively participating in health care decision-making, and adopting healthy habits.



The aim of this study is to evaluate the intervention in a sample of individuals diagnosed with mild or moderate depression. Based on our previous findings, we expect the intervention to be associated with less severe symptoms of depression at the end of an 8-week intervention period compared with a waitlist control group. We will also examine intervention effects after 6 months, as well as intervention effects on quality of life, anxiety symptoms, and mental health–related patient empowerment and self-management skills.

Methods

Study Design

We are conducting a monocenter 2-arm randomized controlled trial with 3 assessment points (baseline, postintervention at 8 weeks, and follow-up at 6 months). Participants in the intervention condition will receive access to MindDoc with Prescription in addition to care as usual. Participants in the control condition will only have access to care as usual. Care as usual includes any form of treatment, including psychotherapy, unless psychotherapy has already been started or planned at the time of inclusion in the study. The study design is illustrated in Figure 1.

Figure 1. Study design. ITT: intention-to-treat.

XSL•FO
RenderX

Procedures

Study participation includes a web-based screening, a diagnostic interview (baseline), 3 additional web-based surveys (baseline, postintervention, and follow-up) and a clinician rating (postintervention). In the intervention group, it additionally includes access to a digital health application (DiGA). The process is described in more detail below. All study data will be collected in an electronic data capture (EDC) system provided by Climedo Health GmbH in the form of electronic case report forms and electronic patient reported outcome forms.

Applicants first receive written information on the study procedure and must explicitly agree to participate in the study via electronic consent by ticking a number of checkboxes before they can proceed to the screening questionnaire. The responses are logged in the study database and can only be changed by the participants themselves. By ticking the checkboxes, they confirmed that they had thoroughly read and understood the information about the study procedures and data security measures (including information on how to contact the study team if they had questions) provided to them. This approach is General Data Protection Regulation (GDPR) compliant and was approved by the ethics committee.

After consent has been given, applicants proceed to a screening questionnaire, on which the majority of exclusion criteria are assessed. The applicants who do not fulfill any exclusion criteria are then invited to the diagnostic interview.

The diagnostic interview is conducted via telephone by a clinical psychologist or clinical psychologist in training. Before the actual interview begins, the participants are given another opportunity to ask questions about the study. They are also informed verbally once again that their participation is voluntary and that they can withdraw their consent at any time without giving reasons and without disadvantages. Immediately after the interview, applicants receive feedback on whether or not they can participate in the study.

The diagnostic interview is then followed by the actual baseline survey for the study. The link to the survey is sent to the participant's email address.

After the baseline survey has been completed, participants are randomized at the person level with 1:1 group assignment. Randomization is performed as block randomization in blocks of 4, 6, and 8, stratified by sex (male, female, and diverse), diagnosis (F32.0, F32.1, F33.0, and F33.1), and previous psychiatric or psychotherapeutic treatment (yes and no). Randomization lists were generated (1 per stratum) using Sealed Envelope [51] and directly integrated into the EDC system. Randomization is performed in a protected area of the EDC system that can only be accessed by authorized members of the study team without them having access to the randomization lists.

Participants will be notified of the results of the assignment via email. Participants assigned to the intervention group will immediately receive free access to the DiGA described below. Participants in the control group will receive free access to the DiGA after they complete their follow-up assessment.

In both groups, postintervention and follow-up assessments will take place after 8 weeks and after 6 months. The links to the respective surveys are sent to the participant's email address. The postintervention assessment also includes another telephone interview which is conducted by a clinical psychologist or clinical psychologist in training. Interviewers are blinded to the group assignment of the study participants.

If a participant fails to respond to a survey invitation, up to 5 reminders are sent within 14 days. If no response has been received after 28 days, the assessment will be marked as missing.

Eligibility Criteria

Overview

Eligibility criteria were selected to ensure an optimal fit of the study sample with respect to the subsequent implementation of the app in the German health care setting, to meet the requirements of the legal authorities, to minimize the impact of confounding variables, and to ensure comparability with other studies on self-guided digital interventions.

Inclusion Criteria

We are including adults with mild or moderate depression according to ICD-10 criteria (F32.0, F32.1, F33.0, and F33.1). Clinical interviews are conducted to confirm the diagnosis. Raters are clinical psychologists and clinical psychologists in training who are not part of the core study team. They administer the short version of the diagnostic interview for mental disorders [52], a short structured clinical interview for diagnosing mental disorders. The interview assesses current and lifetime diagnoses according to the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) and ICD-10.

Participants must also be fully legally competent, reside in Germany, and have sufficient German language skills. They must have access to their own smartphone (Android, version 6.0, Google, or iOS, version 13.0 or higher, Apple) and the internet, and be willing and able to use the app regularly and participate in the assessments.

Exclusion Criteria

We are excluding individuals who receive outpatient psychotherapy or inpatient treatment for a mental disorder at the point of enrollment or already have such a treatment planned to start within the next 8 weeks. We are also excluding individuals who report changes in antidepressant medication in the past 4 weeks, who report suicidal ideations, or who have a history of bipolar disorder, psychotic disorder, substance use disorder, or suspected substance use disorder. Individuals who report having used the MindDoc App or a comparable digital intervention in the past 12 months will also be excluded.

Recruitment

Participants are recruited via press releases, social media advertising, and cooperating primary care practices. Recruitment will take place over a period of at least 6 months. It is expected that about 2500 prospective participants will have to be screened, of whom 800 will be invited for a diagnostic interview to determine eligibility.

XSL•FO
RenderX

Intervention

MindDoc with Prescription is a digital intervention aimed at supporting individuals with mild to moderate mental disorders from the internalizing spectrum, including depression. The app can be used as a low-threshold psychosocial intervention.

MindDoc with Prescription is a risk class I medical device according to Annex VIII, Rule 11 of the Medical Device Regulation (REGULATION (EU) 2017/745 on medical devices). Intended users include individuals with mild and moderate mental disorders.

The app consists of four key components: (1) continuous self-monitoring of symptoms and personal resources (journal), (2) personalized feedback on symptoms and coping strategies (insights), (3) regular overall assessments of emotional health (result), and (4) courses and exercises for psychoeducation and self-management (discover). All content was developed by licensed clinical psychologists based on established guidelines for the treatment of mental disorders.

The journal component allows users to log symptoms and personal information up to 3 times a day, with mood assessments and free text inputs. The insights section provides personalized feedback based on the information recorded in the journal. The result section provides an overall assessment of emotional health every 14 days, while the discover section offers courses and exercises on coping with symptoms, drawing on cognitive behavioral therapy, and other evidence-based treatments. Recommendations for relevant courses are provided based on users' journal entries. The app is designed to help patients understand and manage their symptoms, promoting self-sufficiency, and empowering them to take control of their mental health.

Participants can contact the study team and the MindDoc customer support by email at any time with questions about app use. Requests will typically be answered within 1 working day.

A detailed description of MindDoc with Prescription is provided in Multimedia Appendix 1. Instructions for use can be viewed on the app manufacturer's website [53].

Measures

Screening and Diagnostic Interview

The screening questionnaire is designed to assess the inclusion and exclusion criteria described above and includes the depression module of the Patient Health Questionnaire-9 (PHQ-9) [54,55] to assess depression symptom severity, the Alcohol Use Disorders Identification Test (AUDIT) [56] to assess problematic alcohol use, and the Drug Use Disorders Identification Test (DUDIT) [57] to assess drug use. It also contains questions on current and previous treatments and diagnoses, as well as questions on sociodemographic data.

The diagnostic interview is a shortened version of the short version of the diagnostic interview for mental disorders (Mini-DIPS) [52], a short structured clinical interview for diagnosing mental disorders. The interview assesses current and lifetime diagnoses according to DSM-5 and ICD-10 and is used to confirm that participants fulfill the diagnostic criteria for depression and to assess comorbidity.

Study End Points

Depression Symptom Severity

Depression symptom severity is assessed using the depression module of the PHQ-9 [53,58], a 9-item questionnaire that is part of the Primary Care Evaluation of Mental Disorders (PRIME-MD) diagnostic instrument for common mental disorders [54] and can be self-administered. The questionnaire evaluates each of the 9 DSM-5 diagnostic criteria for depression [59], with scores ranging from 0 (not at all) to 3 (nearly every day). The PHQ-9 is a reliable and valid tool for measuring depression, with a Cronbach α coefficient of .89.

Quality of Life

Quality of life is assessed with the Assessment of Quality of Life-8 Dimensions (AQoL-8D) [60]. The 35-item self-rating scale can be used to evaluate the impact of health care services on an individual's psychosocial quality of life. It measures 6 psychosocial functioning domains and physical autonomy, and has shown high reliability (with a Cronbach α score of .96) and convergent and predictive validity.

Anxiety Symptom Severity

Anxiety symptom severity is assessed with the Generalized Anxiety Disorder-7 (GAD-7) [58,61], which is a 7-item tool for detecting symptoms of generalized anxiety disorder as defined in the DSM-5. Each item is rated on a scale from 0 (not at all) to 3 (nearly every day), making it an effective and reliable way to screen for anxiety disorders and assess their severity in both clinical settings and research.

Patient Empowerment and Self-Management Behaviors

Patient empowerment and self-management behaviors are assessed with a questionnaire we have developed for our previous study [49,50]. It consists of 10 statement items assessing patient empowerment on a 6-point Likert scale (strongly agree, mostly agree, somewhat agree, somewhat disagree, mostly disagree, and strongly disagree) and 18 question items assessing the frequency of self-management behaviors in the past 8 weeks on a 6-point Likert scale (never, once in a while, less than half the time, more than half the time, most of the time, and all the time). The questionnaire has good internal consistency in data from a previously conducted study. The parallel analysis yields 2 components, and an exploratory factor analysis with 2 factors yields medium to high factor loadings of the respective items on their scales as well as low cross-loadings. Reliabilities (McDonalds ω) are in the good to very good range for both subscales as well as the total scale (ω (self-management)=0.87; ω (empowerment)=0.82; ω (total scale)=0.89). Furthermore, the overall scale of the instrument showed convergent validity in the form of significant correlations (P<.01) with further surveyed constructs from health literacy (knowledge of self-help measures: r=0.44, 95% CI 0.39-0.49; "first aid skills": r=0.38, 95% CI 0.33-0.43), with attitudes toward mental illness (positive attitudes toward help-seeking behavior: r=0.46, 95% CI 0.41-0.51; stigma toward mental illness: r=0.30, 95% CI 0.25-0.36), and with the "coping"

XSL•FO
RenderX

(r=0.40, 95% CI 0.35-0.45) and "relationships" (r=0.37, 95% CI 0.31-0.42) subscales of the AQol-8D.

Other Measures

Depression symptom severity will also be rated by a clinician (clinical psychologist or clinical psychologist in training), using a short version of the Hamilton Rating Scale for Depression (HAM-D) with 6 items. The chosen version best differentiates between groups with and without treatment compared with other versions [62]. HAM-D is the most widely used clinician-administered depression assessment scale. The rating scale was supplemented with the Structured Interview Guide for the HAM-D (SIGH-D) [63,64]).

The therapeutic alliance is measured with a shortened version of the Working Alliance Inventory (WAI-SR) [65] is used, which contains the 8 items of the dimensions (process and goals).

Negative intervention effects were assessed with the Inventory for Balanced Assessment of Negative Effects of Online Interventions (INEP-ON) [66], which captures negative intervention effects from the patient's perspective. The questionnaire also assesses whether patients attribute these effects to the intervention or to other factors.

Confounding Variables

To estimate the influence of potential confounding variables, additional information is collected (see Textbox 1).

Textbox 1. Confounding variables to be investigated in secondary analyses.

Moderators (to be recorded before randomization)

- Duration of illness
- Gender and age
- Psychiatric comorbidity
- Type of depression (first-time, recurrent)
- Severity of depression (Patient Health Questionnaire-9 sum score at randomization)
- Prior treatment (antidepressant medication, outpatient psychotherapy, inpatient treatment or day treatment for a mental disorder, and comparable digital interventions for depression based on cognitive behavioral therapy)
- Personality functioning
- Health literacy

Mediators (to be recorded after 8 weeks and after 6 months, respectively)

- Outpatient visits with psychotherapists or psychiatrists
- Outpatient visits with general practitioners
- Outpatient visits with physicians of other specialties
- Inpatient treatment for mental disorders
- Changes in medication use between baseline and follow-up
- Use of other digital interventions addressing mental health between baseline and follow-up
- Use of alternative treatment methods (eg, acupuncture, osteopathy, homeopathy, and Reiki) between baseline and follow-up
- Use of low-threshold psychosocial services (eg, self-help groups, counseling centers, and social psychiatric service) or preventive services (eg, relaxation training) between baseline and follow-up
- Critical life events between baseline and follow-up

Personality functioning is assessed with the Level of Personality Functioning Scale-Brief Form (LPFS-BF) [67], a brief self-report measure that captures personality functioning in the domains of self and interpersonal pathology and is compatible with the assessment of severity of personality dysfunction according to ICD-11. The German version has high reliability and satisfactory validity. The severity of personality dysfunction was an important predictor of trial discontinuation in a previous study [50].

Health literacy was assessed with the Mental Health Literacy Questionnaire (MHLq) [68], a 29-item scale with 4 dimensions (knowledge about mental health problems, false beliefs or stereotypes, help-seeking and first aid skills, and self-help strategies). Results showed significant differences between individuals with more or less experience with mental health and good internal consistency for the overall outcome.

Safety End Points

To assess the safety of the intervention, the following adverse events were defined and recorded at 8 weeks and at 6 months, respectively: (1) new occurrence or worsening of suicidal ideations during the intervention and follow-up period (recorded via item 9 of the PHQ-9), (2) illnesses and injuries during the intervention and follow-up period (self-report), and (3) inpatient treatment during the intervention and follow-up period (self-report).

XSL•FO
RenderX

Sample Size

The primary end point is the between-group difference in depressive symptoms (PHQ-9 total score) after 8 weeks. The effect regarding the primary end point will be determined by a 2-tailed *t* test. Based on the results of our previous study, an effect of *d*=0.4 (Cohen *d*) is expected and a dropout rate of up to 60% is assumed. A sample size of 570 participants is required to detect the expected difference at 85% probability and α=5% significance in both intention-to-treat and per-protocol analyses.

Data Management

Study Data

All study data are collected and stored in an electronic data capture system (Climedo) in the form of electronic case report forms and electronic patient reported outcome forms All data collected by means of the EDC provided by Climedo Health GmbH are processed and stored in data centers in Frankfurt am Main, operated by Amazon Web Services EMEA SARL (Luxembourg), which acts as an order processor for Climedo Health GmbH. Amazon Web Services is currently ISO 27001, ISO 27017, and ISO 27018 certified hosting provider. The ISO 27001 certification largely corresponds to the requirements of the German Federal Office for Information Security and is compatible with these (eg, BSI-200). ISO 27017 is an international standard for securing cloud services (Cloud Security), while ISO 27018 primarily relates to the protection of personal data (Cloud Privacy). All personal data are stored on servers in Germany. After completion of the data collection, the pseudonymized data will be exported by MindDoc Health GmbH and stored there in digital form for a period of 10 years in accordance with legal requirements.

All data collected from participants will be assigned an 8-digit code consisting of random numbers and letters. Personal information, including name and contact details, are only collected from those participants who do not meet any exclusion criteria in the screening.

A pseudonymization list of names assigned to codes is stored in a protected area of the electronic data capture system, only accessible to authorized members of the study team. The data are protected from unauthorized access, allowing for secure study procedures. The list will be destroyed after the study completion or after 10 years.

All data collected will be handled in accordance with national law and the GDPR. All personal and health data will be stored and handled in accordance with international and national data protection guidelines. Any publication derived from the personal data will be presented in such a way that it is impossible to identify individuals by referring only to group-level statistics. Participants have the right to request the deletion of their records prior to the destruction of the pseudonymization list without giving any reason.

App Data

To use the digital health app, participants must create a user account with a name and email address of their choice, stored separately by MindDoc Health GmbH. Passwords must meet minimum security standards that are checked in real time by an algorithm. Forgotten passwords cannot be recovered and a new password can be set through a link sent via email.

Using the app generates additional usage data (eg, answers, mood ratings, and course or exercise usage) stored by MindDoc Health GmbH. These data can be merged with study data in pseudonymized form using personalized access codes and a 16-digit user ID.

All data collected as part of the app are processed and stored in a high-security data center in Germany. The data center is operated by T-Systems International GmbH, Hahnstraße 43, 60528 Frankfurt am Main, Germany, which acts as an order data processor for MindDoc Health GmbH. All personal data are stored on servers in Germany. Separate consent is obtained for the processing of health data pursuant to Article 9 (2) lit h DS-GVO within the app, without which the app cannot be used. Irrespective of the right to data deletion pursuant to Art. 17 DS-GVO, the data collected in the app can be deleted from the server directly in the app in the “Settings → Data & Security” area at any time. Prior to this, they can be transferred to the user’s own device using an export function.

All communication between the user and the technical platform is automatically encrypted. The app communicates with the server over encrypted connections using transport layer security or hypertext transfer protocol secure, which prevents third parties from unauthorized reading of the data while it is being sent (ie, “in transit”). Both servers and databases are located behind firewalls to prevent access to data while it is being stored (ie, “at-rest”) or while it is being processed (ie, “in process”). In order to independently check system security, test attacks (penetration tests) are carried out at least once a year by an externally contracted IT security company on the servers provided and attempts are made to gain unauthorized access to them on a test basis.

Statistical Analysis

Data will be described using descriptive statistics (eg, frequencies, mean, median, SD, and IQR) and visualizations (eg, histograms, box plots, and bar charts). Assumptions for statistical tests will be checked (eg, normality by histograms and tests, sphericity by Mauchly test, and equal variance-covariance matrices by Box and Levene tests). App usage will be described according to previously proposed standards for reporting adherence to digital interventions [69], and include days of use and engagement with different features of the app.

Significant baseline group differences will be detected using χ^2 and *t* tests on baseline variables and accounted for in all analyses.

The intervention’s effectiveness will be analyzed using an intention-to-treat approach with multiple imputed data. Missing values from the postsurvey and follow-up survey of nonbinary end points will be imputed using all available information collected at baseline by applying an iterative Markov chain Monte Carlo method based on the initial group assignment. For this purpose, imputations will be calculated for 100, 150, 200, 300, 400, and 500 iterations. Then, the fraction of missing

XSL•FO
RenderX

information (FMI) index will be determined for all multiply imputed data sets. The FMI ranges from 0 to 1 (where 1 means that 100% of the information required for the planned conclusions is missing) and is a reliable indicator of the validity of conclusions based on imputed data sets [70]. For the following analyses, the number of imputations that do not result in further improvement in FMI compared to previous imputations will be chosen. Statistical characteristics will be aggregated across the multiply imputed data sets using Rubin's rules. The comparison of intervention effects on all outcomes will be done using *t* tests.

In addition to the primary analysis, further sensitivity analyses will be performed. Analyses of intervention effects on all outcomes will be repeated using analysis of covariance, adjusted for baseline scores. In addition, per-protocol analyses excluding participants who violated the protocol will be conducted. The following protocol violations have been prespecified: (1) failure to download the app and complete the onboarding process in the intervention group, (2) reporting of using a similar digital health intervention during the intervention and follow-up period in the control group, (3) reporting of regular psychotherapy during the 8-week intervention period, and (4) noncompletion of postintervention or follow-up assessment. Subgroup analyses will be done to address potential heterogeneity.

To allow for adjustment of the sample size in this study (for lower dropout), an interim analysis can be performed. This can be done once the primary end point of 182 participants is available. With this sample size, the expected effect can be revealed with a probability of 85% at a significance level of α=10%. The interim analysis will be performed blinded, meaning that the variable "group membership" will be replaced by a dummy variable and the blinded data set will be analyzed by a person who is not part of the core study team and is unaware of the group assignment.

Ethical Considerations

This trial is conducted in compliance with the protocol, the Declaration of Helsinki and good clinical practice. The local ethical committee of Ludwigs-Maximilians-Universität München has approved the protocol (project 22-0984). Amendments to the trial protocol will be immediately communicated to the local ethical committee as well as the trial registry by the corresponding author.

No anticipated risks beyond normal daily life are associated with using the app and participating in the study. Temporary mood changes or increased stress may occur during mental health treatment. Based on preliminary studies with the DiGA, a medical benefit, including a reduction of depressive symptoms, can be assumed.

Participants will not receive compensation for participating in the study, but both groups will get free access to the intervention for a year, and those who complete assessments are eligible for a monthly prize draw for a €50 (US $52) voucher. All measures used in the study were selected both based on psychometric properties and the number of items in an effort to minimize participant burden.

The participants' physical, psychological, and social integrity will be protected. The participants have the option to refuse to answer questions, end participation at any time, and request data deletion (before their data have been anonymized) without any consequences.

If suicidal tendencies are suspected or present before randomization, applicants will not be eligible to participate in the study. If suicidal ideations are reported during the web-based screening process, participants will receive written information on available help resources. If suicidal ideations are detected during the diagnostic interview, the interviewer will conduct a crisis intervention and refer the applicant to the local crisis service.

Since suicidal ideations are among the symptoms of depression, they may occur during the intervention or follow-up period even in participants who did not report them at baseline. In this case, precautions will be taken: (1) participants will receive written information about help resources immediately after completing assessments and (2) the study team will be informed and a member will promptly contact participants to further assess the situation. If a crisis cannot be resolved or a participant cannot be reached, support from local emergency services will be sought and the participant's contact information will be shared with these services. Participants agree to this procedure upon enrollment in the study.

Patient and Public Involvement

Patients or the public were not involved in the design, conduct, reporting, or dissemination plans of our research, although user or patient feedback was an important source for the development and improvement of the mental health app investigated in this trial.

Dissemination

This trial aims to support the eligibility of MindDoc with Prescription for registration as a DiGA (Digitale Gesundheitsanwendung) for patients with mild to moderate depression under the Digitales Versorgungsgesetz (Digital Health Care Act). This law regulates the cost reimbursement by German statutory health insurances for digital health applications.

The publication plan includes a report on the effects of MindDoc with Prescription on outcomes, and a second publication on predictors of effectiveness in low-threshold mental health interventions. Results will be presented at conferences and authorship will be based on contributions.

Results

Recruitment for the trial started on February 7, 2023, and the first participant was randomized on February 14, 2023. As of September 5, 2023, a total of 275 participants have been included in the trial and 176 have provided the primary outcome. The rate of missing values in the primary outcome is approximately 20%.

Discussion

Anticipated Findings

Data from this study will be used to establish whether access to an app-based, self-guided, transdiagnostic intervention addressing common mental disorders is associated with an improvement of depression symptoms in individuals diagnosed with mild or moderate depression and with or without comorbid mental disorders. It will also be used to investigate improvements in quality of life, anxiety symptoms, and patient empowerment and self-management behaviors in relation to access to the intervention.

The results will provide additional insights into the therapeutic alliance in digital interventions and also assess their safety by systematically collecting data on negative intervention effects.

The study will contribute to the evidence base on transdiagnostic digital interventions and at the same time provide information on what role primary care providers can play in facilitating the dissemination of digital mental interventions.

Limitations

A possible limitation of the study could be the composition of the sample. Since participants are recruited over various channels including press releases and social media advertising, it is possible that those with previous (positive) experience with psychotherapy or other psychological interventions are more likely to enroll than those who have not yet sought treatment. In our previous trial, almost 60% of the participants reported previous inpatient or outpatient treatment for a mental disorder. In this trial, we aim to mitigate the risk of an imbalanced sample by cooperating with primary care providers (general practitioners and family doctors) to recruit participants for the trial.

Another possible limitation could be a high dropout rate at postintervention or follow-up, as is common in self-guided interventions. While we determined the sample size accounting for that risk, we also implemented several mitigation measures to reduce dropout, including clinical telephone interviews at baseline and postintervention.

The study is conducted in Germany. Results may not be generalizable to other countries and health care systems, especially free-market health care systems.

Impact and Future Directions

With a focus on both symptom reduction and patient empowerment and self-management behaviors, the study will contribute to expanding the evidence base of transdiagnostic low-threshold digital interventions.

Furthermore, the study aims to provide insights into factors impacting the effectiveness of transdiagnostic digital interventions in mental health care. By examining potential moderators and predictors of outcomes, the study will inform decision-making in stepped care and improve mental health care.

General psychopathology and personality dysfunction have previously been shown to predict treatment response in digital interventions, rendering these factors as potential predictors of outcome in this trial. Further, improvement of mental health–related self-management skills and literacy through app usage may constitute an important mediating factor for change in psychopathology. In addition, the detailed assessment of help-seeking behavior and mental health care use may help to disentangle the direct and indirect effects of transdiagnostic digital interventions on mental health.

Acknowledgments

We would like to thank all users of the MindDoc App who provided us with feedback on their user experience through reviews and usability studies.

Data Availability

The data sets generated and analyzed during this study will be available from the corresponding author on reasonable request after the main results of the trial have been published in a peer-reviewed journal.

Conflicts of Interest

IB is the chief science and clinical officer at MindDoc Health GmbH. CD is a staff researcher at MindDoc Health GmbH.

Abstract

Background: Many university students experience mental health problems such as anxiety and depression. To support their mental health, a transdiagnostic mobile app intervention has been developed. The intervention provides short exercises rooted in various approaches (eg, positive psychology, mindfulness, self-compassion, and acceptance and commitment therapy) that aim to facilitate adaptive emotion regulation (ER) to help students cope with the various stressors they encounter during their time at university.

Objective: The goals of this study are to investigate whether the intervention and its components function as intended and how participants engage with them. In addition, this study aims to monitor changes in distress symptoms and ER skills and identify relevant contextual factors that may moderate the intervention's impact.

Methods: A sequential explanatory mixed methods design combining a microrandomized trial and semistructured interviews will be used. During the microrandomized trial, students (N=200) will be prompted via the mobile app twice a day for 3 weeks to evaluate their emotional states and complete a randomly assigned intervention (ie, an exercise supporting ER) or a control intervention (ie, a health information snippet). A subsample of participants (21/200, 10.5%) will participate in interviews exploring their user experience with the app and the completed exercises. The primary outcomes will be changes in emotional states and engagement with the intervention (ie, objective and subjective engagement). Objective engagement will be evaluated through log data (eg, exercise completion time). Subjective engagement will be evaluated through exercise likability and helpfulness ratings as well as user experience interviews. The secondary outcomes will include the distal outcomes of the intervention (ie, ER skills and distress symptoms). Finally, the contextual moderators of intervention effectiveness will be explored (eg, the time of day and momentary emotional states).

Results: The study commenced on February 9, 2023, and the data collection was concluded on June 13, 2023. Of the 172 eligible participants, 161 (93.6%) decided to participate. Of these 161 participants, 137 (85.1%) completed the first phase of the study. A subsample of participants (18/172, 10.5%) participated in the user experience interviews. Currently, the data processing and analyses are being conducted.

XSL•FO
RenderX

Conclusions: This study will provide insight into the functioning of the intervention and identify areas for improvement. Furthermore, the findings will shed light on potential changes in the distal outcomes of the intervention (ie, ER skills and distress symptoms), which will be considered when designing a follow-up randomized controlled trial evaluating the full-scale effectiveness of this intervention. Finally, the results and data gathered will be used to design and train a recommendation algorithm that will be integrated into the app linking students to relevant content.

Introduction

Background

For young people, the years at university coincide with a transitional period of emerging adulthood [1,2]. This period is not only exciting but also a demanding and uncertain phase in life, and for some, it poses a great risk to their psychological well-being. Globally, it is estimated that between 12% and 50% of all university students are affected by mental health (MH) problems [3-5], the most common ones being anxiety, depression, and substance abuse disorder [3,4,6]. Because of the increased demands for MH support, traditional means of providing it, such as in-person counseling services, are difficult to achieve [7]. Even before the COVID-19 outbreak, which imposed additional challenges to student well-being [8,9], college counseling centers reported that they needed to continually adjust their operations to meet the demands for students' MH needs [10]. In-person MH support also does not fully fit the needs of all students. In fact, students who experience increased MH problems are especially less likely to seek help, and informal and web-based resources are preferred [11]. Moreover, students who experience higher levels of MH-related stigma are less inclined to use face-to-face MH services and are more open to digital tools such as MH mobile apps [12].

To help students navigate this transitional period of their life and equip them with skills relevant for and beyond university life, it is vital to develop preventive and therapeutic interventions that are easily accessible, can counteract MH-related stigma, and are at the same time cost-effective [13]. As part of a student well-being program introduced at Erasmus University Rotterdam (EUR) in 2019, a mobile app consisting of preventive self-guided MH tools is being developed. Its goal is to help students better manage their MH by supporting them in the development of adaptive emotion regulation (ER) strategies.

Digital tools supporting MH have been proven to be good solutions for existing barriers to care, such as long waiting lines and MH-related stigma, owing to their accessibility and ability to maintain students' privacy [14-16]. However, there are often substantial problems with the uptake (ie, use and acceptance) and actual effectiveness of these tools. Specifically, if the tool is not used for a recommended period, it is unlikely that it will have the intended effect [17,18]. Low uptake of interventions is often the result of a mismatch between technology and end users' needs [19]. Technology offers countless possibilities for its use, but if a product is not developed in line with the target user's needs (eg, values, goals, and abilities) or is not engaging and intuitive to use, the likelihood of such a product being integrated, accepted, and adopted by people is low [14,20]. Therefore, it is important to adopt user-centered eHealth design approaches, where the end user is involved across all stages of the design and development of the intervention as informant or co-designer and has a direct influence on both the outcome and the design process [21]. It is also essential to build a deeper understanding of how an intervention and its components function and under what circumstances they can be most beneficial for different users. This understanding can be helpful to tailor digital interventions to different types of users, optimizing their therapeutic benefits.

This paper describes the protocol for the optimization of a mobile app designed to improve students' MH, combining a microrandomized trial (MRT) [22,23] with semistructured interviews. The goals of this study are to examine whether the intervention and its separate categories (ie, groups of exercises rooted in different therapeutic approaches supporting ER) have the intended effects and how students engage with and perceive them. In addition, relevant contextual factors, such as emotional state and the time of day, that may have an influence on intervention effectiveness will be explored. The latter will support the development of the prototype of a recommendation system that will connect students to the relevant content in the app based on their needs and characteristics. Ultimately, the study results will support the optimization and further development of this mobile app, which will later be evaluated for its overall effectiveness in a randomized controlled trial (RCT).

MH Apps for University Students

The current generation of university students, consisting of millennials (those born between 1981 and 1996) and Generation Z (those born between 1997 and 2012), are considered digital natives. Research shows that these generations have developed specific behavioral characteristics owing to the influence of technology on their upbringing; for example, they communicate predominantly through web-based platforms, such as social media networks, because this provides quick and instant delivery of information [24]. This preference is not surprising, given that

XSL•FO
RenderX

both young millennials and Generation Z highly value efficiency and the ability to perform multiple tasks at the same time [25]. These generations are digitally connected socially as well as informationally. They grew up in a society where information is instant and easily accessible, which in turn makes them prone to using more flexible learning methods and settings [25]. This explains why learning with the help of internet-based digital systems, such as games or mobile apps, attracts them [26]. Considering this generation's needs and behavioral characteristics, interventions delivered through mobile phones are a good fit.

Several systematic reviews and meta-analyses have attested that digital interventions have the potential to improve mental well-being among this population [14,15,27-29]. However, most of the scientifically tested digital interventions for this population focus on web-based technologies and less so on mobile technology [14]. Mobile technology enables observation of the immediate context (eg, emotional state, location, and heart rate) through experience sampling and sensors and offers the possibility to recognize an individual's needs and provide relevant support by using recommendation systems [30]. This permits greater precision in lending support at moments and under circumstances when an intervention is most useful and the person is receptive to it, which can play a crucial role in its uptake [30]. The fit between their needs and the delivered content was indicated to be an especially important feature among university students [18].

Despite the many advantages of digital technology in the field of MH, digital interventions struggle with low uptake and high attrition rates [31]. One of the main challenges is involving and keeping users engaged in the intervention over a longer time span [31,32]; for example, a study examining engagement patterns with trendy MH apps (≥10,000 downloads) found that user retention was only 3.9% two weeks after downloading the app [33]. The low uptake of digital MH interventions is considered one of the most potent barriers to beneficial effects on users' MH because the intervention cannot have the potential impact when users do not engage with it [13]. Among university students, the main barriers to the use of MH apps include privacy concerns and concerns about the credibility of information. They prefer MH apps that are safe and secure, user friendly, credible, informative, and fitted specifically to their needs [13].

The Mobile App for Students' MH

Intervention Development

The development of the mobile app was guided by the Center for eHealth Research (CeHRes) road map, an established framework for the development of eHealth tools [19,34] in which evidence and theoretical insights are intertwined with design methods. This road map emphasizes a human-centered participatory design process and iterative approach to eHealth tool development [19]. Following this approach, the mobile app was designed with university students consistently at the center of the process and involved at all stages, from the analysis of the problem and context (ie, contextual inquiry) to the technical operationalization of the intervention. Students acted as informants and co-designers of the intervention. At the early stages of the intervention development, focus groups were conducted with other relevant stakeholders, that is, university psychologists and study advisors who are in close contact with this population. The development process involved a thorough review of scientific literature and multiple rounds of expert sessions involving MH professionals and behavioral scientists to lay a strong evidence- and theory-based foundation for our intervention. In collaboration with serious game and interaction designers, all intervention concepts and designs were tested with end users using qualitative and quantitative methods and iteratively adjusted in line with the results.

A Transdiagnostic Approach to MH

The intervention incorporates a transdiagnostic approach to MH (ie, Unified Protocol for Transdiagnostic Treatment of Emotional Disorders [35]) and implements techniques from various therapeutic approaches, such as positive psychology [36], mindfulness [37], acceptance and commitment therapy (ACT) [38], self-compassion [39], and cognitive behavioral therapy [40], to accommodate the diverse needs and content preferences of the student population. Using a transdiagnostic approach implies operating outside the traditional psychodiagnostics boundaries (ie, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition categories), focusing on the factors that cause or maintain problems that students present with. Instead of restrictedly following protocols aimed at specific disorders, this app will provide evidence-based interventions in a flexible fashion and in line with the needs and preferences of individual students [41].

Targeted psychological factors include negative self-referential thoughts, rumination, experiences of prolonged negative emotional states, and lack of MH literacy. These factors have been highlighted in the scientific literature [35,42-45] as well as by students, university psychologists, and study advisors interviewed at the start of this project. Targeting these transdiagnostic factors has been shown promising in the reduction of depressive and anxiety symptoms [35], both of which are prevalent among the university student population [3,4].

Intervention Structure

The current version of the mobile app consists of a suite of MH interventions in the form of short exercises. The goal of these exercises is to teach students how to use adaptive ER strategies such as acceptance, self-soothing, and reappraisal instead of maladaptive strategies such as avoidance, suppression, and rumination. In the short term, this will help them manage their emotional responses to internal (eg, unhelpful thoughts) or external (eg, failing a test) events by improving their ability to adjust or change the intensity and duration of emotional states [46]. In addition, students are frequently prompted to evaluate their emotional states through ecological momentary assessments (EMAs), which enable them to practice self-awareness and self-monitoring. In the long run, improving self-awareness and adopting adaptive ER strategies can work preventively by decreasing the likelihood of developing serious MH problems such as anxiety and mood disorders [47].

XSL•FO
RenderX

Our Vision for the Final Version of the App

For the final version of our MH app, we envision that students will be able to access multiple exercises at the same time and in any order and consume the content that is most relevant to their unique MH needs. Such a strategy has been previously proven successful in decreasing stress in university students in an Australian program for students called "thedesk" [48]. In addition, our app will include a recommendation system that will suggest exercises to students considering their unique characteristics, such as their goals, intervention preferences, MH state, momentary emotional state, the time of day, and individual app use history. The recommendation system introduces a potential solution to the low engagement and impact of the mobile intervention because efficiency, system responsiveness, and content relevance to users' needs are highly valued among this population and have been reported as lacking in available MH apps [18,49].

Intervention Optimization Using an MRT Method

To design an adaptive system of interventions responsive to users' needs, the optimization of their contents and delivery is crucial. This study will combine an MRT with user experience interviews, a novel study design that can provide information on which intervention is effective for whom and in what context [30].

An MRT can evaluate how different intervention components affect an individual in real time (ie, directly after they have used it), and it assesses how this effect varies over time (eg, an intervention may be effective at the beginning, but its effectiveness may decrease with time). In addition, this method can evaluate the moderating role of contextual factors (eg, current mood or the time of day) on the intervention effect, which is especially helpful when optimizing rules for intervention delivery [50,51]. Although it is a young method, an MRT has been successfully applied to evaluate dynamic and user-tailored eHealth interventions focused on weight management [52], smoking cessation [53], and MH [54]. Within the field of MH, NeCamp et al [55] investigated the optimal timing for delivering a mobile MH intervention to medical interns. The authors found that delivering an intervention when individuals experienced lower levels of MH indicated by low mood, poor sleep, and reduced activity was beneficial, whereas intervening when the individuals were doing well had a negative effect [55]. Another MRT study evaluated the impact of an ACT-based mobile intervention on distress symptoms (ie, depressive and stress symptoms) in first-generation university students [56], and the results suggest that interventions prompting mindful awareness and acceptance of internal experience (ie, thoughts, emotions, and physical sensations) were the most impactful for decreasing depressive symptoms. In addition, interventions delivered in the evening were more predictive of decreases in distress symptoms than those delivered in the morning [56]. Both studies signal the importance of considering contextual factors to optimize the impact of digital MH interventions.

Using MRT research design allows for the gathering of more granular and proximal insights about a given intervention, which cannot be captured through traditional RCT designs. In an MRT, unlike in a traditional RCT where individuals are randomized to an intervention or control group at the beginning of the trial, different intervention components (or no intervention) are repeatedly randomized to the participants at prespecified decision points. Thus, in an MRT, the randomization unit is not the participant but the intervention, and participants act as their own controls. Therefore, compared with an RCT, which focuses on between-participant effects, the MRT measures within-participant effects aggregated across participants. The decision point refers to the time of day at which an individual may or may not receive an intervention. Furthermore, the proximal outcome refers to the short-term goals of the intervention (ie, intervention targets) and is seen as the facilitator of the desired distal outcome of the intervention (ie, a mediator of the long-term outcome); for example, if the focus of an intervention is on increasing physical activity, a proximal outcome would be the number of steps taken within 30 minutes after an intervention was delivered, and the distal outcome would be the overall increase in physical activity at the end of the entire intervention period [51].

Finally, owing to repeated randomization, an MRT allows for the evaluation of the moderating role of contextual factors, such as current mood and time, on the proximal effects of the intervention [22].

Study Objectives

This study combines an MRT design with semistructured user experience interviews to achieve the following research goals.

Evaluation of the Proximal Effects of the Intervention

This study will experimentally evaluate whether the intervention as a whole and its separate intervention categories (ie, groups of exercises categorized into 5 therapeutic approaches) have the intended effects on participants' subsequent emotional states, which, in the long term, may have an impact on students' MH (eg, depressive and anxiety symptoms) and acquisition of ER skills [47], and whether these effects deteriorate over time. Increases in positive affect and decreases in negative affect when an intervention is received compared with when a control intervention is received are expected and considered effective. For exercises targeting unhelpful thoughts (ie, cognitive defusion [CD]), changes in thought believability and discomfort with the thought before and after the exercises will be observed, and unhelpful thoughts are expected to subside as a result of exercise completion.

Evaluation of Intervention Feasibility

The feasibility of the system will be examined by evaluating objective (ie, the pattern of interaction with the exercises) and subjective (ie, participant ratings and experience with the exercises) engagement behavioral patterns.

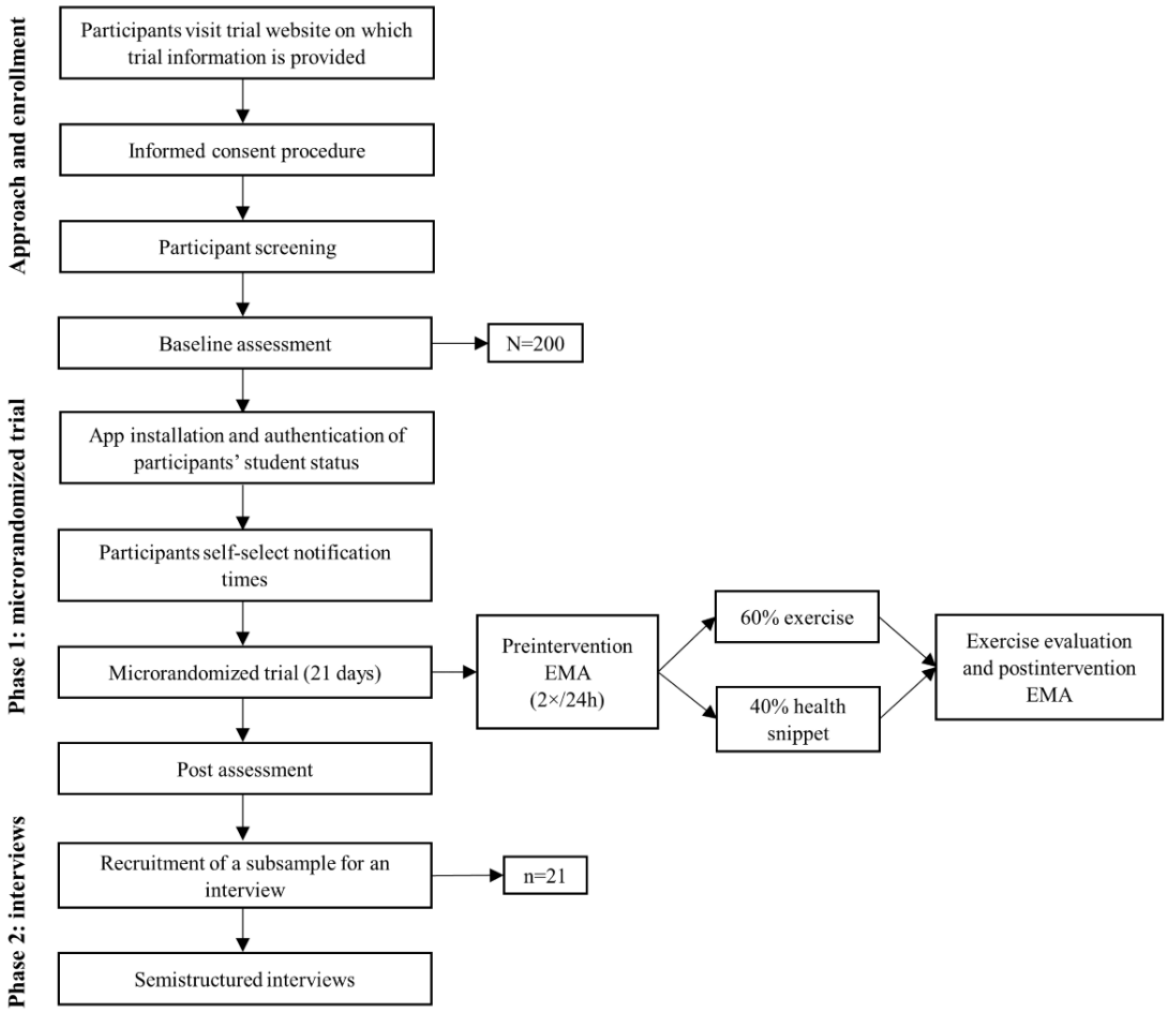
Evaluation of the Distal Outcomes of the Intervention

ER skills and level of distress (ie, stress as well as anxiety and depressive symptoms) will be evaluated before and after the intervention period for the purpose of safety monitoring and to inform the design of a follow-up RCT. In terms of safety, the results will be used to indicate whether negative changes in individuals' MH (ie, distress symptoms) occurred between

XSL•FO
RenderX

baseline and the end of the intervention period. As there is no comparator group, the results will provide only an indication of a potential link between worsened (or improved) distress symptoms and the intervention, which will be further tested in a traditional RCT. In terms of RCT design, given the innovative nature of this intervention, there is no prior data available to estimate its effect size. Therefore, we will use the pre-post evaluation of distal outcomes in this study as a pilot evaluation of changes in the distal outcomes to estimate the potential effect size of the intervention. This estimate will be used to calculate the sample size for the standard RCT, where between-group changes in distal outcomes (ie, ER skills and distress symptoms) will be evaluated.

Exploratory Goal: The Impact of Contextual Moderators on Proximal Intervention Effects



The role of the time of day, momentary emotional state, personality type, preferences, and intervention type as moderators will be explored to determine the context under which the intervention and its categories exercises are the most effective.

Methods

Study Design

This study uses an explanatory sequential mixed methods approach combining an MRT (phase 1) [22] with follow-up semistructured interviews (phase 2; refer to Figure 1 for an overview). During the MRT, the participants (N=200) will be randomized 2 times per day (morning and evening) to the intervention (ie, an exercise supporting ER; 60% probability) or to a control intervention (ie, a health snippet; 40% probability) over a span of 21 days. Data will be collected at baseline and at the end of the 3-week intervention period, as well as daily via the app before and after the completion of each assigned exercise or health snippet. The primary outcomes include changes in emotional states and engagement patterns with the intervention. For the exercises targeting unhelpful thoughts, differences in thought believability and discomfort before and after the CD exercises will be evaluated. The secondary outcomes include changes in the 4 distal outcomes—ER skills, perceived stress level, and levels of anxiety and depressive symptoms—which will be measured at baseline and at the end of the intervention phase (ie, after 21 days; refer to Table 1 for the measurement schedule).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participants' progress through the mixed methods study integrating a microrandomized trial with semistructured interviews. EMA: ecological momentary assessment.

[a]Thought believability and discomfort are measured only before and after the cognitive defusion exercises.

[b]MH: mental health.

[c]The Patient Health Questionnaire-9 is part of the eligibility screening questionnaire; it is not readministered at baseline.

In phase 2, semistructured interviews will be conducted with a subsample of participants (21/200, 10.5%) investigating their user experience. The results of the qualitative phase will be used to interpret the quantitative results, obtaining a well-rounded picture of how the mobile intervention is functioning and its feasibility.

Participants

Phase 1: MRT

Overview

A total of 200 students at EUR will be recruited. A web-based sample size calculator for MRT studies [57,58] was used to calculate the sample size based on the duration of the intervention period (21 days), expected availability intervention randomization probability (60%), and proximal treatment effect. We expect that participants will respond to approximately 70% of the prompts throughout the intervention period (ie, we assume a constant availability of 70%). Furthermore, we assume a linear effect of the intervention on the proximal outcome measures over time with an average size of 0.1 and an initial effect of 0 at the start of the study. In comparison with the large effect size for in-person therapy based on transdiagnostic approaches to emotional disorders [59], we assume a smaller effect size for our study, which is in line with the results of internet interventions for MH in university students [27] and with a similar MRT study protocol examining an ACT intervention [54]. On the basis of these assumptions, 126 participants will generate 80% power to detect the assumed effect with a significance level of .05. We will increase the participant number to 200 to account for a dropout rate of 40%, in line with average attrition rates for MH interventions delivered through smartphones [60].

Eligibility Criteria

Participants are eligible to participate in our study if they are currently enrolled at EUR, are aged between 18 and 27 years, own a smartphone with an active phone number, feel comfortable speaking and writing in English, and score between 5 (mild symptoms) and 19 (moderately severe symptoms) on the Patient Health Questionnaire-9 (PHQ-9) [61]. The last criterion was selected to ensure that participants in the study experience a certain degree of MH problems, thereby making the interventions in the app more relevant to them and allowing for the observation of intervention impact within a population that is likely to derive the greatest benefit from it. Participants who have experienced significant suicidal thoughts over the past month; have a medical diagnosis of psychosis or bipolar disorder, severe clinical depression, or anxiety disorder; or are undergoing psychopharmacological treatment or treatment with experimental drugs are ineligible for this study.

Phase 2: Semistructured Interviews

From the 200 participants included in the MRT study, 21 (10.5%) will be invited to participate in the semistructured interviews that will occur within 2 weeks of the completion of the MRT study. We expect that 21 participants will provide adequate saturation of themes [62,63]. The subsample will consist of participants with different intervention completion rates (low [<30%], medium [30%-70%], and high [>70%]) to gain a better understanding of engagement patterns and user experiences with the intervention. We aim to balance the sample across gender and study level (ie, bachelor's or master's course) using a purposive sampling strategy. Each adherence group would thus consist of 7 participants: 3 (43%) women, 3 (43%) men, and 1 (14%) nonbinary individual. We will attempt to ensure that this subsample comprises roughly equal proportions of bachelor's students and master's students. In case thematic saturation is not reached after interviewing 21 participants, we

XSL•FO
RenderX

will attempt to recruit additional participants. However, should saturation be achieved before interviewing 21 participants, we may opt to stop recruitment earlier.

Intervention

Overview of the App Content

The intervention under study is delivered through the student well-being app developed by EUR in collaboration with IJsfontein, a media company specializing in serious game design. The version of the app used in this study consists of 3 core features building the intervention flow: (1) EMAs assessing participants' emotional states before and after engaging in the assigned exercise or control intervention, (2) a visualization of participants' emotional states acting as immediate feedback to EMA completion, and (3) a total of 20 exercises targeting different ER skills as well as 20 health facts (control intervention; refer to Multimedia Appendix 1 for example intervention pages).

The exercises are categorized into 5 intervention categories that correspond to the 5 therapeutic approaches integrated in this app: *upregulation of positive affect, mindfulness, CD, relaxation and breathing,* and *self-compassion* (refer to Textbox 1 [36, 37, 39, 64] for a list of the exercises). Each therapeutic approach is explained in an article available to participants when they engage in the corresponding exercise. The exercises are relatively short (each lasts between 3 and 12 min) and actionable in the moment. They were selected owing to their potential to directly regulate students' emotional states and can be completed without extensive exercise background knowledge. Each exercise includes a brief explanation of the rationale behind the exercise as well as debriefing information explaining how the exercise works in general and what the reason might be for experiencing discomfort upon its completion.

Textbox 1. Overview of the exercises classified into 5 intervention categories. The content of the exercises is grounded in the therapeutic principles of positive psychology [36], mindfulness [37], acceptance and commitment therapy [64], yogic breathing, and self-compassion [39].

Upregulation of positive affect

- 3 good things (adapted from Seligman et al [65])
- Savoring the present moment
- Positive self-talk

Mindfulness

- 5 senses exercise
- Tracking your thoughts in time (adapted from Hayes and Smith [66])
- Follow your breath (adapted from Hayes and Smith [66])
- Body scan

Cognitive defusion

- Milk, milk, milk (adapted from Hayes and Smith [66])
- Bad news radio (adapted from Hayes and Smith [66])
- Labeling (adapted from Hayes and Smith [66])
- Leaves on stream (adapted from Hayes and Smith [66])
- Naming and thanking your mind (adapted from Hayes et al [64] and Harris [67])
- Shape your thought (adapted from Hayes and Smith [66])

Relaxation and breathing

- Alternate nostril breathing
- Boxed breathing
- Diaphragmatic breathing
- Progressive muscle relaxation (adapted from Jacobson [68])

Self-compassion

- Self-compassion break (adapted from Germer and Neff [69])
- Talking to a friend (adapted from Germer and Neff [69])
- The compassionate friend (adapted from Germer and Neff [69])

XSL•FO
RenderX

Intervention Categories

Upregulation of Positive Affect

Positive emotions play an important role in people's well-being. They alleviate the effects of negative emotions that are considered the root of anxiety and depressive disorders and promote resilience and positive MH [70-72]. Several meta-analyses have shown that positive psychology interventions targeting feelings of gratitude, savoring of experiences and sensations, and hope and meaning lead to improved well-being and reduced depressive and anxiety symptoms in both general populations and those considered vulnerable [73-75]. The goal of the exercises in this category is to encourage a focus on positive thoughts and away from negative ones in relation to the current situation or about oneself. These exercises may play an important role in enhancing student well-being because higher levels of positive affect are linked to better psychological and physical health [70,72,76].

Mindfulness

Mindfulness refers to present-moment awareness and the acceptance (ie, nonjudgment) of experience independent of one's emotional state [77,78]. Various studies have shown that being mindful is related to better mental [79,80] and physical [81-83] health in university students. Being in touch with the present moment enables one to react to a stressful situation in an adaptive way by using reappraisal or acceptance [38,77,84] instead of engaging in avoidant and ruminative behaviors. Being mindful helps one to endure a distressing experience by perceiving it as less unpleasant and shifts attention to the here and now rather than to the negative reaction to the current distressing event [85]. Supporting students to practice strategies that will enable them to nonjudgmentally engage with the present moment may help improve their ability to cope and flourish in the academic environment.

CD Technique

CD is defined as a process in which people look upon thoughts in a more objective manner and see them as separate from one's sense of self [86,87]. By contrast, cognitive fusion (the opposite to CD) is a state in which thoughts are perceived as the total truth and thus dominate and regulate one's behaviors and emotions, potentially leading to maladaptive and inflexible behavioral outcomes [88]. Cognitive fusion is especially maladaptive when people experience negative self-referential thoughts. These types of thoughts are related to elevated psychological distress among students [42] and constitute a risk factor for depression, anxiety [89], and eating disorders [90]. Targeting self-critical thoughts within this population is especially important because many students experience maladaptive perfectionistic tendencies characterized by unrealistic expectations of oneself and problematic evaluations of self-worth and performance [89]. Therefore, the intervention includes exercises that teach different CD techniques, such as deliteralization, labeling, and distancing.

Relaxation and Breathing

People can mitigate their emotional states by controlling their breathing [91]. Relaxation and breathing techniques help individuals to decrease their feelings of tension and anxiety, physically and psychologically, and to increase feelings of calmness and evoke relaxation responses that counteract physiological stress responses such as heart palpitations, shortness of breath, and muscle tension. These techniques have a long-standing tradition in psychotherapy and stress management programs [92]. To help students mitigate negative emotional states, such as stress, anger, and tension, the intervention offers breathing and relaxation exercises.

Self-Compassion

Self-compassion is considered an effective mood-stabilizing strategy [93]. It refers to the act of being kind, empathic, supportive, and understanding of oneself in moments of hardship. Those practicing self-compassion are less likely to use maladaptive ER strategies such as rumination and suppression and unhelpful behaviors such as self-criticism [94]. Self-compassion is considered a protective factor against academic stress [39,95], homesickness, depression, and problems in the transition to college [96,97]. Teaching students self-compassion techniques may help them stabilize their mood and make space to adaptively cope with the challenges presented by the academic environment.

Control Intervention

In the control intervention condition, participants receive short snippets of health information about, for example, nutrition, exercise, and sleeping habits. These health-related notions will be phrased in a general, impersonal, and informative fashion. For example, "Did you know that by sneezing the human body is getting rid of infected cells and an average sneeze will spread over 100,000 virus cells up to nine meters? On average, adults catch two to three colds each year. School-age children can have 12 or more colds in a year." Introducing health information as a control intervention condition will act as a placebo intervention with no effect on ER and keep participants engaged in the postintervention EMA evaluation when they are not randomized to an exercise. The health information might influence participants' emotional states but to a minimal extent.

Outcome Measures

Primary Outcomes

Changes in a Momentary Emotional State

Participants will be asked to evaluate 7 emotional states by answering the question "How [*affect*, eg, happy] do you feel at the moment?" on a scale ranging from 1 (not at all) to 5 (very much). The emotional states are combined into 2 categories of affect: negative (stressed, frustrated, sad, and fatigued) and positive (happy, energetic, and relaxed) [98]. The scores of the emotional states will be averaged per category for preintervention and postintervention EMA assessment. The 2 composite outcomes will be calculated by subtracting the results of the preintervention EMA from those of the postintervention EMA for the positive affect and negative affect categories.

Changes in Thought Believability and Discomfort

The CD exercises include a measure of thought believability and discomfort. Participants are asked to assess "How uncomfortable is the thought?" and "How believable (true) is the thought?" on a scale ranging from 1 (not at all uncomfortable

XSL•FO
RenderX

or believable) to 100 (very uncomfortable or believable) [99] before and after they engage in the CD exercise.

Intervention Engagement

Objective engagement parameters are retrieved from app use analytics (ie, log data) and consist of exercise completion rate, average time spent per exercise, and the times when participants most frequently engaged in an exercise (morning or evening). Subjective engagement parameters of exercise likability ("How much did you like the exercise?") and helpfulness ("How helpful did you find the exercise?") scores measured on a scale ranging from 1 (not at all) to 100 (very much) are assessed at the conclusion of each exercise.

User Experience Evaluated in Semistructured Interviews

Participants' user experience with the intervention will be examined qualitatively in follow-up semistructured interviews with a subset of participants (refer to the *Participants* subsection). Students will first be asked to report on their experience with the whole intervention, followed by a discussion focusing on the separate intervention categories and exercises they engaged in during the trial. They will be asked which aspects of these exercises they liked, disliked, or found difficult to complete. Finally, they will be prompted to share what things they would like to see implemented in the further development of the intervention. Apart from this, the interviewees will be asked about their motivations to participate and general experience related to the study participation. The full interview protocol is available in Multimedia Appendix 2. Additional questions may be derived from the evaluation of engagement metrics. In particular, in the interviews, we might pay extra attention to exercises that were evaluated as unhelpful or unlikable to understand why and to figure out how they could be improved.

Secondary Outcomes

ER will be measured with the Emotion Regulation Skills Questionnaire [100], which evaluates 8 types of ER skills: awareness, sensation, clarity, understanding acceptance, tolerance, compassionate self-support, readiness to confront distressing situations, and modification of negative emotions. Each skill is assessed with 3 items rated on a scale ranging from 0 (not at all) to 4 (almost always). Apart from the scores on separate subscales, the Emotion Regulation Skills Questionnaire consists of a total score computed as the average of all items. Higher scores indicate higher ER skills.

Symptoms of depression and anxiety are measured with the PHQ-9 [61] and the Generalized Anxiety Disorder-7 (GAD-7) [101] questionnaire, respectively. The PHQ-9 consists of 9 items measuring depressive symptoms, and the GAD-7 is composed of 7 items measuring anxiety symptoms. Both questionnaires instruct participants to indicate how often they have been bothered by different symptoms over the last 2 weeks on a scale ranging from 0 (not at all) to 3 (nearly every day). The summed scores for the PHQ-9 range from 0 to 27 and for the GAD-7 from 0 to 21, with higher scores indicating higher levels of depressive and anxiety symptoms. The PHQ-9 is used both to screen for eligibility and to assess the baseline level of depression.

Stress levels will be assessed with the Perceived Stress Scale-14 [102], which consists of 14 items and instructs participants to indicate how often they felt or thought a certain way over the last month on a scale ranging from 0 (never) to 4 (very often). The summed scores range from 0 to 56, with higher scores indicating higher levels of perceived stress symptoms (refer to Table 1 for an overview of the measurement schedule).

Other Measures

Demographics information includes age; gender; university discipline of study (eg, law and medicine); study program (ie, bachelor's or master's); prior experience with MH apps (ie, use); and preknowledge and use of, and experience with, the therapeutic approaches included in this study. For the purposes of the recommendation system development, additional information on students' MH, vulnerability (eg, care duties and functional impairments), and personality traits is collected at the baseline only. These outcomes will be used to explore whether these factors play a role in recommending exercises to students.

Students' MH is screened with the General Health Questionnaire-12 (GHQ-12) [103]. The GHQ-12 consists of 12 items, each assessing the severity of an MH problem over the past few weeks using a 4-point scale (ranging from 0 to 3). The total scores range from 0 to 36, with higher scores indicating lower psychological well-being.

Personality traits are measured with the Ten-Item Personality Inventory [104], which assesses 5 personality dimensions: extraversion, agreeableness, conscientiousness, emotional stability, and openness to experience. Participants are asked to evaluate to what extent they agree with each statement on a scale ranging from 1 (disagree strongly) to 7 (agree strongly). An example statement is "I see myself extraverted; enthusiastic."

Study Procedure

Recruitment and Informed Consent Procedures

To secure a diverse sample in terms of gender and students' university discipline of study, participants will be approached through various pathways. Students who had subscribed to our user research participant pool over the last couple of years will be contacted via email. The study will be advertised on EUR's campus screens and social media platforms (ie, well-being website and Instagram account); in November 2022, it was advertised during a Student Well-being Week event. Promotional material for the study will be sent to students via communication and marketing offices and student associations.

Interested students will subscribe to the study via a QR code or hyperlink. Those subscribing to the study will be emailed a link to a web page with information for participants and will have 2 weeks to review the information and decide on participation. They will be invited to contact the researcher via phone or email for any study-related question. Students who are interested in participating can indicate this preference at the bottom of the web page and will be automatically directed to the digital informed consent form. Once the informed consent form is signed, participants are screened for eligibility.

XSL•FO
RenderX

Phase 1: MRT

Eligible participants will fill in the baseline questionnaires and be asked to install the app on their mobile phones through which the intervention will be delivered over a period of 3 weeks.

Each student will receive a unique randomly generated user ID to access the app to protect their privacy. Participants' status as EUR students will be verified through the authentication of their student accounts. Once the authentication phase is concluded, participants will be asked to select 1 morning (7 AM to noon) and 1 evening (5 PM to 10 PM) time slot when they believe they are most likely to have time to complete the daily assessments and exercises (Multimedia Appendix 1).

During the intervention phase, participants are asked to complete the intervention flow (ie, preintervention EMA, followed by exercise or health snippet, followed by postintervention EMA) 2 times per day. The prompts (eg, "Good morning! Don't forget to take a moment for yourself." or "Psst, did you check your evening exercise for today?") to complete the flow will be sent to participants at the 2 self-selected time slots. Participants can self-initiate the intervention flow during each time frame by opening the app. If they complete the intervention flow before the self-selected time slot, the reminder for this time slot is skipped. Of note, participants must complete the preintervention EMA to be able to continue and complete the intervention flow. The intervention flow will be available to participants to complete between 7 AM and 2 PM (morning time slot) and between 5 PM and midnight (evening time slot). The completion of tasks in the app is not possible outside of the predetermined time slots. In addition, to ensure that the changes in emotional states are most likely a result of exercise completion rather than other factors, a time limit was set. Participants will have 30 minutes to complete the intervention flow; otherwise, they need to start the intervention flow from the beginning, starting with the preintervention EMA.

Every time participants fill in the preintervention EMA, they have a 60% chance of receiving an exercise and a 40% chance of receiving a health snippet. The 60:40 ratio was chosen to ensure a higher chance of receiving an intervention at every decision point. This strategy has been used in previous MRT studies too [51,52]. For this study, a simple randomization with replacement will be used. The randomization is carried out automatically within the app and is as follows: randomization of exercise (60% chance) or control intervention; if an exercise is chosen, a second randomization to the intervention categories follows (20% chance for each intervention category), followed by the random selection of 1 exercise within the randomized intervention category (equal chance across exercises); if a control intervention is randomized (40% chance), a second randomization takes place in which a health information snippet is selected. Participants will be asked to complete 42 preintervention EMAs and 42 postintervention EMAs in total during the study. They can receive an exercise 0 times, 1 time, or maximally 2 times in a day. On average, they will be prompted to engage in 1.2 exercises per day and 25.2 exercises throughout the study.

Upon the completion of either the exercise or the control intervention, the participants are asked to reassess their emotional state by completing the postintervention EMA. When assigned to an exercise, in addition to the postintervention EMA, participants will be asked to rate the likability and helpfulness of the exercise. When CD exercises are selected, participants will also complete the corresponding measures of thought believability and discomfort before and after the exercise.

Given that the primary objective of this study is to evaluate the functioning of the intervention rather than observe it in a naturalistic setting, we have implemented an adherence protocol to enhance completion rates and ensure high-quality data. To support participants in staying engaged, they will receive emails or telephone calls from researchers, depending on the number of missed sessions. The adherence protocol is presented in Multimedia Appendix 3.

Immediately after the intervention period is concluded, participants will complete the postintervention assessment, including the secondary outcome measures (refer to Table 1 for an overview of the measurements performed during phase 1 of the study).

Phase 2: Semistructured Interviews

In the second phase, semistructured interviews will be conducted with 21 (10.5%) of the 200 study participants. A purposive sampling strategy will be used to balance the sample across gender, study level, and the level of adherence during the MRT. Participants who consented to participate in the user experience interviews will be selected based on the aforementioned characteristics and contacted by the researcher to set up an interview session within 2 weeks of completing the follow-up questionnaire. The interviews will take place on the web or at the EUR behavioral laboratory and will last between 45 and 60 minutes. An overview of the study procedures is presented in Figure 1.

Ethical Considerations

The study has been approved by the EUR institutional review board (ETH2122-0677) and is registered at ClinicalTrials.gov (NCT05576883).

Participant informed consent will be obtained electronically. The participants will be informed about the study-related goals, procedures, potential benefits and risks, and compensation, as well as privacy and confidentiality aspects. Consenting to participate in interviews and allowing data use beyond the study's research goals (eg, educational purposes and further research) will be optional, and opting out will not preclude participation in phase 1 of the study.

To protect participants' privacy and confidentiality, the study procedures as well as research data servers and the app itself comply with the General Data Protection Regulation standards. Research data and personal data will be stored separately. Participants will be assigned unique identifiers, enabling linkage among data collected during the different study phases. Only the primary researchers will have access to the research data and identification key.

Finally, participants in this study will be compensated with digital vouchers for completing the assessments and participating in an interview. To incentivize participants to complete both

XSL•FO
RenderX

assessments, the voucher for the baseline assessment is worth €5 (US $5.5), and, for the final assessment, it is worth €15 (US $16.2). The subsample of participants taking part in the semistructured interviews will receive a €10 (US $10.8) voucher to compensate them for their time. Those completing ≥80% of the EMAs during the intervention phase of the study will be included in a lottery, and 4 of them will be randomly selected to win a €50 (US $54.7) voucher each.

Data Analysis Plan

Preliminary analyses exploring the data set will be conducted, including descriptive statistics and exploratory graphing for all the variables of interest measured during the study, which will allow for the identification of outliers (eg, measurements or recording errors and logical inconsistencies in data). The key baseline variables (eg, sex) will be considered as plausible covariates in the planned analyses.

Primary Outcome Analysis

Effects of the Intervention on the Proximal Outcomes

The weighted and centered least squares method developed by Boruvka et al [105] to evaluate data from MRT studies will be used to estimate and test the causal excursion effects of the intervention on the proximal outcomes. This method assesses parameters in treatment effect models and allows for the inclusion of covariates that can reduce the variance of the treatment effect estimates. Similar to generalized estimating equations and multilevel models, this method can effectively manage nested data (ie, decision points nested within participants) and within-person dependencies across time in the outcome. A detailed explanation of the analyses is available in Multimedia Appendix 4 [23,51,105,106].

As a primary goal of this study, we will test the overall (average, across all decision points) effect of engaging in any intervention versus engaging in the control intervention on the emotional states measured with the postintervention EMA upon intervention completion. Furthermore, we aim to evaluate whether this effect deteriorates over time by estimating the interaction between the overall intervention effect and the day in the study.

As a subgoal, we will examine differences in the overall effect of engaging in a suggested intervention versus engaging in the control intervention on emotional states for each intervention category separately. We will control for the pretreatment scores of positive and negative affect measured by the preintervention EMA across all models. To account for repeated dependent measures, robust SEs will be calculated using a sandwich estimator, and because we are comparing multiple outcomes, the results will be controlled for multiple testing using Bonferroni correction, that is, we will divide the α value by the number of comparisons being made (ie, 2; hence, we will use α=.025).

Data may be missing if participants do not complete the EMAs before and after an exercise because without the completion of both measurements the observation for the proximal outcome will be missing. If no more than 10% of the data are missing, our primary analysis will be performed as a complete case analysis. If >10% of data are missing, the missing data will be handled by using multiple imputation approaches and outcome models averaged across imputations to adhere to the intention-to-treat principle.

Thought Believability and Discomfort Outcome

A multiple linear regression model will be applied to assess the effects of CD exercises on the level of thought believability and discomfort measured before and after CD exercise completion.

Feasibility Outcomes

Objective Engagement Patterns

Descriptive statistics of engagement metrics (ie, completion rate, average time spent, and the time of day when participants completed the exercises) per exercise and exercise categories will be examined to evaluate exercise performance and inform further design revisions. A linear mixed model will be used to analyze whether there is a relationship between the time of day and exercise completion rates.

Subjective Engagement Patterns

To gain insights into subjective engagement with the exercises, we will combine information on (1) the exercise likability and helpfulness ratings and (2) semistructured interviews with a subset of participants purposefully recruited based on their adherence levels (refer to the *Participants* subsection).

Exercise Likability and Helpfulness

For every exercise, average scores on likability and helpfulness scales are computed across all participants, with higher scores indicating higher levels of likability and helpfulness of the exercise. Exercises will then be ranked from the most liked and helpful to the least, informing on which exercises may be perceived as difficult by participants and pointing to potential design revisions of exercise content or user experience design.

Semistructured Interviews

Information gathered from semistructured interviews with a subsample of study participants will be analyzed using ATLAS.ti software (ATLAS.ti Scientific Software Development GmbH). A multistage standardized thematic analysis will be performed: familiarization with the data, generating preliminary codes, gathering potential themes, reviewing the themes, refining the themes and labeling them, and conducting the write-up of the analysis [107]. Two members of the research team will code the responses for process alignment [108]. In the analysis, we are interested specifically in participants' experiences with the different types of exercises, in what way these were helpful (or not), and whether participants were able to understand the different approaches and exercises embedded in the intervention (eg, ACT, CD, and self-compassion).

Secondary Outcome Analysis

Analysis of Distal Outcomes: ER Skills and Distress Symptoms

For estimating the effect of the intervention on participants' ER skills and levels of distress, we will apply a multiple linear regression model with the following covariates: gender, age,

XSL•FO
RenderX

study year, preknowledge of therapeutic approaches, and intervention adherence (ie, number of completed exercises).

Analysis of Exploratory Outcome Analysis: Contextual Moderators

For the purposes of optimization of the mobile intervention app, exploratory analyses will be carried out to explore contextual factors, that is, the time of intervention delivery (morning vs evening), momentary emotional state, and vulnerability to MH problems indicated by higher scores on the GHQ-12, as potential moderators of perceived helpfulness and of the proximal effects on changes in emotional states among the intervention and intervention categories. Additional exploratory variables of interest include personality traits and gender. This information will help us form initial decision rules for the algorithm that is being designed for this intervention.

Results

The study commenced on February 9, 2023, and the data collection was concluded on June 13, 2023. Of the 172 eligible participants, 161 (93.6%) decided to participate. Of these 161 participants, 137 (85.1%) completed the first phase of the study. In the qualitative phase, interviews were conducted with 18 participants: 7 (39%) from the high-adherence group, 7 (39%) from the medium-adherence group, and 4 (22%) from the low-adherence group. Currently, the data processing and analyses are being conducted.

Discussion

Overview

This study will investigate the effectiveness and feasibility of digitally delivered therapeutic exercises designed to facilitate adaptive ER among university students. A secondary goal of this study focuses on the evaluation of distal outcomes, that is, changes in ER skills and distress symptoms as a result of the intervention, which will serve as a safety indicator and inform the sample size estimation of the RCT to follow. In addition, contextual moderators that could be relevant for the recommendation system that will link students to exercises relevant to their needs and preferences will be explored.

Compared with other methodologies used for intervention evaluation such as an RCT, the MRT design makes it possible to observe proximal changes in participants' emotional states directly after they complete an exercise, in addition to requiring fewer participants to achieve sufficient power to detect the proximal main effect of an intervention component [52]. This enables insight into the mechanisms of change (ie, changes in emotional states), elucidating on how the intervention and its components stimulate the desired benefits (ie, increase in ER skills and decrease in depressive and anxiety symptoms). Combining results from the MRT with information on user engagement patterns (ie, log data analytics) and user experience (ie, exercise ratings and user experience interviews) will help unpack the black box typical of studies of digital MH interventions, where often little is known about the mechanisms by which the interventions exert their benefit [109]. The combined results will also indicate intervention components that might need improvements or should be discarded when they play no significant, or possibly impeding, role in facilitating the desired change. This means that if an intervention category is perceived as unhelpful, unlikable, or unclear or was hardly used by participants, and when it was used, it showed a negative or no effect on proximal outcomes, the intervention category (or specific exercises) could be removed from the intervention library or redesigned. Furthermore, the use of a mixed methods approach not only offers the opportunity to gather valuable insight into how the current generation of students perceive and engage with digital MH interventions but also sheds light on how they receive the MRT as a method of evaluation. This information can help optimize future endeavors in the development and evaluation of tools for digital MH interventions. Finally, the results of exploratory analyses and the data set obtained in this study will be used to develop and train the recommendation algorithm, maximizing the likability and usefulness of exercises for users based on individual (ie, personality and MH status) and contextual (eg, the time of day and momentary emotional states) characteristics. Creating a system that can suggest content relevant to its users has been indicated as a top priority for university students to engage and remain engaged in an MH app [18]. Therefore, designing and implementing a recommendation system in the app may be crucial in improving its uptake and effectiveness.

All in all, this study will contribute to the optimization of the intervention content and the system functionalities (ie, recommendation system). An optimized version of the app will be evaluated in an RCT where the full-scale effectiveness on clinical outcomes (eg, ER skills as well as depressive and anxiety symptoms) will be examined.

Limitations

The results of this study will need to be considered in light of some limitations. First, this study relies heavily on students' self-reports of emotional states through EMA before and after completing an exercise. Therefore, the participant burden is considered relatively high. However, this was chosen because user research indicated that students do not like to be monitored and consider passive sensing tracking (eg, collection of location and acceleration data) as too invasive. This is in line with studies examining the acceptability of sensing technology among university students [110,111].

Second, in this study, participants are compensated for completing the baseline and follow-up assessments and for participating in the interview (when applicable). In addition, they are incentivized to complete the daily assessment by the prospect of inclusion in a lottery for a €50 (US $54.7) voucher when they achieve a completion rate of ≥80%. Therefore, this design only allows the evaluation of certain aspects of engagement, such as how participants interacted with the exercises and the average likability and helpfulness ratings. We cannot draw any firm conclusions about the actual engagement level with the intervention when used freely in a naturalistic setting.

Third, our mobile app combines various types of exercises based on different therapeutic approaches ranging from self-compassion to positive psychology. The exercises were

XSL•FO
RenderX

designed in such a way that they can be completed in the moment, without users' preknowledge of the approach. In this study, we offer them materials educating them about the underlying exercise approach, but this is kept optional. There is a possibility that some exercises might be more effective when presented in combination with psychoeducational material. In addition, given the randomized nature of the exercises, participants might find some suggestions less appropriate when reporting certain states (eg, recommending an exercise belonging to the upregulation of positive affect category when participants report a high-stress state). However, the experimental goal of the study is to empirically examine how the exercises affect participants' emotional states and participants' reactions to the exercises (whether they like them or find them helpful) instead of drawing conclusions based on current psychological theories and our hunches. Current psychological theories seem to be insufficient to inform the development of mobile interventions that include high levels of interactivity and flexibility. This is because prevailing behavior change theories are still based on data providing information on static snapshots of behavior (ie, the predictions of behavior are based on pre-post evaluations) rather than accounting for contextualized and transitory changes in mood states and behavior at the granular level [112-114]. However, an MRT can address the limitations of traditional research methods, such as RCTs, which have shaped current behavior change theories. Specifically, an MRT offers a deeper understanding of the dynamics involved in health behaviors and behavior change, which are influenced by a myriad of contextual factors, including emotional states, physical context, social norms, and expectations [115]. These factors seem to play a role in intervention functioning [51,55,56]. Therefore, with this study, we hope to gather insights and draw experimentally informed conclusions regarding which intervention option is appropriate for whom and in what context.

Conclusions

In sum, the results of this study will inform further development of the content and system of the digital MH tool that is being developed for university students. The optimization method will help us optimize our mobile app and shed light on how different therapeutic approaches work and why. Such information will hopefully be valuable to the development of modern theories of behavior change because this design can provide information on how different therapeutic exercises influence ER in near time.

Acknowledgments

The authors want to acknowledge Susan A Murphy (Department of Statistics, Harvard University, Cambridge, Massachusetts, United States) for providing her expert input on the study design, methodology, and analytical approach.

Data Availability

The data collected in phase 1 of the study will be available in the Open Science Framework (OSF) data repository [116].

Authors' Contributions

TL, DR, RCMEE, MB, and DSM designed the study. TL, MB, and SK designed the approach to statistical analysis. TL prepared the study material, designed the intervention material, and collected the data. TL drafted the first version of the manuscript; all authors provided feedback and edited the manuscript. All authors reviewed and approved the final version of the manuscript before submission.

Conflicts of Interest

TL, RCMEE, DR, and MB are employed by Erasmus University Rotterdam and are directly or indirectly involved in the development of the intervention. All other authors declare no other conflicts of interest.

Abstract

Background: Hypertension is a major contributor to various adverse health outcomes. Although previous studies have shown the benefits of home blood pressure (BP) monitoring over office-based measurements, there is limited evidence comparing the effectiveness of whether a BP monitor integrated into the electronic health record is superior to a nonintegrated BP monitor.

Objective: In this paper, we describe the protocol for a pragmatic multisite implementation of a quality improvement initiative directly comparing integrated to nonintegrated BP monitors for hypertension improvement.

Methods: We will conduct a randomized, comparative effectiveness trial at 3 large academic health centers across California. The 3 sites will enroll a total of 660 participants (approximately n=220 per site), with 330 in the integrated BP monitor arm and 330 in the nonintegrated BP control arm. The primary outcome of this study will be the absolute difference in systolic BP in mm Hg from enrollment to 6 months. Secondary outcome measures include binary measures of hypertension (controlled vs uncontrolled), hypertension-related health complications, hospitalizations, and death. The list of possible participants will be generated from a central data warehouse. Randomization will occur after enrollment in the study. Participants will use their assigned BP monitor

XSL•FO
RenderX

and join site-specific hypertension interventions. Cross-site learning will occur at regular all-site meetings facilitated by the University of California, Los Angeles Value-Based Care Research Consortium. A pre- and poststudy questionnaire will be conducted to further evaluate participants' perspectives regarding their BP monitor. Linear mixed effects models will be used to compare the primary outcome measure between study arms. Mixed effects logistic regression models will be used to compare secondary outcome measures between study arms.

Results: The study will start enrolling participants in the second quarter of 2023 and will be completed by the first half of 2024. Results will be published by the end of 2024.

Conclusions: This pragmatic trial will contribute to the growing field of chronic care management using remote monitoring by answering whether a hypertension intervention coupled with an electronic health record integrated home BP monitor improves patients' hypertension better than a hypertension intervention with a nonintegrated BP monitor. The outcomes of this study may help health system decision makers determine whether to invest in integrated BP monitors for vulnerable patient populations.

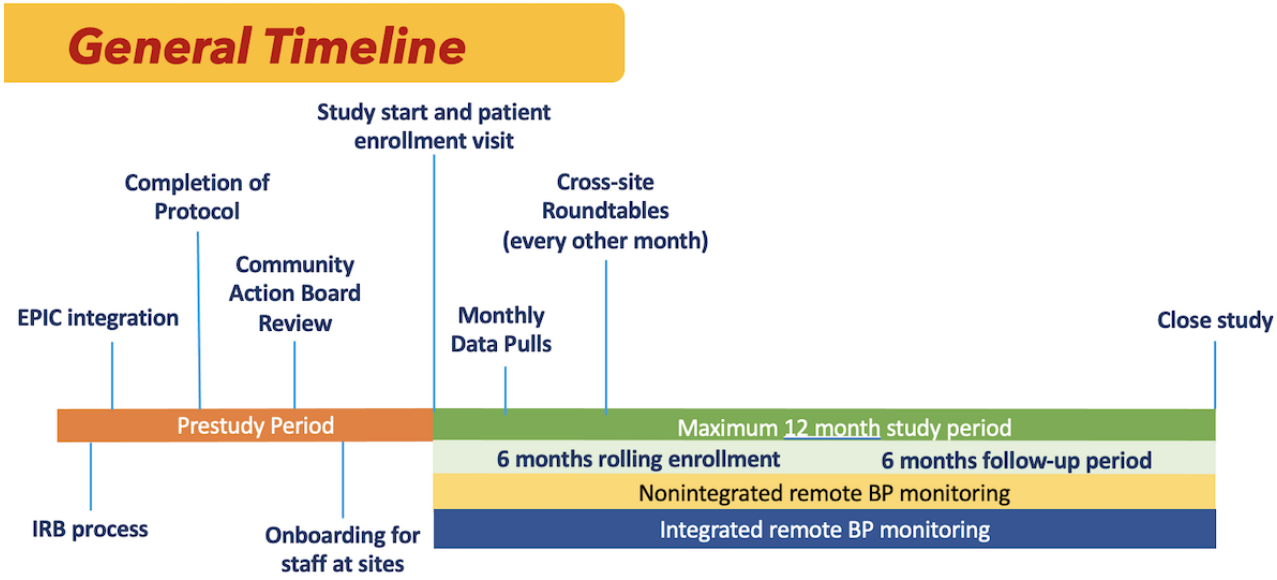
Introduction

Hypertension is a marked modifiable risk factor for many adverse health outcomes, with the highest attributable risk for cardiovascular disease and death [1]. About half of the US adult population has hypertension, with the majority having uncontrolled hypertension [2]. The inadequate treatment of hypertension for certain groups is a large source of health disparities [3]. Clinically, the diagnosis of hypertension is made using office-based blood pressure (BP) measurements at several week intervals [4] and confirmed with an out-of-office reading or using ambulatory BP monitoring [5,6], as there is growing evidence showing differences in BP measurements in the office compared to the home setting [7,8]. Variations in adherence to clinical guidelines on how to properly perform BP readings, patient anxiety, environmental factors, and "white-coat hypertension" all contribute to these differences [6,9]. Additionally, many studies have shown the superiority of home BP monitoring compared to office BP monitoring in terms of cardiovascular and renal outcomes, all-cause mortality [1,8,10,11], and patient empowerment and adherence to medical therapies for hypertension [12].

Although the benefits of home BP monitoring compared to office-based monitoring are well studied, optimal methods for obtaining home BP readings are less clear. A previous study showed improvements to systolic BP at 1 year after a self-monitoring and digital intervention involving a health care provider-managed lifestyle modification and medication titration approach compared to usual care [7]. Whereas a single-center study found no difference in BP change using an electronic health record (EHR)–connected smartphone device to record BP using a standard self-monitoring strategy [13]. This randomized, comparative effectiveness trial adds to the existing literature by including multiple sites and comparing an EHR-integrated monitor with automated BP data uploads to a standard self-monitoring approach.

In developing the protocol for this study, we used the eHealth Enhanced Chronic Care Model (eCCM) [14] to shape our theoretical understanding that remote BP monitoring can improve patients' and health care providers' "wisdom" [15,16] to provide interventions capable of improving hypertension control. This project aligns with a joint scientific advisory on hypertension control from the American Heart Association, the American College of Cardiology, and the Centers for Disease Control and Prevention, which argued for systems-level, population-health-level initiatives to control hypertension, involving the community around a patient, leveraging data from EHRs, and patient-provider engagement [17].

This manuscript was developed to describe the protocol for this pragmatic multisite study that evaluates whether an integrated BP monitor performs better at controlling hypertension than a self-reporting strategy. We define the roles and responsibilities of key partners, study design, key outcomes, and statistical analyses.



Methods

Setting and Study Design

The University of California (UC) Health System is a large academic health system serving a diverse patient population throughout California, the United States, and internationally. It includes teaching hospitals, affiliations with community health clinics, health professional schools, research centers, and other health care entities. This study protocol describes a randomized, comparative effectiveness trial that will be conducted at 3 of the UC Health System sites (UC Davis [UCD], UC Los Angeles [UCLA], and UC San Francisco [UCSF]). Figure 1 describes the general timeline. Enrollment will occur over 6 months after study initiation, and each participant will be followed for 6 months after enrollment.

XSL•FO
RenderX

Figure 1. Timeline for the study. Participants will be followed for 6 months after enrollment date. BP: blood pressure; IRB: institutional review board.

Defining Key Partners and Study Preparation

The UCLA Value-Based Care Research Consortium (VBCRC) will lead the planning, implementation, and evaluation of this study in collaboration with the UCLA Department of Medicine Statistics Core, the UC Office of the President (UCOP), and each UC site. The UCLA VBCRC is a team that aims to improve value in health care through partnerships with health systems and researchers. The UCOP team will provide input into study design and feasibility, as well as funding for the study, including the BP monitors. Each UC site will have a designated site champion, program manager, and IT lead (Multimedia Appendix 1 details the responsibilities of these roles). The UCLA VBCRC team will facilitate regular meetings with representatives from each team, focusing on cross-site learning, troubleshooting implementation issues, and providing updates on progress. Further evaluation of cross-site variations, barriers to implementation, and understanding of patient experiences will be obtained from qualitatively coding and analyzing these regularly scheduled meetings with the sites.

In preparation for the study, the UCLA VBCRC met with a community action board consisting of representatives from community organizations serving large numbers of diverse members with hypertension to understand patient concerns and perspectives regarding this study. Overall, the community action board supported the need for this project but raised concerns regarding proper training for using the BP monitors for participants in the study. They also reiterated the importance of providing instructional materials at various education and literacy levels, as well as individualized support for participants when needed. This feedback was provided to the sites and the BP monitor company.

Site-Specific Hypertension Interventions

In addition to following core protocol instructions, each site will design and implement a hypertension intervention for both arms of the study. The study sites are given the autonomy to create their own site-specific hypertension intervention to fit their patient population needs and available resources. Table 1 compares interventions across each UC site, including whether the intervention is web-based only or hybrid (component of in-person and web-based), the main health care providers involved in the intervention, specific details about the intervention, discharge criteria from the program, and site-specific inclusions and exclusions.

XSL•FO

Table 1. Comparison of site interventions.

	University of California, Davis	University of California, Los Angeles	University of California, San Francisco
Web-based only, hybrid (in-person and web-based)	• Hybrid	• Web-based only	• Hybrid
BP[a] monitor distribution plan (eg, mail, in person, etc)	• Mailed directly to the patient	• Mailed directly to the patient	• Mailed directly to the patient
Main providers involved in the intervention	• Pharmacist	• Pharmacist • Patient service representative • Primary care provider • Program supervising physician	• Pharmacist • Primary care provider • Health care navigator
General structure of study arms	• Intervention: EHR[b] integrated remote BP monitor with pharmacist follow up • Control: nonintegrated BP monitor with pharmacist follow up	• Intervention: EHR integrated remote BP monitor + web-based patient portal • Control: nonintegrated BP monitor + web-based patient portal	• Intervention: EHR integrated remote BP monitor + usual care and follow-up • Control: nonintegrated BP monitor + usual care and follow-up
Frequency of BP checks	• There is no minimum per month. • Ideally, at least 16 per month.	• There is no minimum per month. • Ideally, at least 16 per month.	• There is no minimum per month; however, patients will receive daily reminders. • Ideally, at least 16 per month.
Site-specific intervention	• Initial visit (60 minutes): (1) The pharmacist will provide disease management (ie, monitor BP readings and help titrate medications accordingly). (2) Notify the PCP[c] of patient participation or access to monitor. • Clinic visits (1 minimum): (1) Before the pharmacist's intervention. (2) As needed to facilitate care plans and achieve BP goals	• Initial visit (40 minutes): (1) Review: PMH[d] relevant to treatment, calculate 10-year ASCVD[e] risk, labs, current BP management, diet and exercise, medication adherence, access to a home BP monitor, and BP measurement techniques. (2) Treatment: develop an individualized treatment plan, including starting antihypertensive medications, hypertension education, lifestyle management, and reviewing BP measurement techniques. (3) Communication: send a visit summary to PCP. (4) Visits performed by pharmacists or supervising program physicians. (5) Schedule: next visit in 2-4 weeks (monthly follow-up). • Follow-up visit (20 minutes): review the individualized treatment plan, home BP measurements, and access to medications (if any).	• Initial visit (40 minutes): (1) Review: PMH relevant to treatment, current blood pressure management, diet and exercise, labs, medication adherence, access to a home BP monitor, and BP measurement techniques. (2) Treatment: create an individualized plan that may include starting a new antihypertensive, dose adjustment, or tapering medications contributing to high BP, and set or reinforce target BP goals. (3) Schedule: next visit in 4 weeks. (4) Visits performed by a pharmacist, primary care doctor, nurse practitioner, or registered nurse. • Follow up: every 1-2 months.
Control group	• Self-report BP. Intervention is the same as above.	• Self-report BP. Intervention is the same as above.	• Self-report BP. Intervention is the same as above.
Discharge from the program	• BP at goal for 2 consecutive visits • Resistant hypertension criteria • Clinical concerns develop, for example, recurrent orthostatic symptoms with systolic BP <100 mm Hg, persistent changes in labs (electrolytes and GFR[f]), significant excursions in BP after confirming measurement technique, and unstable symptoms • BP is above goal after 6 months • The patient requests discharge	• BP at goal for 2 consecutive visits • Resistant hypertension criteria • Clinical concerns develop, for example, recurrent orthostatic symptoms with systolic BP <100 mm Hg, persistent changes in labs (electrolytes and GFR), significant excursions in BP after confirming measurement technique, unstable symptoms • BP is above goal after 6 months • The patient requests discharge	• BP is well controlled. • Patient request or lost to follow-up. • Complicating comorbid conditions develop

Site-specific inclusion criteria	• None	• The participant must be active on the web-based patient portal.	• The participant must be active on the web-based patient portal.
Site-specific exclusion criteria (if any)	• None	• None	• None

[a]BP: blood pressure.

[b]EHR: electronic health records.

[c]PCP: primary care physician.

[d]PMH: patient medical history.

[e]ASCVD: atherosclerotic cardiovascular disease.

[f]GFR: glomerular filtration rate.

Eligibility, Inclusion, and Exclusion Criteria

A complete list of eligibility, inclusion, and exclusion criteria is listed in Textbox 1. Eligible participants must be 18 years of age or older, willing and functionally able to use the BP monitor, and have access to the web-based health care patient portal (with help from another person if needed). Participants will be included if they have had an outpatient visit within the last year and 2 readings of systolic BP ≥140 mm Hg or diastolic BP ≥90 mm Hg within 6 months of each other, have a primary care physician within the health care system, and are taking three or fewer antihypertensive medications. There is no language preference or maximum age cutoff for this study.

Participants will be excluded if they had a recent BP measurement greater than or equal to 180/110 mm Hg (office BP) or greater than or equal to 175/105 mm Hg (self-monitored BP), have a history of conditions that could lead to refractory hypertension (Textbox 1), are currently incarcerated, are enrolled in home health, hospice, or a hypertension management program, have cognitive impairment that prevents them from participating in intervention activities, or have a white coat hypertension diagnosis. Individuals with BP measurements greater than or equal to 180/110 mm Hg (office BP) or greater than or equal to 175/105 mm Hg (self-monitored BP) will be excluded because they may have treatment-resistant hypertension or may need more intensive intervention than is being provided with this program.

XSL•FO
RenderX

Textbox 1. Complete list of eligibility, inclusion, and exclusion criteria.

Eligibility criteria

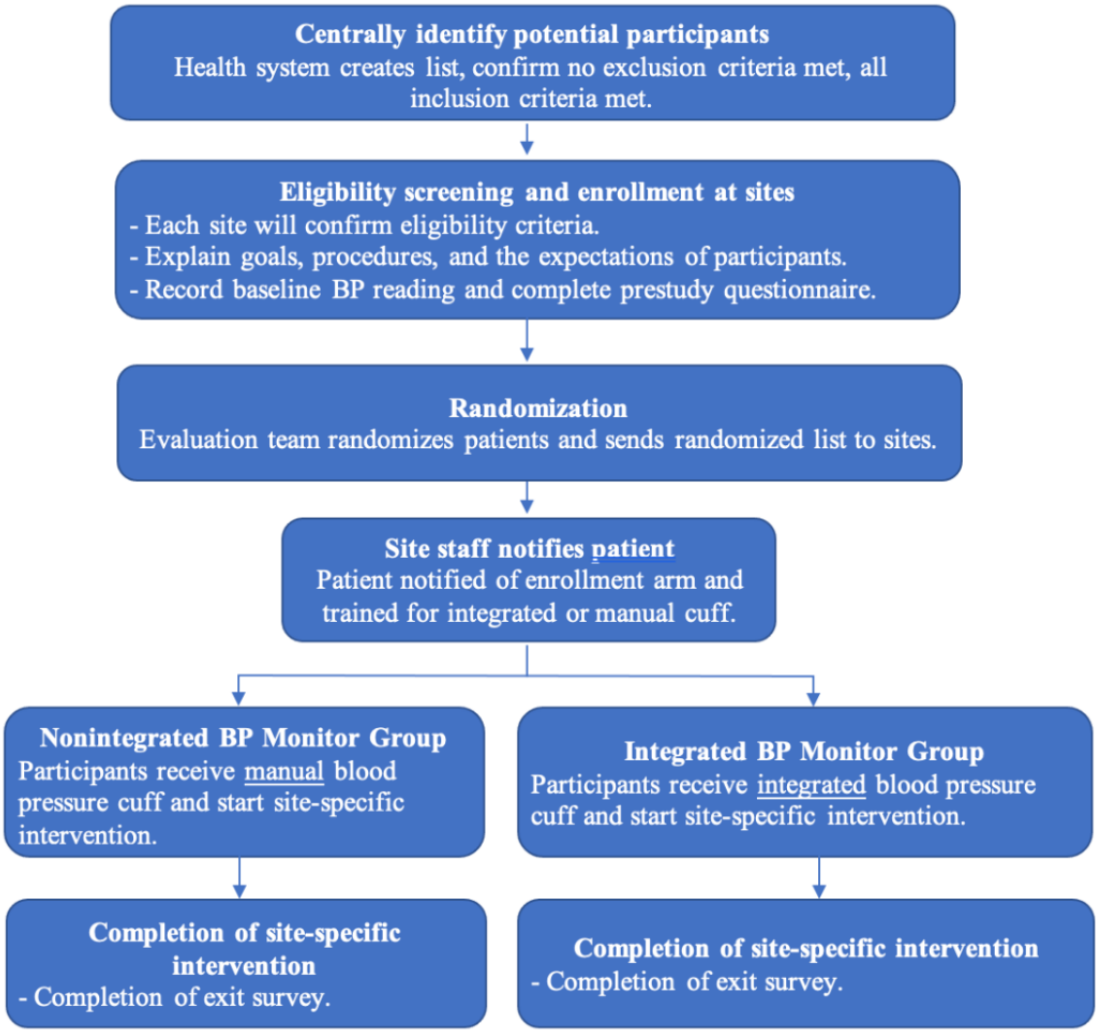
- Aged 18 years and older.
- Must be willing and functionally able (with help from another person if needed) to perform remote blood pressure (BP) monitoring.
- Have access to the web-based health care portal (with help from another person if needed).

Inclusion criteria

- Have outpatient visit within the last 12 months, and have a previous visit within 6 months of inclusion outpatient visit with diagnosis of hypertension, defined as having 2 readings of systolic BP >140 mm Hg or diastolic BP >90 mm Hg
- Has at least one visit with primary care physician in prior year.
- Takes 0 or 3 antihypertensive prescriptions (can include pills with 2 different drugs so could be on 2 medications).

Exclusion criteria

- BP > 180/110 mm Hg (office) or > 175/105 mm Hg (self-monitored BP measurements)
- Pheochromocytoma
- Uncontrolled hypothyroidism or hyperthyroidism
- Renal artery stenosis
- Conn's syndrome
- End Stage Renal Disease (ESRD)
- Chronic Kidney Disease (CKD) Stage 3b (CrCL <45) and worse
- Transplant patients—used the code that if they ever had a transplant
- Pregnancy
- Severe aortic stenosis
- Hospice or end-of-life or palliative Care
- Left Ventricular Ejection Fraction (LVEF) <30%
- Acute cardiac event in the last 3 months (eg, myocardial infarction)
- Heart block and arrhythmias
- Recurrent or symptomatic hypotension (systolic BP <100 mm Hg or diastolic BP <60 mm Hg)
- Drug and alcohol abuse
- Orthostatic hypotension (drop in systolic BP >20 mm Hg)
- Other secondary causes of hypertension
- Receiving hypertension management from other services (home health, hospice, already enrolled in hypertension management program)
- White coat hypertension



Enrollment, Randomization, and Study Initiation

Figure 2 describes the study phases, starting with the creation of the potential participant list obtained from the Center for Data-Driven Insights and Innovation (CDi2) and the UC Health Data Warehouse (UCHDW), verification of eligibility criteria, and study enrollment, which we aim to start in the second quarter of 2023. This study plans to enroll 660 participants (about 220 per site and 330 participants in each arm of the study). These power calculation estimates are based on previous literature reviews [18,19] to achieve an 80% power to detect a difference of 0.23 SDs and an anticipated 10% attrition rate. An enrollment script will be provided to each site (Multimedia Appendix 2). Randomization will occur after enrollment using a randomization allocation template within REDCap (Research Electronic Data Capture), a secure web-based platform designed to help capture data and operationalize research studies [20,21].

After enrollment and randomization, participants will receive their BP monitor (integrated or nonintegrated) and complete a prestudy questionnaire (Multimedia Appendix 3). Each UC site will then administer their site-specific hypertension intervention, which will be administered to both arms of the study. At the end of the 6-month follow-up period, a similar poststudy questionnaire evaluating participant experiences will be completed (Multimedia Appendix 4). Given the nature of the different BP management interventions, site representatives and participants will not be blinded to study arm assignments; however, the UCLA VBCRC evaluation team will be blinded.

XSL•FO
RenderX

Figure 2. Study phases. BP: blood pressure.

Blood Pressure Monitors, Electronic Health Record Integration, and Operations

Both integrated and nonintegrated BP monitors Omron 5 Series Model, BP7250 (Omron Healthcare Inc) will be directly mailed to participants' homes, and participants will be asked to follow standard instructions for measuring BP.

EHR integration refers to the secure transfer of data from the remote BP monitor to the health system's electronic medical record through DataHub (Omron). The process of integration will occur in collaboration with site IT leads, Omron representatives, and the Redox (Redox Inc) team. Redox is a backend integration platform that provides a standardized method for receiving and sending data between health care EHR systems and technology vendors such as Omron Healthcare Inc. Though more time- and labor-intensive to implement, the Redox platform allows for the immediate upload of data into the EHR without the use of a mobile app. For all participants with the integrated BP monitor, BP measurements will be immediately available in the EHR for intervention.

In terms of operations, the integrated BP monitors will store measurements in the provided DataHub, which will then automatically transmit BP measurements to Redox. At the backend, these BP measurements in Redox will then be transmitted to the patients' medical records and stored as a flowsheet item in the EHR that can be acted upon by local site-specific interventions. In contrast, the nonintegrated BP monitor will require participants to self-report BP measurements to their health care provider through the site-specific web-based patient portal. Participant and staff training on how to use the integrated BP monitor, techniques for taking BP, and further technical support in multiple languages will be conducted by Omron representatives. Omron representatives will call the participant after the monitor has been delivered and follow a standardized script that includes asking the participant to take multiple BP measurements and ensuring BP readings are properly captured in the database.

Primary and Secondary Outcomes

The primary outcome is the difference in BP from baseline compared to 6 months between study groups (integrated vs nonintegrated BP monitor), defined as a continuous measure of BP in mm Hg. Secondary outcomes include a binary measure of controlled versus uncontrolled hypertension (where uncontrolled is defined as systolic BP >130 mm Hg or diastolic BP >80 mm Hg based on American College of Cardiology and American Heart Association Practice Guidelines [22]), hypertension-related health complications by the end of the study, including acute coronary syndrome (myocardial

XSL•FO
RenderX

infarction), stroke (ischemic and hemorrhagic), decompensated heart failure, syncope, electrolyte abnormalities (hyponatremia, hypokalemia, and hyperkalemia), hospitalization, and mortality (all-cause). Hypertension-related health complications will be captured using International Classification of Diseases Ninth or Tenth Revision codes after the participants have started the study.

Statistical Analysis

For the primary outcome, linear mixed effects models will be used to compare changes from baseline home BP to 6 months from enrollment between the integrated and nonintegrated remote monitoring arms of the study. Models will include random site effects to account for the clustering of patients within sites. Models will adjust for demographic and clinical characteristics including age, sex, race, and ethnicity, as well as social vulnerability (the census tract Social Vulnerability Index). The evaluation of each arm will be based on a Wald test of the primary model term, and estimated differential changes will be reported along with a 95% CI. For the dichotomous secondary outcomes, we will use mixed effects logistic regression models with similar specifications and report differences in terms of odds ratios. A significance level of .05 will be used, and all analyses will follow the intention-to-treat principle. For patients who do not have a BP reading at 6 months, we will use the reading closest to 6 months, with a minimum 2-month period between the baseline and final reading [23,24]. Missing data will be handled through multiple imputations using pattern-mixture models. For the exploratory pre-post analysis, we will use linear mixed effects models to evaluate changes in BP. The analysis will be performed using SAS (version 9.4; SAS Institute Inc).

Ethical Considerations

The UCLA institutional review board (IRB) approved the study (IRB #22-000036) before study initiation on May 27, 2022, and agreed to serve as the IRB of record for UC Davis and UC San Francisco. All amendments to the protocol will be submitted for approval by the IRB. Results will be presented at clinical conferences and in the scientific literature. Based on findings from this study, similar remote BP monitoring programs may be disseminated to other UC sites not included in this study.

The UCLA VBCRC team will use Observational Medical Outcomes Partnership (OMOP) Common Data Models (CDM) in collaboration with CDi2 and the UCHDW to access BP data and secondary outcome measures from the EHR during the study period. The VBCRC team will monitor data quality at monthly intervals.

Results

All 3 clinical sites will begin enrolling participants during the second quarter of 2023. We anticipate the study to conclude in the first half of 2024 for all 3 sites. The results of this study will be available in 2024, and we aim to publish them by the end of 2024.

Discussion

Improving hypertension outcomes depends on timely and accurate BP measurements. This study is a pragmatic trial that focuses on clinical effectiveness, testing whether an integrated BP monitor is more effective than a nonintegrated BP monitor at BP improvement while documenting cross-site variation, barriers to implementation, and patient experiences.

One limitation to this study design is the risk of contamination across study arms; it is possible that providers taking care of patients in the integrated BP monitoring arm might escalate the level of care they provide to their patients in the nonintegrated arm, biasing the study to the null. Because the major difference between the study arms is the integration itself, we do not anticipate this to be a major limitation. Another limitation is the possibility of poor fidelity to the intervention; participants in both arms may choose to not actually take their BP, limiting the impact of the interventions. As a pragmatic trial of a quality improvement intervention, there are also limits to the types of data that can be collected; for example, we will not be collecting insurance type, primary language spoken, or telehealth use, all of which would be interesting to know whether these had a moderating effect on the intervention.

Overall, the findings from this study will inform health system decision makers in determining whether to invest resources in integrated BP monitoring for their patient populations. Additionally, it could support the development of programs to evaluate whether remote patient monitoring is a viable option, particularly for geographically dispersed populations.

Acknowledgments

The authors would like to recognize the University of California Office of the President for providing guidance and funding for this project, including the purchase of blood pressure equipment by Omron Healthcare Inc. We would also like to thank the participants for joining this study. CS was supported by a National Institute on Aging award (1K24AG047899-01) and the University of California, Los Angeles (UCLA) Clinical and Translational Science Institute National Institutes of Health (NIH)/National Center for Advanced Translational Science Grant (UL1TR001881). LHC received funding as a Clinical Translation Science Institute TL1 Fellow, Agency for Health Care Research and Quality Los Angeles Area Health Services Research Training Program Trainee, Gates Millennium Scholar (Bill and Melinda Gates Foundation), Cota Robles Fellow (UCLA Graduate Division), Progressive Vietnamese American Organization, board member, and policy co-chair. TCT reports a relationship with UCSF Partners in Care (Ron Rankin Grant) that includes funding grants related to telehealth; Mount Zion Health Fund Inc and Community Tech Network that include funding grants related to telehealth; and Epic Systems Corporation, which includes nonfinancial

support and a position on the Epic System's Telehealth Advisory Council. DRL was supported by an NIH T32 research training grant.

Data Availability

The data sets generated during or analyzed during this study are available from the corresponding author on request.

Authors' Contributions

All authors contributed to the study conceptualization and development of study methods. SV provided biostatistical support. RP contributed to the data abstraction. DRL, MC, LHC, CWV, and CS drafted the manuscript, and all authors provided input and edits. JB, HW, CCM, MH, SAS, MMM, AD, KNP, MA, and PFB contributed to the development and implementation of the University of California, Los Angeles (UCLA) site intervention. TCT and LB contributed to the development and implementation of the UC San Francisco site intervention. HM, RG, and LP contributed to the development and implementation of the UC Davis site intervention. All authors approved the final draft and contents of this protocol manuscript.

Abstract

Background: Daily and event-driven HIV pre-exposure prophylaxis (PrEP) with oral tenofovir-emtricitabine is highly effective to prevent HIV in men who have sex with men (MSM). PrEP care generally consists of in-clinic monitoring every 3 months that includes PrEP dispensing, counseling, and screening for HIV and sexually transmitted infections (STIs). However, the optimal frequency for monitoring remains undetermined. Attending a clinic every 3 months for monitoring may be a barrier for PrEP. Online-mediated PrEP care and reduced frequency of monitoring may lower this barrier.

Objective: The primary objective of this study is to establish the noninferiority of online PrEP care (vs in-clinic care) and monitoring every 6 months (vs every 3 months). The secondary objectives are to (1) examine differences between PrEP care modalities regarding incidences of STIs, HIV infection, and hepatitis C virus infection; retention in PrEP care; intracellular tenofovir-diphosphate concentration; and satisfaction, usability, and acceptability of PrEP care modalities; and (2) evaluate associations of these study outcomes with sociodemographic, behavioral, and psychological characteristics.

Methods: This study is a 2×2 factorial, 4-arm, open-label, multi-center, randomized, controlled, noninferiority trial. The 4 arms are (1) in-clinic monitoring every 3 months, (2) in-clinic monitoring every 6 months, (3) online monitoring every 3 months, and (4) online monitoring every 6 months. The primary outcome is a condomless anal sex act with a casual partner not covered or insufficiently covered by PrEP (ie, “unprotected act”) as a proxy for HIV infection risk. Eligible individuals are MSM, and transgender and gender diverse people aged ≥18 years who are eligible for PrEP care at 1 of 4 participating sexual health centers in the Netherlands. The required sample size is 442 participants, and the planned observation time is 24 months. All study

XSL•FO
RenderX

participants will receive access to a smartphone app, which contains a diary. Participants are requested to complete the diary on a daily basis during the first 18 months of participation. Participants will complete questionnaires at baseline and 6, 12, 18, and 24 months. Dried blood spots will be collected at 6 and 12 months for assessment of intracellular tenofovir-diphosphate concentration. Incidence rates of unprotected acts will be compared between the online and in-clinic arms, and between the 6-month and 3-month arms. Noninferiority will be concluded if the upper limit of the 2-sided 97.5% CI of the incidence rate ratio is <1.8.

Results: The results of the main analysis are expected in 2024.

Conclusions: This trial will demonstrate whether online PrEP care and monitoring every 6 months is noninferior to standard PrEP care in terms of PrEP adherence. If noninferiority is established, these modalities may lower barriers for initiating and continuing PrEP use and potentially reduce the systemic burden for PrEP providers.

Introduction

Oral tenofovir (TFV) disoproxil combined with emtricitabine (FTC) is highly efficacious as pre-exposure prophylaxis (PrEP) for the prevention of HIV infection [1,2]. PrEP can be taken daily [3-5] or in an event-driven schedule by cisgender men or transgender and gender diverse people (TGDP) assigned male at birth, who are not taking exogenous estradiol-based hormones [6-8]. Globally, the standard of care generally entails in-clinic PrEP initiation and in-clinic monitoring visits every 3 months, including PrEP prescription and dispensing, counseling on PrEP adherence and other HIV prevention strategies, and HIV testing, and may include kidney function testing [8,9]. PrEP programs are recommended to integrate PrEP monitoring visits with testing for bacterial sexually transmitted infections (STIs) and for hepatitis B virus and hepatitis C virus (HCV) infections [8-12]. If combined with the recommended HIV testing frequency, such testing is commonly performed every 3 months, although in practice, the frequency of testing could depend on sexual behavior [8-12].

In-clinic PrEP care faces several challenges that stem from the recommended frequency of monitoring visits (every 3 months). Clients might have to take time off from work, school, or family obligations, and may incur travel costs for attending in-clinic visits [13-17]. Persons interested in PrEP may also feel burdened with perceived stigma [18,19], cultural or social insensitivity [16,20,21], and lack of privacy [14,15] at the clinic. Providers might have capacity problems at facilities owing to shortages of health care staff or budget constraints, and might be forced to limit the number of clients or prioritize certain clients [22-24]. These client and provider barriers may contribute to individuals not initiating PrEP or discontinuing PrEP, which in turn increases the risk of avoidable HIV infections [23,25].

Limiting the number of in-clinic visits by offering online-mediated PrEP care may address some of these barriers [8,26,27]. Different models of digital PrEP services had been implemented across income settings prior to the COVID-19 pandemic, and implementation accelerated since the start of the pandemic [8,26-29]. Online PrEP care generally includes a combination of the following components: telephone or video consultation to collect data regarding medical history, sexual behavior, and PrEP intake, which are needed for PrEP prescription and counseling [8,26-29]; specimen collection for HIV and STI testing at a local laboratory [30], at home using a self-sampling kit [31,32], or a combination of both [30,33]; and delivery of PrEP tablets at locations preferred by users (eg, at home, other addresses, or health facilities) [30,33]. Since online PrEP care involves less intensive contact between PrEP users and health care providers and thus less guidance on PrEP use, it could theoretically have an adverse effect on PrEP adherence. Studies so far have shown high acceptability of online PrEP services among PrEP users. However, these studies were small in scale and were predominantly descriptive in nature and thus did not provide rigorous evidence on PrEP adherence in comparison to the standard of care [29,34], with the exception of an ongoing randomized controlled trial in the United States [31]. In their study, the authors aimed to compare online PrEP care with the standard of care with respect to protective levels of tenofovir diphosphate (TFV-DP) in dried blood spots (DBSs), and the results of this study are still pending [31]. Other trials related to online PrEP care in the European context do not yet exist.

Limiting the number of in-clinic visits through a reduction in the frequency of PrEP monitoring may pose challenges for the timely screening of HIV and other STIs. Regular HIV testing during PrEP use is essential to identify breakthrough HIV infections in suboptimally adherent PrEP users and, rarely, in highly adherent PrEP users [35,36]. It allows for commencing HIV treatment as soon as possible and avoiding onward transmission and the development or transmission of drug-resistant strains. While the current guidelines recommend HIV testing every 3 to 6 months [8-12], few studies have formally investigated the impact of HIV screening frequency on PrEP adherence [8]. A lower frequency of contact moments and HIV testing may negatively affect PrEP intake. One randomized noninferiority trial in Kenya found similar PrEP adherence in adults with dispensing of PrEP every 6 months at

XSL•FO
RenderX

the clinic combined with home-sampled HIV testing at 3 months after dispensing and in adults with dispensing of PrEP and HIV testing every 3 months at the clinic as the standard of care [37]. More evidence from other regions and from different groups of PrEP users is needed to further evaluate the implications of reduced frequency of monitoring. Particularly in high income settings with low HIV prevalence and high community-level PrEP uptake and PrEP adherence, HIV testing every 6 months might be sufficient. PrEP monitoring visits for men who have sex with men (MSM) in these settings are commonly combined with STI testing, but the optimal frequency of STI screening among MSM who use PrEP is unknown [2,22,38]. On the one hand, reducing the frequency of PrEP monitoring might lead to delayed diagnosis and treatment of asymptomatic STIs and onward transmission. On the other hand, it might avoid antibiotic use related to asymptomatic chlamydia and gonorrhea [39-41], and a lower STI screening frequency might be sufficient for MSM with lower levels of sexual activity.

The *E-Health for Zero Infections - facilitating access to and use of Pre-Exposure Prophylaxis in the Netherlands* (EZI-PrEP) study has been designed to assess whether online-mediated PrEP care and a reduced frequency of monitoring are noninferior compared to standard practice. The secondary research aims include assessing the effect of reduced monitoring frequency on HIV and STI testing behaviors and assessing whether the frequency of testing matches the level of behaviors associated with acquiring these infections. In the EZI-PrEP study, we will develop, implement, and evaluate an online-mediated PrEP care service and a less frequent monitoring schedule (every 6 months) among MSM and TGDP in 4 regions in the Netherlands. This paper describes the design and methods of the EZI-PrEP study.

Methods

Study Objectives

The primary objective of the EZI-PrEP study is to assess whether online-mediated PrEP care is noninferior to standard in-clinic care and whether monitoring every 6 months is noninferior to standard monitoring every 3 months. We defined the primary outcome measure as a condomless anal sex act with a casual partner during which PrEP was not used or insufficiently used (herein referred to as an “unprotected act”). Ideally, incident HIV infection would be the primary outcome, but this outcome is expected to be exceedingly rare for use in a clinical trial [42]. The outcome “unprotected act” can be regarded as a behavior that carries the most risk for HIV acquisition and is expected to occur frequently enough to serve as the primary outcome.

The secondary objective is to compare differences between PrEP care modalities in the incidences of bacterial STIs (ie, chlamydia, gonorrhea, and syphilis), HIV infection, and HCV infection; intracellular concentrations of TFV-DP; retention in PrEP care; total number of STI consultations (in addition to PrEP monitoring visits); and satisfaction, usability, perceived quality, acceptability, and time and cost investments of PrEP care.

Furthermore, to investigate how suitable the offered PrEP care modalities are for participants, we will study the associations of the sociodemographic, behavioral, and psychosocial predictors of PrEP adherence with all outcomes mentioned above, and assess whether these associations vary between study arms. More specifically, we will study the associations of unprotected acts with problematic alcohol and drug use, risk perception of acquiring STIs and HIV infection, and sexual compulsivity. Adequate PrEP adherence is key to its effectiveness in preventing HIV, and regular PrEP adherence counseling is therefore recommended. While ample evidence exists on the facilitators and barriers of medication adherence across different populations and settings [43] (eg, medication for the prevention and treatment of cardiovascular diseases [44], chronic disease management [45], and HIV treatment [46]), this remains an understudied topic for MSM who use PrEP. We are interested in how PrEP intake is integrated in daily life, what circumstances may lead to inadequate PrEP adherence, and whether these factors are associated with fewer contact moments between health care providers and PrEP users. We will therefore study the relationship between habit formation and PrEP intake. We will also analyze mental well-being (eg, positive and negative emotions, depression, stress, and anxiety) in relation to adherence and unprotected acts, and explore the mediating effects of personality-related variables (eg, emotion regulation, coping skills, conscientiousness, and resilience). Finally, we will investigate to what extent having a social environment, which is measured by social norms, loneliness, and support systems, is related to PrEP adherence and retention in PrEP care.

Study Setting

The EZI-PrEP study will be embedded in the government-funded National PrEP Pilot Program (NPP) that plans to run from August 2019 until July 2024 [47]. This program provides PrEP care to persons at high risk for HIV infection, notably MSM and TGDP, and is implemented by the sexual health centers (SHCs) of the public health service (PHS) regions throughout the Netherlands. The PrEP care offered consists of in-clinic monitoring visits every 3 months that are free of charge. PrEP tablets are provided at a reduced price of €7.50 (US $7.88) per 30 tablets (paid out-of-pocket by the PrEP user) and are provided only to those completing a monitoring visit. Following the Dutch PrEP guidelines applicable at the time when the study started (ie, April 15, 2019 [10]), each PrEP monitoring visit includes screening for HIV infection, bacterial STIs, and HCV infection, and, every 6 months, screening for kidney function (Table 1). It also includes counseling based on motivational interviewing techniques to stimulate informed and conscious decision-making by PrEP users in relation to their own sexual health, PrEP intake, and usage of other HIV-prevention strategies. PrEP naïve people are allowed to commence PrEP immediately after screening and counseling, and have to return to the SHC after the first month of PrEP use for repeat HIV testing. Three months after commencing PrEP, routine PrEP care begins with the first in-clinic monitoring visit (performed every 3 months). Individuals are allowed to test for HIV, STIs, and HCV free of charge in between regular PrEP monitoring visits at their own initiative. Individuals can freely

XSL•FO
RenderX

choose and switch between daily or event-driven PrEP regimens. These guidelines have since been updated in 2022, with the most relevant modification being that the monitoring frequency may be adapted under certain individual cases [11].

Table 1. Overview of testing for HIV infection, sexually transmitted infections, hepatitis C virus infection, and kidney function as part of routine pre-exposure prophylaxis care for each EZI-PrEP study visit at sexual health centers in the Netherlands (based on Dutch national pre-exposure prophylaxis guidelines; April 19, 2019).

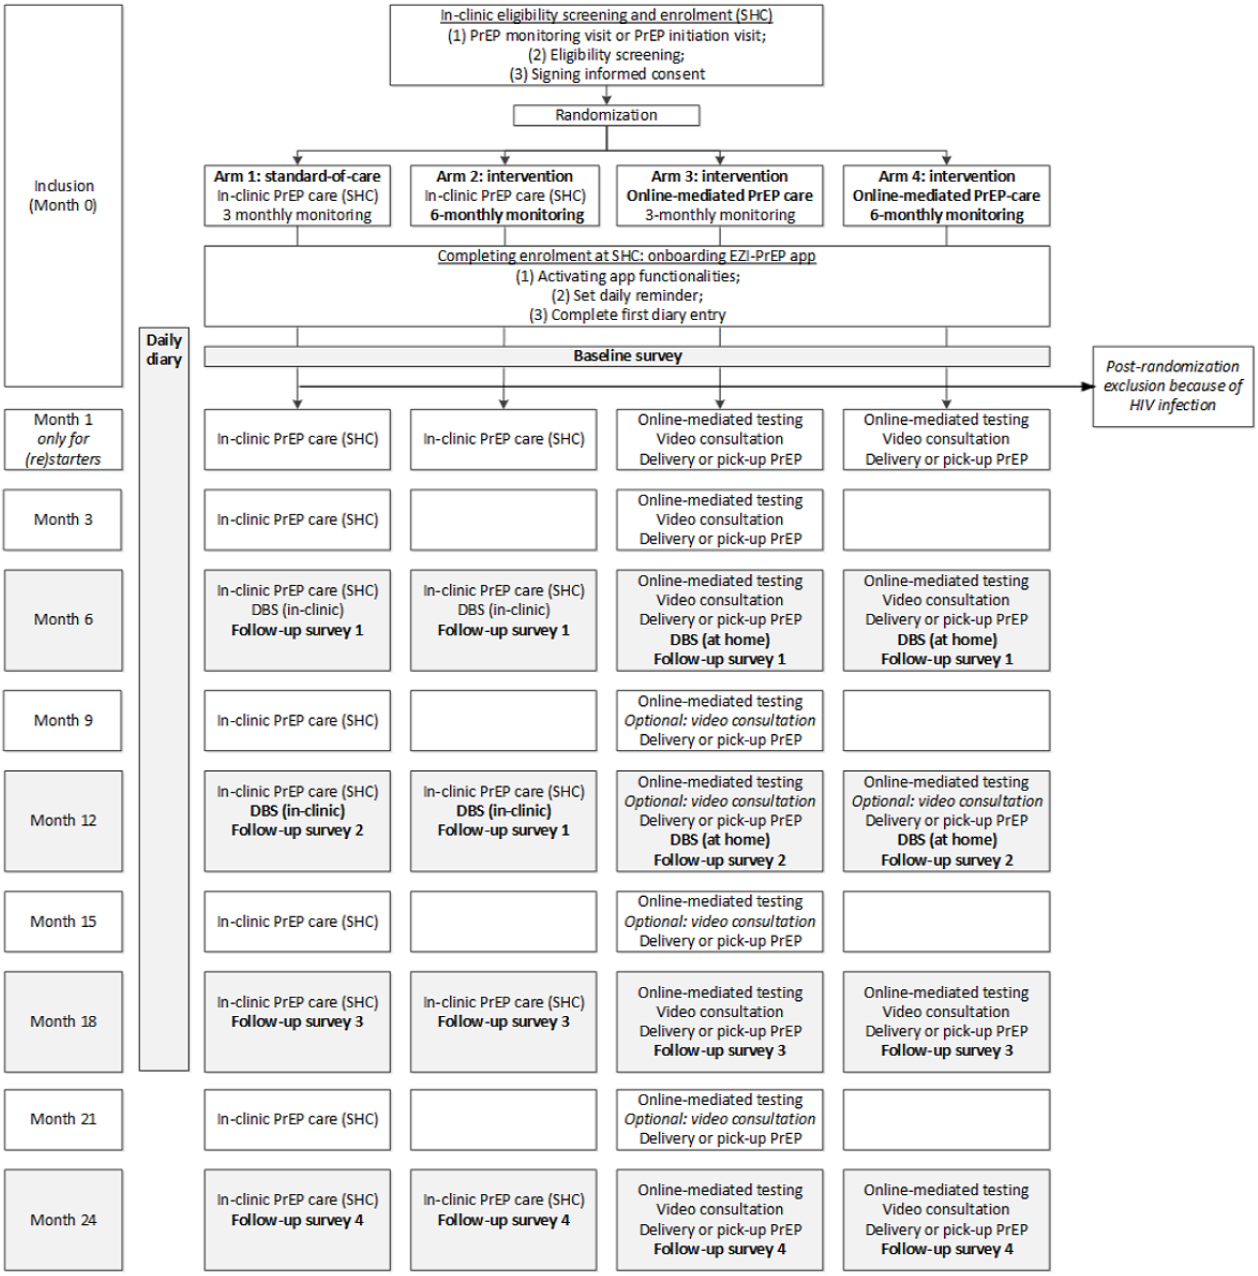
[a]Only pre-exposure prophylaxis starters and restarters have a pre-exposure prophylaxis monitoring visit at month 1.

[b]HCV: hepatitis C virus.

In the Netherlands, PrEP can also be obtained through a general practitioner, although, in this instance, neither PrEP tablets nor laboratory testing are fully reimbursed by the Dutch health insurance. The Dutch insurance system has an obligatory deductible excess, meaning that the first €385 (US $404) of health care costs, including laboratory testing ordered by primary care providers, are paid for out-of-pocket. Moreover, knowledge and willingness to prescribe PrEP varies across general practitioners. Most people who are using or want to use PrEP in the Netherlands therefore procure PrEP through the NPP. This program has been capped at 8500 PrEP users, which has resulted in individuals being placed on waiting lists to obtain PrEP from the NPP [24].



Study Design

The EZI-PrEP study will be a 2×2 factorial, 4-arm, open-label, multi-center, randomized, controlled, noninferiority trial. Study participants will be randomized to 1 of 4 arms: (1) in-clinic monitoring every 3 months (standard of care), (2) in-clinic monitoring every 6 months, (3) online monitoring every 3 months, or (4) online monitoring every 6 months (Figure 1). The study will be implemented at SHCs in Amsterdam, Rotterdam-Rijnmond, Haaglanden, and Gelderland-Zuid (Figure 2). For each individual participant, the planned observation time is 24 months, starting after eligibility screening and enrollment.

All study participants will receive access to a smartphone app (the “EZI-PrEP app”), which contains a diary. Participants will be required to complete this diary daily during the first 18 months of the study period. This information will be used to measure the primary outcome (ie, unprotected acts). DBSs will be collected at months 6 and 12. Routine clinical data registered during PrEP monitoring visits and any additional STI testing or treatment visits from inclusion until the final monitoring visit at month 24 will be retrieved from the national STI surveillance system. Participants will be requested to complete 5 questionnaires (at baseline and at 6, 12, 18, and 24 months) to collect data on PrEP intake; sexual behavior; psychosocial characteristics; and the experiences, acceptability, and usability of the interventions. We will extract automatically registered data on app usage from the app.

Study Population

We aim to include 442 individuals who are already using PrEP through the Dutch NPP or will be starting or restarting PrEP. Individuals starting PrEP are PrEP naïve (herein referred to as "PrEP starters"), whereas individuals restarting PrEP are persons who have used PrEP more than 6 months prior to inclusion and will recommence PrEP at inclusion (herein referred to as "PrEP restarters"). Both groups of individuals need to have a monitoring consultation after 1 month of starting or restarting PrEP as part of standard-of-care procedures and are therefore grouped in the protocol as "PrEP starters or restarters." Our intention is that at least 25% of study participants will be PrEP starters or restarters.

The eligibility criteria will be as follows: (1) being eligible for the Dutch NPP (Textbox 1) [45]; (2) being 18 years or older; (3) living in the catchment area of a participating PHS; (4) being able to complete informed consent, medical history, the daily diary, and questionnaires in English or Dutch; (5) having an email address; (6) owning an iOS or Android mobile phone capable of running the study app; (7) having daily access to an internet connection; (8) being able to make online payments; and (9) providing informed consent. The exclusion criteria will be as follows: (1) having an HIV infection; (2) being advised by a physician to wait with starting or restarting PrEP (PrEP starters or restarters) or being advised to stop with PrEP (current PrEP users) for more than 1 month, such as in the case of decreased kidney function with an estimated glomerular filtration rate (eGFR) of less than 60 mL/min/1.73m^2 or other kidney problems, or chronic use of medication that interacts with TFV/FTC; (3) being advised to have in-clinic monitoring every 3 months, such as in the case of adverse mental health conditions or life circumstances, chronic or acute hepatitis B virus infection, or other medical conditions that require special attention when using PrEP or may need a referral, such as osteoporosis or other bone diseases; and (4) participating in another clinical trial or research project related to HIV prevention.

Textbox 1. Eligibility criteria of the Dutch national pre-exposure prophylaxis pilot program (Dutch national pre-exposure prophylaxis guidelines dated April 15, 2019).

Men who have sex with men or transgender and gender diverse people who in the 6 months prior to the pre-exposure prophylaxis (PrEP) request or PrEP consultation:

- Had anal sexual intercourse without a condom with a male partner having an unknown HIV status
- Had anal sexual intercourse without a condom with a male partner having a known HIV-positive status and a detectable viral load
- Was diagnosed with a rectal sexually transmitted infection or syphilis
- Received a prescription for HIV postexposure prophylaxis

XSL•FO
RenderX

Recruitment

We will recruit participants mainly at the SHCs of the participating PHSs. Current PrEP users will be recruited during regular PrEP monitoring visits by a health professional (usually a nurse or a physician). Individuals who are starting or restarting PrEP will be recruited from the waiting lists for PrEP care via email, SMS text messaging, or a phone call and routine communication channels of the respective SHC. The enrollment visit will be scheduled together with the first PrEP consultation. To support the recruitment efforts of the SHCs, we developed a website [48] and promotional materials for distribution to SHC clients. In addition, depending on the recruitment rate in the participating SHCs, we plan to conduct 3 advertising rounds on the MSM dating platform Grindr, targeting potential participants living in the catchment areas of the 4 participating PHSs. All promotional materials and advertisements will link to the EZI-PrEP website page with a short application form.

Enrollment Procedures

In preparation of the enrollment visit, potential participants will receive an email with the patient information folder and will be asked to download the EZI-PrEP study app. The enrollment interview will begin with a regular PrEP consultation at the SHCs, which will be combined with eligibility screening (Figure 1). Noneligible individuals will continue or commence routine PrEP care. Eligible individuals will be guided through study procedures and asked to sign an informed consent form, and will be subsequently randomized to 1 of the study arms. Each participant will then onboard the EZI-PrEP app and complete the diary for that day to ensure understanding of the questions asked in the diary. This first diary entry will not be used for analysis because it is completed in the presence of a health care worker. The enrollment interview will be finalized with scheduling of the next monitoring appointment and PrEP provision.

The Dutch PrEP guidelines allow for combining STI and HIV test specimen collection with PrEP dispensing, as long as a client can be easily reached to communicate HIV and STI test results [10,11]. In case of a positive HIV test result, the PrEP user will be notified immediately to discontinue their PrEP and will be referred to HIV care. This strategy may lead to postrandomization exclusion from the EZI-PrEP study within 1 week after randomization.

Randomization

Participants will be randomized (stratified by PHS and by PrEP experience, that is, those starting or restarting PrEP, and current PrEP users) to 1 of 4 study arms in permuted blocks of 4. Randomization will be performed by a statistician of PHS Amsterdam who is not part of the EZI-PrEP study team at initiation of the study, using Stata Intercooled 15.1 (StataCorp). Sequentially numbered and colored nontransparent envelopes will be made, containing a code for the study arm. Each PHS will receive 2 sets of envelopes, red ones for those starting or restarting PrEP and blue ones for current PrEP users. During the enrollment interview, in the presence of the participant and dependent on their PrEP experience, the health care provider will open the next envelope to reveal the study arm and study number.

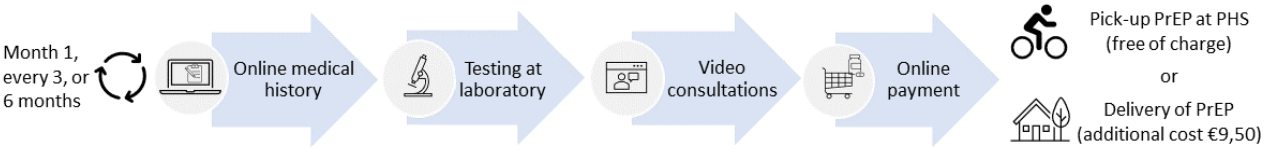
Interventions

PrEP Care Every 6 Months

Participants in arms 2 and 4 (Figure 1) will receive PrEP care every 6 months. All study participants, irrespective of study arm, will be allowed to get screened free of charge for HIV and STIs in between scheduled PrEP monitoring visits (eg, after a partner notification for an STI or in case of STI-related symptoms). To allow for monitoring in between testing, we will ask participants to visit the SHC where they receive PrEP care.

Online PrEP Care

Participants in arms 3 and 4 (Figure 1) will receive online-mediated PrEP care that mimics in-clinic PrEP care. Figure 3 depicts the process of online-mediated PrEP care. First, participants will access an established online HIV and STI test request platform for MSM called Testlab [49]. On this platform, participants will complete standard intake questions for a PrEP consultation. The number of PrEP tablets needed until the next monitoring date will also be reported. All medical information will be stored in the electronic patient files. Participants reporting STI symptoms at the scheduled online monitoring visit will be asked to visit the clinic for physical examination and treatment.



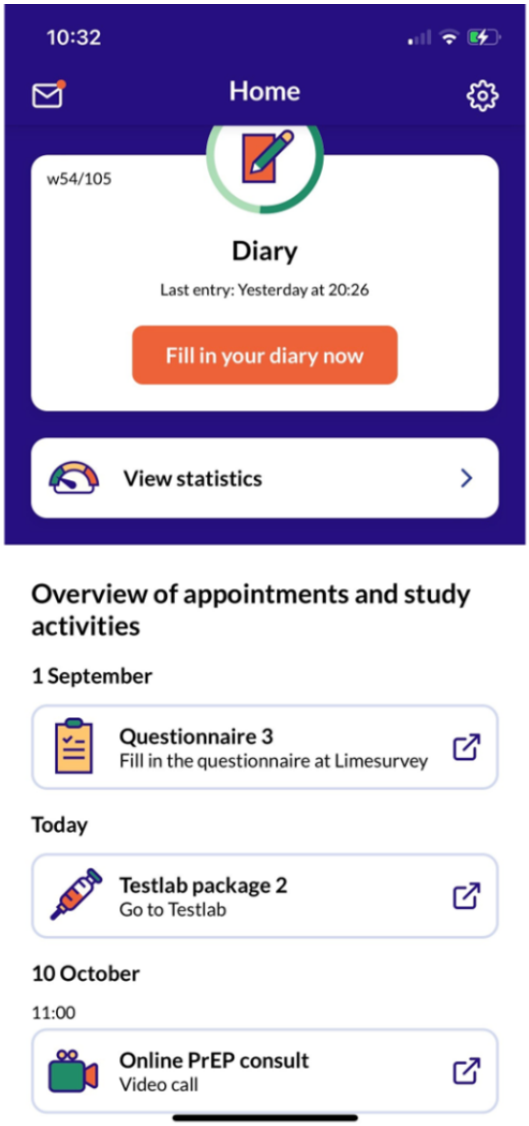
The participant will then receive a lab order from the Testlab platform to visit one of the connected laboratories to provide samples for HIV infection, STI, HCV infection, and kidney function testing (Table 1). Negative test results for HIV infection, STI, and HCV infection; normal kidney function test results; and positive test results for bacterial STIs will be communicated via the Testlab platform. Treatment of bacterial STIs will occur in the clinic at SHCs. In case of a positive test result for HIV or HCV, or a decreased kidney function, participants will receive a phone call to make an appointment on the same day.

To provide counseling on sexual well-being, PrEP intake, and other HIV prevention strategies, a video consultation will take place. These video consultations will become optional after 6 months. The continuation of video consultation will be based on shared decision-making between the participant and the SHC health care provider. Self-reported medical history and testing for HIV infection, STIs, HCV infection, and kidney function will remain mandatory for PrEP provision. For the purpose of the study, a mandatory video consultation will take place at 18 and 24 months to inform participants about study procedures that change at those time points (Figure 1).

Participants in the online arms may opt for home delivery of PrEP tablets, for which a service fee of €9.50 ($9.98) will be requested and will require an online payment. Pick up of PrEP tablets from the SHC will also be possible without any additional cost. The SHC physician will determine the number of tablets that a participant is able to obtain based on the intended PrEP regimen and the number of tablets requested by the participant in the self-reported medical history.

XSL•FO
RenderX

Figure 3. Process of online-mediated EZI-PrEP care. It should be noted that 6 months after inclusion, the video consultations will become optional, and PrEP provision will then be based on online (self-reported) medical history and test results. A currency exchange rate of €1=US $1.05 is applicable. EZI-PrEP: E-Health for Zero Infections - facilitating access to and use of Pre-Exposure Prophylaxis in the Netherlands; PHS: public health service; PrEP: pre-exposure prophylaxis.



EZI-PrEP Applications

EZI-PrEP App

All participants will get access to the free-of-charge, password-protected EZI-PrEP app through the Apple and Google Play stores. App functionalities will depend on their allocated mode of PrEP care provision. All participants will have access to the daily diary, the summary of data entered in the diary, and a timeline with an overview of upcoming PrEP monitoring visits and study questionnaires (Figure 4). Participants receiving online PrEP care will also receive access to the online-mediated test request platform, video consultation software, and PrEP payment module. All functionalities will be immediately accessible by clicking on the activity in the timeline of the app via a single sign on. All participants will be able to receive messages in the app from SHC health care workers and study staff, but will not be able to send messages via the app (Figure 4).

Figure 4. Homepage of the EZI-PrEP app. It should be noted that Testlab package 2 and online PrEP consultation are only visible to EZI-PrEP participants in arms 3 and 4. Arm 3: online monitoring every 3 months; Arm 4: online monitoring every 6 months; EZI-PrEP: E-Health for Zero Infections - facilitating access to and use of Pre-Exposure Prophylaxis in the Netherlands; PrEP: pre-exposure prophylaxis.

XSL•FO
RenderX

EZI-PrEP Administration Portal

The EZI-PrEP app and all functionalities, except for the diary, will be controlled by SHC health care workers and EZI-PrEP study staff via a web portal that uses a cloud platform to exchange data with the EZI-PrEP app. The administration portal will be used to activate participant accounts, with functionalities enabled according to the study arm allocation. The portal will include an event planner to register the date and time of in-clinic visits, online-mediated testing, and video consultations, and activate the PrEP payment module upon entering the number of tablets that can be obtained by the online participants. The portal will also be used for scheduling questionnaires and, for online participants only, to activate home delivery of a DBS home sampling kit. In-app messages will be sent via the administration portal as well. Health care workers will be able to only access the accounts of participants receiving PrEP care at their SHCs.

Laboratory Procedures

Laboratory procedures will be performed according to routine STI and PrEP care clinical protocols, which may slightly differ across study sites. A detailed description of the laboratory procedures at each study site can be found in Multimedia Appendix 1.

Data Collection Methods

EZI-PrEP Diary

To minimize recall bias and increase the accuracy of self-reported PrEP intake, casual anal sex, and condom use, participants will be requested to complete a daily diary for primary outcome measurement [50]. Completing the diary may be burdensome for certain participants and could result in less motivation to remain in the study. Minimizing the length of the diary collection period could help maintain sufficient motivation to complete the diary and continue study participation. During the first 18 months of the study, each participant will be completing 4 to 6 daily questions. These diary questions ask about PrEP use, sexual behavior of the previous day, and current mood. The first question (“Do you use daily or event-driven PrEP?”) will be asked once and set as default (ie, prefilled) until the participant changes to a different regimen, which can be selected in a new diary on the following day. The second question (“How many PrEP pills did you take?”) will need to be answered with 0, 1, or 2. In case of 1 or 2 tablets, the third question will be prompted (“At what time did you take PrEP?”), which will need to be answered with a specific time. The fourth question (“Did you have anal sex with a casual partner?”) will need to be answered with yes or no. If yes is answered, the fifth question (“Did you use a condom every time?”) will be prompted, which will need to be answered with yes or no. The sixth question (“How do you feel today?”) will need to be answered on a discrete scale with 5 options, ranging from 1 (depicted by a red sad face) to 5 (a green happy face). Participants will be allowed to change their answers until automatic submission of the diary when the final question is answered. The average expected duration of completing the daily diary is 90 seconds.

The diary that is completed on a given day will ask about PrEP intake and sexual behavior of the day before, which is indicated on the top of the screen. If a participant forgets to enter their information in the daily diary, they will be allowed to retrospectively fill in information, but only for the past 2 days.

To increase diary completion adherence, we will send automated daily notifications at 10 AM Central European Time (CET); however, it will be possible to deactivate this reminder in the settings of the app. If a participant has not completed their diary for 7 days, an email with a reminder and explanation of the importance of the diary for the study will be sent. After 14 days, another reminder that the diary is crucial for the study will be sent to the participant and to the PHS where they are under care, so that the importance of diary completion can be discussed in the upcoming monitoring visit. Being unable to complete the diary will not be considered as a reason to end participation in the study.

DBS Collection

We will collect DBSs to measure intracellular concentrations of TFV-DP and emtricitabine-triphosphate (FTC-TP). Blood will be spotted on Whatman 903TM Protein Saver Cards (GE Healthcare Bio-Sciences Corp). For participants receiving in-clinic PrEP care, study nurses will collect whole blood via phlebotomy and spot this onto the DBS card during the 6- and 12-month PrEP monitoring visits. Participants receiving online-mediated PrEP care will receive a DBS home sampling kit after completing their PrEP monitoring visit at months 6 and 12. This kit contains the DBS card with 5 spots, 2 contact-activated lancets (2.0-mm BD Microtainer), an alcohol wipe, a gauze wipe, 2 band aids, a grip seal bag, a desiccant sachet with a humidity indicator (MiniPax, Multisorp Technologies), a preposted envelope, and paper instructions with a QR code to an instruction video. Participants will be requested to send the completed DBSs in the preposted envelope to the Amsterdam regional microbiology laboratory. All DBS cards will be stored at −20°C at the Amsterdam regional microbiology laboratory and shipped in batches for analysis to Skaggs School of Pharmacy and Pharmaceutical Sciences (University of Colorado Anschutz Medical Campus). Owing to financial constraints, only DBS cards from daily PrEP users will be analyzed. The procedure to measure TFV-DP and FTC-TP in DBSs has been described previously [51]. The results will not be reported back to the participants. For participants with incident HIV infection, the most recent DBS prior to infection will be analyzed for TFV-DP, FTC-TP, and HIV RNA

Clinical Data

We will obtain the clinical data of all PrEP and STI consultations of study participants between enrollment and study completion from the Dutch national SHC surveillance database (SOAP). During every consultation at the SHC, data are collected on the following: (1) sociodemographic characteristics (age, gender, highest educational level, country of birth, and country of birth of parents); (2) sexual behavior and STI/HIV risk factors (number of sex partners, condom use, group sex, use of alcohol and drugs during sex, sex work, having been a victim of sexual violence, and sex partners from STI or HIV endemic countries); (3) reason for consultation (partner notification, STI-related

XSL•FO
RenderX

symptoms, PrEP, and STI testing); (4) PrEP use (history of PrEP use, reasons for stopping PrEP, and number of PrEP tablets provided); and (5) HIV infection, STI, and HCV infection testing and diagnosis. Data on kidney function and proteinuria will be retrieved from the electronic patient files.

Study Questionnaires

The first 4 questionnaires (ie, at baseline, and 6, 12, and 18 months) will ask about PrEP intake, sexual behavior, risk perception related to STIs and HIV infection, and STI testing at facilities other than SHCs. We will include several psychosocial measurements in the questionnaires (summarized in Table 2). The questionnaire at month 12 will include questions on social norms with respect to PrEP use, loneliness, and the presence of social support systems. To investigate the usability and acceptability of the PrEP care modality, we will include questions based on Davis' model of technology acceptance [52] at months 6, 12, and 18. These questionnaires will also include questions regarding experiences with PrEP care and to what extent participants felt supported in their PrEP use. To assess the usability and acceptability of online-mediated PrEP care specifically, we will include the system usability scale [53] at month 18 for online study participants. We will also ask them to rate the different steps during their online PrEP care. The fifth (and last) questionnaire, at month 24, will focus on the quality of PrEP care within the EZI-PrEP study and in the Netherlands in general, as well as the time and cost investments of study participants in receiving PrEP care.

Table 2. Overview of psychosocial measurements within the EZI-PrEP study in each survey round.

Scale	Abbreviation	Aspect measured	Baseline survey (month 0)	Follow-up survey			
				Month 6	Month 12	Month 18	Month 24

[a]HEXACO is an acronym for "Honesty-humility," "Emotionality," "Extraversion," "Agreeableness," "Conscientiousness," and "Openness to experience."

Data Analysis

Primary Outcome

The primary outcome ("unprotected act") will be assessed using daily self-reported data on sexual behavior, pill intake, and condom use. We will use all available data, meaning that observation time and all data of those who are lost to follow-up or have dropped out will be included until their last day in the study. We will determine, for each day of follow-up, whether a condomless anal sex act with a casual partner took place. We will also determine whether sufficient PrEP pills were taken around the time of this condomless anal sex act. Using this information, the condomless anal sex act will be considered as either unprotected or not. We will then calculate the total number of unprotected acts (n) and the total person-years of observation. Incidence rates per 100 person years will be calculated by dividing the sum of all unprotected acts by the sum of person-years of observation and multiplying the result by 100. We will calculate the incidence rates among participants of online PrEP care (arms 3 and 4), in-clinic PrEP care (arms 1 and 2), monitoring every 6 months (arms 2 and 4), and monitoring every 3 months (arms 1 and 3). Two main analyses will be conducted in which we will test the ratio of the incidence rates of unprotected acts for (1) online PrEP care versus in-clinic PrEP care and (2) monitoring every 6 months versus monitoring every 3 months. The analyses will be based on crude unadjusted incidence rate ratios.

A noninferiority trial intends to demonstrate that one intervention is not unacceptably worse than a comparison intervention [54]. To do so, the lower limit of the 95% CI (or 2-sided 97.5% CI) should not extend beyond a predefined margin, which is referred to as the noninferiority margin. In this study, noninferiority will be tested using a 1-sided test based on maximum likelihood estimators with a type 1 error at 0.0125 (ie, with 2 comparisons using Bonferroni corrections=0.025/2) [40] and a noninferiority ratio of 1.8. If the upper 2-sided 97.5%

XSL•FO
RenderX

CI of the incidence rate ratio is below 1.8, we will conclude that the intervention arms are noninferior to the comparator arms.

To determine whether the incidence rates change over time, we will model the number of unprotected acts as a function of 1-month intervals using Poisson regression (or negative-binomial regression, if the standard deviation is far greater than the mean of the outcome, ie, overdispersion) and test for changes in time using a Wald χ^2 test. We will test for the interaction between time and intervention arm.

Secondary Outcomes

We will assess intracellular concentrations of TFV-DP and FTC-TP using DBSs collected at month 12 in all participants using daily PrEP. The lower limit of detection is determined as 25 fmol/punch and 50 fmol/punch for TFV-DP and FTC-TP, respectively. The distribution of the intracellular concentrations of TFV-DP and FTC-TP will be compared between daily PrEP users in (1) online PrEP care versus in-clinic PrEP care and (2) monitoring every 6 months versus monitoring every 3 months, using a rank-sum test. In a secondary analysis, the log-transformed values will be compared using a linear regression.

The incidence rates of HIV infection and TFV/FTC-resistant HIV infection, and the incidence rates of bacterial STIs (ie, chlamydia, gonorrhea, and syphilis), HCV infection, and eGFR of less than 60 mL/min/1.73m^2 will be assessed. The incidence rates are calculated by dividing the number of diagnoses by the person-years of observation. The incidence rates will be compared for (1) online PrEP care versus in-clinic PrEP care and (2) monitoring every 6 months versus monitoring every 3 months.

Retention in PrEP care is defined as having had a PrEP prescription no longer than 8 months ago. Participants will be considered lost to follow-up when they do not complete a PrEP monitoring visit at month 18 within 2 months of the planned date. They will be regarded as lost to follow-up from the date of the last contact with the study (ie, completed a diary, questionnaire, or consultation). We will compare proportions of participants who are retained in PrEP care or are lost to follow-up for (1) online PrEP care versus in-clinic PrEP care and (2) monitoring every 6 months versus monitoring every 3 months, using the Pearson χ^2 test.

Satisfaction with PrEP care will be compared between study arms. Furthermore, we will analyze how usability of the online PrEP service differs between online-mediated PrEP care every 3 months and every 6 months. For these analyses, we will use the Wilcoxon signed-rank test of the Likert score outcomes.

We will investigate the associations between sociodemographic and psychosocial determinants and the incidence rates of unprotected acts; HIV infection, STIs, and HCV infection; retention in PrEP care; and loss to follow-up. A wide range of parameters, mentioned in the Data Collection Methods section, will be included in our analyses. The analyses will involve logistic models, Cox proportional hazards models, and Poisson regression models.

Power and Sample Size Calculation

We assume that the primary outcome measure of unprotected acts will be Poisson distributed with the total number per 100 person-years given as an incident rate (λ) and the total time during monitoring (t). We define the incidence rate in the experimental arm as λ_e and the incidence rate in the control arm as λ_c. We aim to reject the null hypothesis that the ratio λ_e/λ_c is greater than or equal to a predetermined noninferiority ratio (r). We consider that a noninferiority ratio of 1.8 is able to preserve clinically acceptable noninferiority bounds with increasing λ.

In a previous PrEP study in the Netherlands (Amsterdam PrEP demonstration project [“AMPrEP study”]), the overall incidence rate of unprotected acts was 78/100 person-years [50]. The AMPrEP study included participants with a high number of sex partners and very high incidence of bacterial STIs. Participants of the NPP have reported fewer casual sex partners and have a lower incidence of bacterial STIs [55]. The EZI-PrEP participants are therefore expected to have fewer unprotected sex acts than the AMPrEP participants. We expect the incidence rate of unprotected acts in the experimental arm (λ_e) and control arm (λ_c) to be at least 36/100 person-years. We also assume a median monitoring time of 18 months. Using a Bonferroni-corrected 1-sided type 1 error of 0.0125 (=0.025/2 for a total of 2 comparisons), we will need 368 participants to have 90% power to demonstrate noninferiority using the test statistic based on maximum likelihood estimators from Stucke and Kieser [56]. If λ is higher than 36/100 person-years, we will have sufficient power to demonstrate noninferiority. Considering expected loss to follow-up, we have increased the target sample size by 20%, and thus, the total required sample size is 442.

Ethical Considerations

This study has been approved by the medical ethics committee of the Amsterdam University Medical Centers (file number 2020_154 - NL74494.018.20). The trial has been registered at ClinicalTrials.gov (number NCT05093036).

Results

The results of the primary outcome assessment are expected by Fall 2024. Completion of the 24-month questionnaire and retrieval of STI data are expected by Fall 2024. Analysis of secondary outcomes will be conducted in 2024 and 2025.

Discussion

We have designed the EZI-PrEP study in order to assess whether online-mediated PrEP care and a reduced frequency of monitoring are noninferior compared to standard practice. In this study, we will develop, implement, and rigorously evaluate an online-mediated PrEP care service and a less frequent monitoring schedule (every 6 months) among MSM and TGDP in 4 regions in the Netherlands. Studies in countries with concentrated HIV epidemics and PrEP programs for MSM show the potential of PrEP programs to reduce population-level HIV incidence [57,58]. Reducing the number of in-clinic visits may

XSL•FO
RenderX

reduce the burden of PrEP care and might help increase uptake and improve retention. Additionally, it may improve access to PrEP as it may make more resources available and enlarge capacity at facilities providing PrEP. Online-mediated PrEP care and monitoring every 6 months are promising options to reduce in-clinic PrEP visits, but it is unclear how this affects PrEP adherence. Since both modalities involve less intense contact between PrEP users and health care providers, and thus less guidance in PrEP use, it could theoretically have an adverse effect on PrEP adherence. The EZI-PrEP study will be able to provide evidence on the efficacy and safety of online-mediated PrEP care and PrEP care every 6 months compared to standard in-clinic PrEP care every 3 months in terms of PrEP adherence as a proxy for HIV risk. If these services are found to be noninferior, both online access to PrEP and reduced monitoring frequency could become viable evidence-based PrEP care options.

The EZI-PrEP study will contribute crucial data to the ongoing debate on optimal HIV and STI screening frequency for MSM who use PrEP. By comparing incidence rates of HIV infection, STIs, and HCV infection between the 3-month and 6-month monitoring study arms, we will provide evidence on the impact of testing every 6 months on STI diagnosis and treatment. If noninferiority in terms of PrEP adherence is concluded and STI incidence rates are similar between the 6-month and 3-month monitoring arms, a stronger case can be made to offer PrEP monitoring every 6 months as the standard of care. If STI incidence rates are not similar between the study arms, we will be able to examine to what extent this is related to particular sociodemographic, sexual behavior, or psychosocial factors and advise on implementation accordingly. EZI-PrEP study participants will be allowed to test for HIV, STIs, and HCV in between regular PrEP monitoring visits at their own initiative. The EZI-PrEP study will also be able to quantify the extent to which in-between visits occur among PrEP users receiving monitoring every 6 months.

Since adherence to the PrEP intake regimen is crucial for its effectiveness [3,5-7], having a thorough understanding of enabling and disenabling factors of PrEP adherence is important. The EZI-PrEP study will provide new insights on the associations between sociodemographic and psychosocial variables on the one hand and PrEP adherence on the other hand. Insights into the role of such sociodemographic and psychological factors in the context of adherence may be used to further improve the content or conduct of PrEP consultations and inform interventions that support PrEP adherence. Furthermore, we will investigate the relationship of these factors with PrEP adherence, STIs, retention, and satisfaction with PrEP care, according to the study arm. The results of these analyses could be used to determine if these new PrEP care modalities should be implemented widely or should be offered to specific subpopulations.

The main methodological challenge of this study is the measurement of the primary outcome measure, which is based on self-reported PrEP intake and sexual behavior. In the AMPrEP study, it was found that reporting of daily data decreases over time, which may confront us with a substantial amount of missing data. We will therefore implement an intensive scheme of reminders. Additionally, the diary in itself may cause behavioral changes (ie, Hawthorne effect). For instance, PrEP intake may be affected due to the daily reminder to complete the diary. Completing the diary on a daily basis might also be too burdensome for some participants, and as a result, their motivation to complete the study could be low. However, because of randomization, any effect of daily diary entry on behavior or participation is not expected to differ across the 4 arms. A major strength of our study is that it is embedded in routine PrEP care, which increases the generalizability of study outcomes and will provide a realistic perspective on the implementation of 2 new PrEP care modalities. If these modalities are found to be noninferior, they can be easily implemented in routine care using the workflows developed in this study and applied to the 4 participating PHSs. Furthermore, combining monitoring every 6 months and online-mediated PrEP care in this trial offers a unique opportunity to study real-life implementation of these PrEP modalities.

In conclusion, the results of the EZI-PrEP trial will provide evidence on the noninferiority of online-mediated PrEP care compared to in-clinic care and the noninferiority of monitoring every 6 months compared to monitoring every 3 months in terms of PrEP adherence. It will also provide insights into screening every 6 months for HIV infection, STIs, and HCV infection among MSM who use PrEP, and thereby will contribute to the literature on the optimal STI screening frequency among PrEP users. Moreover, the study will investigate to what extent these PrEP care modalities are appealing to PrEP users in general and if particular PrEP users would benefit more from these modalities than others. Finally, the study will provide insights into the sociodemographic and psychosocial factors that influence PrEP adherence. The EZI-PrEP study aims to inform policymakers and sexual health centers in deciding which strategies would be appropriate for PrEP care. The findings will contribute to accessible, low-cost, scalable, and sustainable PrEP care.

Acknowledgments

The EZI-PrEP (E-Health for Zero Infections - facilitating access to and use of Pre-Exposure Prophylaxis in the Netherlands) trial is supported by 2 grants from Stichting Aidsfonds – Soa Aids Nederland (project numbers P-42701 and P-54201). The EZI-PrEP trial has also received support from the internal small grants scheme of public health service (PHS) Amsterdam (project numbers 2021-5 and 2022-2). The authors would like to thank all EZI-PrEP study nurses and physicians at the SHCs, especially Maudy Sluimer (study nurse, PHS Rotterdam-Rijnmond), for their commitment to develop the EZI-PrEP study protocol, smartphone app, website, and administration panel amidst the COVID-19 pandemic. We would also like to thank Janneke Bil for her work on the project during the pregnancy leave of MLGB. We are also grateful for the contributions of the following researchers,

XSL•FO
RenderX

nurses, and physicians who were involved in the developmental phase of this study: Wim Zuilhof, Noëmie Nijsten, Mark van den Elshout, Ilya Peters, Daphne Sassen, Sarah Brevet, Jeannine Hautvast, Amber Hof, Remy Welleman, Sophie Kuizenga Wessel, Fokke Postma, and Fetzen de Groot. Furthermore, we would like to thank the colleagues at PHS Amsterdam (Bart-Jan Mulder, Roelien Prins, Liesbeth Flobbe, Frank Mouthaan, Maarten van Haagen, Karin Tang, Ertan Ersan, and Dominique Loomans) for their guidance and hard work when developing the digital applications of EZI-PrEP. We would like to thank Amsterdam regional microbiology laboratory (Margreet Visser, René Vork, Wilma Vermeulen-Oost, and Sylvia Bruisten) for making kidney function testing possible at Testlab in Amsterdam in collaboration with Atalmedial and for their assistance in preparing the dried blood spot packages as well as checking and storing all returned dried blood spot cards. We would also like to thank all other labs that are connected to Testlab and are willing to expand their testing options for EZI-PrEP, including Mireille van Westreenen and colleagues at the Department of Medical Microbiology at Erasmus MC laboratory and Annemiek Baltissen-van der Eijk and colleagues at the Virology Department; Suzanne van Veen and colleagues at Haaglanden Medical Centre; and Matthew McCall and colleagues at the Department of Medical Microbiology at Radboud UMC. We would like to thank DC Pharmacy (Rosalie Zieck and Laurens Maussen) for believing in this project, becoming our partner, and organizing the delivery of pre-exposure prophylaxis and dried blood spot packages. Finally, we would like to thank the members of the EZI-PrEP advisory group (Bea Vuylsteke, Marc van der Valk, Chris Tearno, David Burger, Hanna Bos, Jan den Hollander, John de Wit, Janny Dekker, Kai Jonas, Silke David, Sebastiaan Verboeket, Janneke van de Wijgert, and Paul Zantkuijl) for their feedback on the design of this study and its data collection methods.

Data Availability

Data sharing is not applicable to this article as no data sets have been generated or analyzed.

Authors' Contributions

UD, MFSvdL, EH, MP, AB, AM, LC, ARF, FvH, and MLGB conceptualized and designed the EZI-PrEP (E-Health for Zero Infections - facilitating access to and use of Pre-Exposure Prophylaxis in the Netherlands) trial. UD, MFSvdL, JW, KY, SB, HMG, JMB, KV, and MLGB were involved in the development of the online pre-exposure prophylaxis care trajectory, smartphone app, administration panel, and website, and organized the implementation of the study. MLGB drafted the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

UD received unrestricted research grants and speaker fees from Gilead Sciences, paid to his institute. MFSvdL participated in Advisory Boards of Merck Sharp & Dohme, for which fees were paid to his institute. MFSvdL received a research grant from GlaxoSmithKline, paid to his institute. EH received unrestricted research grants from Gilead Sciences, paid to her institute. MP received unrestricted research grants and speaker/advisory fees from Gilead Sciences and Merck Sharp & Dohme, all paid to her institute. All other authors declare no competing interest.

Abstract

Background: For adolescents and young adults, a cancer diagnoses can magnify feelings of social isolation at an inherently vulnerable developmental stage. Prior studies have highlighted the importance of peer groups during cancer treatment. Support groups help foster connection and resilience, but patients find in-person participation difficult due to a variety of factors. Additionally, physical changes brought on by cancer makes these patients hesitant to meet in person. The COVID-19 pandemic magnified these difficulties. Virtual reality (VR) allows for the creation of a therapist-curated, computer-generated social space that potentially enables support groups for this population.

Objective: This protocol describes a pilot study examining the efficacy, feasibility, and acceptability of a social VR support group intervention for adolescent and young adult patients with cancer.

Methods: We approached 20 participants aged 17-20 years, and 16 agreed to participate. Moreover, 1 participant dropped out due to hospitalization. Participants attended virtual, professionally facilitated support groups using Meta Quest VR headsets. The groups consisted of 4 participants and 1 facilitator, amounting to a total of 22 individual sessions. Each session lasted 45-60 minutes and took place weekly for 4-6 weeks. The primary aim of this study was to collect quantitative and qualitative data on the feasibility and acceptability of the intervention. Feasibility was measured through session participation rates and overall retention rates. The acceptability of the intervention was explored through brief in-person interviews with participants at the end of the final intervention session. The secondary aim of this study was to collect data on the preliminary efficacy of the intervention in decreasing symptoms of participant depression and anxiety and increasing positive affect and resiliency.

Results: In total, 15 patients aged 17-20 years participated in 22 sessions between November 5, 2019, and July 8, 2021. The median age was 19 (IQR 17-20) years. Overall, 10 (62%) participants identified as male, 5 (31%) as female, and 1 (6%) as transgender female. Furthermore, 5 (31%) participants identified as Hispanic, 1 (6%) identified as non-Hispanic Asian, 3 (19%) identified as non-Hispanic Black, 6 (38%) identified as non-Hispanic White, and 1 (6%) identified as other race or ethnicity. Hematologic malignancies or bone marrow failure was the most common diagnosis (8/16, 50%). The mean attendance rate was 72.8% (SD 25.7%) and retention was 86.7% (SD 0.35%). Moreover, 45% (10/22) of sessions had to be postponed by a week or more due to unexpected participant scheduling issues.

XSL•FO
RenderX

Conclusions: The use of VR to deliver psychosocial support for adolescents and young adults with cancer may reduce common barriers associated with attending in-person peer support groups while improving quality-of-life measures. The data from this study will inform future studies focused on conducting VR support groups in other rare disease populations, including older adults with cancer.

Introduction

Background

Approximately 90,000 adolescents and young adults were diagnosed with cancer in 2020, with around 9000 having lost their lives [1]. In the group of patients aged 15-39 years, a cancer diagnosis brings unique medical and psychosocial needs. Complications of treatment are both medical and psychosocial and include infection, fatigue, hair loss, mouth sores, anxiety, infertility, depression, boredom, and isolation. Feelings of social isolation, depression, and anxiety are magnified in this group as their life experiences violently diverge from those of their peers. Support from caregivers and interactions with adolescents and young adults going through a similar experience improves the quality of life for this population [2].

One of the most requested and effective psychosocial interventions for this population are peer support groups, whether in person or via videoconference [3,4]. These groups give adolescents and young adults with cancer the opportunity to shed the defining attribute of their cancer diagnoses and engage with peers who have had similar experiences while finding true empathy among peers. Despite the clear benefits of these groups and patients' desire to participate in them, personal communications with various adolescents and young adult cancer centers and personal experience in attempting to organize these groups have proven the difficulty of assuring in-person attendance. The reason for this is multifold, including active immunosuppression; prolonged hospitalizations; geographic constraints; and patients' other responsibilities to their schools, families, and jobs. In addition, the inherent physical changes brought on by an adolescents and young adult cancer diagnoses make these patients less willing to meet in person or show themselves on a screen.

Potential Technologic Approaches to Solve the Problem of Poor Adherence

Although support groups have traditionally been conducted through real time face-to-face gatherings, a lack of access due to distance, time, and transportation has long been cited as one of the most prominent barriers to support group participation and adherence [5]. For individuals with long-term health conditions, such as cancer, these barriers are further amplified [6]. The past decade has seen the steady development of virtual support groups that use the communication technology of virtual worlds to overcome the logistical barriers presented by face-to-face meetings [7,8]. In addition to minimizing logistical barriers, virtual support groups offer further affordances including anonymity, which may facilitate disclosure, autonomy, and help-seeking [9], whereby users can control how much they share and with whom. In the case of persistent online worlds including social media, the asynchrony of participation allows individuals to access the service whenever they choose [10]. Although the COVID-19 pandemic propelled mainstream acceptance of videoconferencing software such as Zoom (Zoom Video Communications) as a convenient tool for remote social connection, the use of live videoconferencing for support groups is not well defined in the literature, although initial reports of its use during the pandemic show it has promise as a solution to the logistical barriers to attendance [11].

Social virtual reality (VR) is an emerging technology in which multiple users can interact with one another in a shared, immersive 3D virtual environment [12]. Compared to other forms of virtual interaction that mainly support screen-mediated communication (including videoconferencing, social media, and persistent online social worlds), social VR is characterized by full-body tracked avatars. These avatars enable real-time embodied interaction that is similar to face-to-face communication in that it includes verbal *and* nonverbal interactions such as voice, gestures, proxemics, gaze, and facial expression [13]. The opportunity for embodied and immersive experiences mediated through VR technology has the potential to replicate people's everyday activities and is likely to play a role in forming and maintaining interpersonal relationships. Given that VR can be used from the convenience of one's own home, or even their hospital bed, support groups offered through social VR settings overcome logistical barriers of physical distance and immunosuppression while still maintaining much of the nuance of nonverbal communication and physicality that are seen as hallmarks of in-person support.

Previous VR Studies in Adolescents and Young Adults, Cancer, and Telemedicine

Multiple studies have demonstrated the benefits and viability of using VR as an intervention in the pediatric and adolescent and young adult health care setting. In a group of pediatric patients with cancer aged 10-17 years undergoing chemotherapy, it was found that patients' self-reported symptom distress immediately after chemotherapy was significantly lower when they used VR with 1 of 3 distractive experiences (CD ROM-based scenarios: Magic Carpet, Sherlock Holmes Mystery, and Seventh Guest viewed via a head-mounted display) as compared to a session during which they did not use VR [14].

XSL•FO
RenderX

Another adolescent cancer group showed equally promising effects on pain and discomfort using a VR experience during lumbar puncture in the form of a distracting video viewed via a head-mounted display [15]. In a group of pediatric patients using distractive VR while undergoing chronic wound care, pain and anxiety as measured by patients, caregivers, and nurses was significantly lower during and after dressing changes in the VR group versus the group receiving standard distractions; additionally, the time to complete each dressing change was significantly less in the VR group. The distractive VR came in the form of the Ice Age 2: The Meltdown game. In the game, players control "Sid the Sloth," who slides down a snowy path while trying to collect acorns and avoid obstacles [16].

Prior studies in adolescents and young adults have illustrated the utility of group-based interventions in this particular age demographic. For example, in a group of 15 adolescents and young adults with type 1 diabetes, hemoglobin A_{1C} improved after participation in peer support groups with a psychologist [17]. More significantly, in the Adolescents and Young Adult Health Outcomes and Patient Experiences study [18], adolescents and young adults with cancer who did not receive, but reported needing support groups, were about 4 and 13 times as likely to report needs for talking about their cancer experience with family and friends and meeting peer survivors, respectively.

Given the proven viability, benefits, and safety of VR in the health care setting, as well as the importance of support groups in the adolescent and young adult population, the combination of these 2 interventions may provide increased psychosocial support for adolescents and young adults with a recent cancer diagnosis.

Commercially Available Social VR Platforms

Over the past 5 years, social VR apps such as VR Chat, AltspaceVR, Horizon Worlds, and Rec Room have emerged as a few exemplars of social VR platforms where people meet, interact, and socialize in new and more immersive ways using a head-mounted display and hand-tracking hardware. Many social VR platforms can be characterized by customizable avatars and persistent virtual worlds, with some platforms emphasizing opportunities for world customization while others favor social gaming or large-scale events such as concerts. Most platforms provide users with an opportunity to create private rooms or environments that only designated "friends" can access, as well as public worlds or spaces where anyone can interact. These platforms continue to attract more users and improve both in interaction quality, features, and ease of use, with many futurists predicting that VR social interaction will become the next major technological evolution for computer-mediated human communication. Indeed, the social VR market is expected to grow at a 14.1% compound annual growth rate between 2021 and 2027 [19].

While many commercially available social VR apps do exist, this project required a specific platform that was (1) Health Insurance Portability and Accountability Act (HIPAA) compliant, (2) easy to use, (3) contained minimal distractions within the experience, (4) used high-quality spatial audio, and (5) facilitated the expression of subtle body language through player avatars. For this study, we used the Foretell Realities platform, as described within the *Methods* section of this paper.

Study Aims

The primary aim of this study is to evaluate the feasibility and acceptability of a VR intervention to facilitate support groups for adolescents and young adults with cancer. Intervention feasibility is examined through the number of sessions completed by participants and participant retentions rates at the end of this study. The acceptability of the intervention will be examined through participant interviews conducted at the end of the last VR session and solicited feedback at the end of each individual session.

We hypothesize that our intervention will be feasible as measured by overall participation rates of >50% and retention rates of >50%. These numbers were chosen in the context of historical data showing adolescent and young adult patient participation in clinical trials to fall at less than 20% [20,21] and only 41% of Americans with mental health disorders initiating treatment services, with just 33% engaging in enough services for them to be deemed adequate [22]. Our secondary aim is to collect data on the preliminary impact of the intervention on participants' depression, anxiety, positive affect, and resilience skills. We hypothesize that participants will report a significant decrease in symptoms of depression and anxiety and an increase in positive affect and resiliency skills as measured by standardized patient report instruments from baseline to immediately after intervention. The results of this aim are beyond the scope of this paper and are currently being reviewed for submission of a subsequent mixed methods analysis.

Methods

Ethical Considerations

Formal evaluation and adoption of novel human interventions at major institutes include the need for proper and thoughtful assessment by first, a Protocol Review Committee (PRC) to ensure appropriate scientific rigor and then, an institutional review board (IRB) to ensure participant safety. The formal goal of the PRC is to ensure "assessment of the scientific rationale and merit of a proposed study in addition to protocol design, safety parameters, and biostatistical analysis to determine that high quality and appropriate designs have been incorporated" [23]. In the case of this study, the PRC of review was that of Yale Cancer Center, which consists of voting members from various scientific and epidemiologic disciplines. All procedures were approved first by the PRC and then by the Yale University IRB (ID#2000023701). The participants did not receive any compensation.

Data Collection

The following personal identifying and medical information were collected: email address, phone number, diagnoses, diagnoses date, end of treatment date (if relevant), treatment modalities, gender identity, race and ethnicity, and insurance status. All data collected from the assessments were entered by participants directly into the secure web-based system, Qualtrics (Qualtrics International Inc), which is Yale's enterprise-wide

XSL•FO
RenderX

data management system or directly onto deidentified paper questionnaires, depending on participant choice. This ensured participant confidence that their data would remain confidential. Written consent was obtained via signature from all the participants before their participation, as detailed in the *Study Population and Study Flow* section.

The confidentiality of assessment data was assured by assigning a unique identifier to each participant once they registered for this study. A document linking this study's identifiers to the patient's name was maintained by the principal investigator (PI) and was destroyed upon the completion of data collection. All computer data were password protected and all nondigital data (including consent forms) were stored in locked cabinets.

Study Design

This pilot study uses a pre-post design to evaluate the feasibility, acceptability, and preliminary efficacy of a social VR support group intervention for adolescent and young adult patients with cancer. The team was led by a team with expertise in adolescent and young adult cancer, onco-psychology, social VR, adolescent development, and clinical trial design and evaluation.

Study Population and Study Flow

Recruitment

Candidates for this study were identified through the Yale University School of Medicine's Pediatric Hematology and Oncology Department and adolescent and young adult clinic. The Director of the adolescent and young adult clinic is the PI and one of the treating oncologists at Yale New Haven Hospital who has firsthand knowledge of the potential participants, participants' medical and psychiatric histories, and social situations. The PI consulted with the candidate's primary treating oncologist, other health care providers, and their psychosocial team to assist in determining if a participant was an appropriate candidate for this study. Candidates were considered eligible to participate if they met the following criteria: (1) between 13 and 30 years of age, (2) actively receiving treatment for cancer or completed treatment for no more than 1 year prior to enrollment, (3) English speaking, and (4) able to don a head-mounted display. Exclusion criteria included (1) not English speaking; (2) the lack of reliable access to the internet; and (3) patients who are prone to motion sickness or are experiencing nausea, vomiting, seizures, or other health problems that the medical team deem them unstable to participate. If all inclusion criteria were met and no exclusion criteria were noted, the PI approached the family or patient for study participation.

If a participant was of age to sign the consent form, consent was obtained directly from the participant. In the case of participants under 18 years of age, youth's assent was obtained along with legal guardian permission from the participant's legal guardian. If permission could not be obtained from the patient or their parent or legal guardian, the participant was not enrolled. Consent (or assent and permission) were sought after the research protocol and the risks of participation in this study were fully explained. All participants and participants' families were encouraged to read the appropriate forms and ask questions about any aspect of this study that was not clear. Participants were reminded that they could withdraw from this study at any time if desired and that the decision to not participate would have no impact on their care or relationship with the physicians or investigators.

Assessments

To evaluate the preliminary impact of this study, we collected assessment data at 2 time points: prior to the beginning of the first VR group session (baseline) and immediately after the final session.

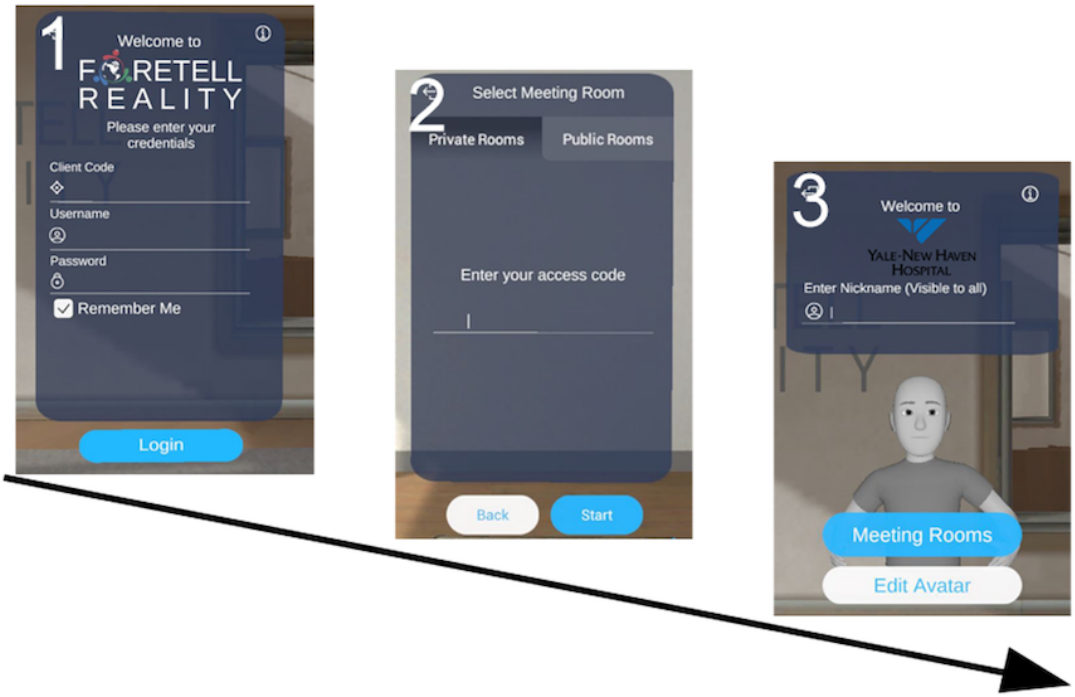
To assess participants' depression, anxiety, and positive affect, we used PROMIS (Patient-Reported Outcomes Measurement Information System) questionnaires. The pediatric PROMIS short forms (version 1.0; Depressive Symptoms 8a July 28, 2016 [8 questions]; Anxiety 8a July 27, 2016 [8 questions]; and Positive Affect 8a July 14, 2016 [8 questions]) were used for participants 17 years of age and younger while the adult short forms (Depression 8a June 26, 2016 [8 questions]; Anxiety 8a June 2, 2016 [8 questions]; and Positive Affect 15a July 18, 2017 [8 questions]) were used for participants 18 years of age or older [24-26]. These surveys have been validated in pediatric and adolescent patients with cancer as well as in children and adolescents in other health care settings [24,27].

To assess resilience, we used the Connor-Davidson Resilience Scale (25 questions), which has been validated in multiple settings, including in young adults and in the outpatient psychiatric context [28,29].

Brief In-Person Interviews

We conducted brief in-person interviews with participants at the end of the final VR group session to explore participants' perceptions of the acceptability of the intervention. Participants were also encouraged to write out their responses to the open-ended questions after the interview if they had additional thoughts or comments that they would like to contribute (see Textbox 1). Responses were recorded as field notes by the group moderator in a secured Microsoft Word document.

Textbox 1. Open-ended questions for in-person interviews.



- Did you experience any physical or emotional discomfort during the virtual reality (VR) session – specifically, nausea or anxiety?
- Is there anything you would drastically change about the virtual environment in which we met – for example: colors, virtual items, or general surroundings?
- Do you feel there were any distractions preventing you from fully participating in the session?
- Would you like to see more opportunities to interact with each other, for example, through games or the ability to share digital media (photos, music, etc.)?
- Is there anything else you would like to share about the experience you just had?

XSL•FO
RenderX

Description of Intervention

Foretell Reality is a social VR platform that leverages VR technologies to bring people together for meaningful interaction in a virtual space. After a simple and secure sign-in process, invitees share the same immersive environment, as depicted in Figure 1. Participation can occur from anywhere in the world with an internet connection. The environment used in our intervention is that of a therapeutic space with participants seated in a circle (Figure 1). Though not tested as part of our pilot, optional activities directed by facilitators such as simple games (eg, "catch the ball"), drawing in 3 dimensions, joint viewing of 360 videos and pictures, presentation of documents, meditation, and physical exercise (eg, stretching or chair yoga) are available [30]

Figure 1. Sign-in process and example of the immersive therapeutic space.

Seated in a circle, users feel a sense of social presence in VR. This is achieved through the tracked body movements and hand gestures of users' customized 3D avatars, as well as spatial audio communications. Users can mask their voices and choose nicknames that allow for complete anonymity, which can help remove barriers to vulnerability. The platform is HIPAA

XSL•FO
RenderX

compliant, does not store any identifiable personal information, is protected by individual login usernames and passwords, and requires special access codes to enter private meetings.

Working with Foretell Reality allowed us full control and customization of the features we chose to include in our support groups and provided us close support and training for our professional personnel and patients. For example, to ensure a calming and familiar environment where patients could focus on the session at hand, a room was created to resemble the Adolescents and Young Adults Lounge at Yale New Haven Hospital with minimal distractions. We specifically requested that features such as the ability to pass a ball around the room and move away from the seated area were turned off. Limiting movement around the room ensured a low likelihood of introducing experiences that could result in motion sickness.

Study Procedure

Participants enrolled in this study were assigned to a support group on a first come first serve basis, assuming they met enrollment criteria. Groups were run one at a time with subsequent groups only enrolling after the previous group completed all sessions. Upon enrollment, patients were briefly oriented to the headset and software and given their sign in information.

During a support group session, 4 adolescent and young adult patients with cancer used the Meta Quest 1 (Meta Platforms, Inc; previously Oculus Quest 1) VR headset—a portable, low cost (US $300 manufacturer's suggested retail price) piece of hardware running Foretell Studios (Foretell Studios) software—to participate in 6 virtual, professionally facilitated support groups. Participants received brief training on hardware and software use when the hardware was initially distributed prior to the start of the support groups. Participants also received a brief operating manual. The rules of engagement (Textbox 2) were reviewed with each participant prior to their enrollment.

Textbox 2. Rules of engagement.

- Share only what you feel comfortable sharing.
- What is discussed in group, stays in group (unless there are concerns about safety).
- Be respectful/everyone should have an opportunity to share/speak.

Each support group session included 4 patients, a facilitator, and a research assistant (or the PI). The patients and facilitator were represented by a customized avatar, each with a chosen name displayed floating above their head. The research assistant or PI did not have a visible avatar, but participants were made aware that study personnel were potentially observing each session via VR headset or desktop computer. Participants were informed that the VR headsets could be used in the patients' homes, inpatient hospital room, or any other space that had an active Wi-Fi signal and was convenient, private, and desirable for the patient. The 4 participants in each group were curated by the facilitator of the group in order to ensure the grouping of appropriate ages and development levels. In total, 4 separate groups of 4 participants each were assembled for a total of 16 participants and a goal of 22 individual support group sessions (the number of sessions was increased from 4 to 6 after string feedback from group 1). Each session lasted 45-60 minutes and was scheduled with a goal of occurring once weekly for 6 weeks. Sessions were postponed if fewer than 2 participants were available to participate during any 1 scheduled session.

Support groups were facilitated by an appropriately credentialed and trained clinical psychologist, psychiatrist, or social worker or their trained designees who reviewed the "Rules of engagement" (Textbox 2) prior to each session.

Once a group completed their last session, headset disinfection was done following methods of those described in a paper published by Roberts et al [31] using isopropyl alcohol wipes on all high-touch surfaces.

Safety

With the introduction of any new technology, it is important to consider all possible malfunctions and emergent scenarios. All participants were given 2 phone numbers at the beginning of each session: the direct phone number to the facilitator and the direct phone number to the observing or on-call research assistant or PI. Additionally, the facilitator had an emergency phone number for each participant, as well as the physical location from which the participant was participating. While the hardware and software being used in this trial has been extensively tested and is commercially available, we developed troubleshooting and emergency intervention (Multimedia Appendix 1) protocols that were given to all participants. The greatest concern that we felt had to be addressed was that in an immersive, remote setting where patients are addressing topics with significant risk of inducing posttraumatic stress disorder, depression, and anxiety, it was important that they could find support immediately and at any time. In addition, given the new technologies we were dealing with, it was important that tech support was also available at any point during the session.

Statistical Analysis

Quantitative Analysis

Descriptive statistics were obtained for each of the categorical variables pertaining to participant characteristics, including age, type of cancer diagnosis, documented gender identity within the electronic medical record (EMR), documented race and ethnicity within the EMR, and documented insurance status within the EMR. Attendance data were collected for each of the participants within each support group to evaluate attendance rates. Participants' scores for the Connor-Davidson Resilience Scale and each of the PROMIS domains (positive affect, anxiety,

XSL•FO
RenderX

and depression) before and after the support group will be compared using a 2-tailed *t* test with 95% CI. All statistical analyses will be completed using Stata (version 16.0; StataCorp).

Qualitative Analysis

Participant responses of the open-ended questions during the brief in-person interviews were recorded as field notes by the research coordinator and organized in a secure Word document. Using a grounded theory approach [32], we will use the rigorous and accelerated data reduction (RADaR) technique [33], which is used to organize, reduce, and analyze qualitative data. The RADaR technique is a rigorous, systematic approach to qualitative analysis that provides an expedited and user-friendly way of organizing, reducing, coding, and analyzing qualitative data. The RADaR technique is often used to manage smaller pilot projects that use grounded theory [27].

Results

Enrollment

Between November 5, 2019, and July 8, 2021, a total of 20 participants aged 17-20 years were approached to be a part of this study, and 16 agreed to participate. Reasons cited for not agreeing to participate included the lack of time and lack of interest. No patients expressed concerns around using the VR headset itself.

The enrollment of group 1 was completed in November 2019, in February 2020 for group 2, in August 2020 for group 3, and in May 2021 for group 4. Of note, groups 3 and 4 were enrolled amid the COVID-19 pandemic, and group 2 was recruited just before and subsequently ran during the pandemic. This resulted in prolonged times between group enrollments due to risks of COVID-19 being spread by unnecessarily returning to clinic for study consents, orientation, and headset exchange.

Sample Demographics

The patients who enrolled had a median age of 19 (IQR 17-20) years. Overall, 62% (n=10) were male and 31% (n=5) were female, with 1 (6%) patient who identified as transgender female. In total, 5 (31%) participants identified as Hispanic, 1 (6%) identified as non-Hispanic Asian, 3 (19%) identified as non-Hispanic Black, 6 (38%) participants identified as non-Hispanic White, and 1 (6%) identified as other, as described in Table 1.

Table 1. Participant demographics and characteristics (n=16).

Characteristics	Value
Age (years), median (IQR)	19 (17-20)
Documented gender identity in EMR[a], n (%)	
Male	10 (62)
Female	5 (31)
Transgender female	1 (6)
Documented race and ethnicity in EMR, n (%)	
Hispanic (all races)	5 (31)
Non-Hispanic Asian	1 (6)
Non-Hispanic Black	3 (19)
Non-Hispanic White	6 (38)
Other	1 (6.)
Documented insurance status in EMR, n (%)	
Medicaid	7 (44)
Private	9 (56)
Type of cancer or disorder, n (%)	
Hematologic malignancies or bone marrow failure	8 (50)
Solid tumor	6 (38)
Central nervous system tumor	2 (12)

[a]EMR: electronic medical record.

Participation rates for each of the groups are shown below in Table 2. Group 1 was only scheduled for 4 total sessions, and future groups were increased to 6 sessions due to overwhelming requests from the first group to increase the total number of sessions. Of note, 1 of the participants in group 2 (g2p2) had a lengthy hospitalization shortly after they consented to this study. Given the inability of the hospital internet bandwidth or hot spot to support the system, they were unable to participate in any of the sessions—this hurdle was later remedied with a long-term evolution hot spot. Additionally, part of group 2's and all of group 3's and group 4's sessions occurred during the COVID-19 pandemic. Further, 45% (10/22) of sessions needed to be postponed by a week or more, but only 18% (4/22) by more than 2 weeks.

RenderX

Defining retention as attending any of the first 3 sessions in combination with any of the last 3 sessions, all but 2 patients met the criteria (g3p2 and g4p4) for a retention rate of 86.7% (SD 0.35%). Patients g3p2 and g4p4 described scheduling issues and the lack of interest as reasons for attrition.

Table 2. Participation rates.

Group and participant ID	Sessions attended, n (%)
Group 1 (n=4 sessions)	
g1p1	4 (100)
g1p2	3 (75)
g1p3	4 (100)
g1p4	4 (100)
Group 2 (n=6 sessions)	
g2p1	5 (83)
g2p3	3 (50)
g2p4	5 (83)
Group 3 (n=6 sessions)	
g3p1	4 (67)
g3p2	1 (17)
g3p3	5 (83)
g3p4	6 (100)
Group 4 (n=6 sessions)	
g4p1	4 (67)
g4p2	5 (83)
g4p3	3 (50)
g4p4	2 (33)

Discussion

Principal Findings

This protocol review describes the implementation of social VR support groups for a rare disease population with substantial participation (72.8%, SD 25.7%) and retention rates (86.7%, SD 0.35%). These rates compare favorably to historical data describing outpatient mental health attrition rates ranging widely with a range of 25% to 75% in children and adolescents [34]. Prior to the launch of our VR-based approach, and despite expressing a desire to participate in support groups, our adolescent and young adult cancer social worker was unable to convince any significant number of patients to return to the hospital for in-person groups. With the VR group option, however, we had a generally successful experience with manageable hurdles to implementation. No sessions needed to be canceled due to purely technical issues. We had no patients refuse to participate due to consent concerns and enthusiastic patients and families expressed a desire for expanded groups to include more sessions as well as requests for opportunities for caregivers to participate in their own groups.

The process of protocol development and review, however, have revealed an academic and health care system unprepared for the incoming wave of digital health interventions and subsequent implementation. PRCs and IRBs are designed to be led by experts and laypersons versed in the proposed interventions and familiar with the expected timelines and processes required for a smooth launch. These committees are required and helpful check points prior to the launch of any clinical trial at the Yale Center for Clinical Investigation. As this trial involved cancer patients with cancer, these committees have had substantial experience reviewing, recommending amendments to, and launching clinical trials involving early and late phase pharmaceutical trials. A supportive care trial involving cutting edge digital technologies requires an entirely different set of experience and skills. As a result, approval for what is a relatively benign intervention took more than 9 months, multiple protocol revisions, expansion, and the need to incorporate multiple outside entities including technology and psychologic experts to ensure scientific merit and safety. Due to this experience, we recommend an ad hoc digital health subcommittee be put in place at institutes interested in pursuing such digital interventions.

At a minimum, we propose that a digital health intervention protocol review and human protection committee would incorporate the expertise of digital privacy experts, software or hardware developers, and psychologists versed in the effects of immersive reality. To expedite a review, this committee would act as a first line, prior to submission to the PRC and subsequently the IRB. Given the inherent risks of health data (including biometric data) collection during the use of digital

XSL•FO
RenderX

interventions, the committee would ensure appropriate security protocols are in place to ensure HIPAA compliance. With the increasing disconnects in the speed between technologic advancement and academic processes, they would additionally ensure that the technologies being studied are the most up to date and not soon to be outdated. Finally, this committee would be cognizant of the significant potential psychologic effects of immersive technologies and be prepared to address them.

Additional institutional barriers experienced included in-hospital networking protocols that limited the use of certain security approaches used by Foretell's software. Subsequently, the hospital wireless network was not a viable solution. Fortunately, we were able to secure a reliable (long-term evolution) connection via mobile hot spot router, which was used for connection when study participants were in the hospital.

These barriers revealed challenges that may arise in attempting to implement similar interventions in more rural areas and counties other than the United States. While network speed demands are not high (we found no difficulty running sessions with upload and download speeds in the 10-30 Mbps range), reliability and stability are important. We anticipate that other high-income countries with a robust and reliable internet infrastructure should be successful in similar approaches. The expansion of this study will be looking specifically at non–English-speaking populations, rural populations, and populations defined as low socioeconomic status.

A noted limitation to this study is that participants were told that they may be observed by a team member other than the facilitator (PI or research assistant) during their sessions. This may have influenced how a participant behaved or what was said during a session. To mitigate this concern, observers were made invisible during the sessions and there was no indication of whether the observer was present or not. Given that the social worker themselves was present, visible, and participating in avatar form in every session, we suspect that any bias that may have been introduced by knowing an additional observer may be there was likely mitigated.

A final barrier to safe implementation of the above protocol was safe disinfection of the headsets themselves. This study coincided with the COVID-19 pandemic, so finding a safe way to continue offering support groups was essential. Concurrent with this project, we conducted an examination of VR equipment disinfection protocols, the results of which appear in the *Journal of Medical Internet Research* [31]. Despite initial excitement over ultraviolet disinfection, isopropyl alcohol or quaternary ammonium products were ultimately found to be most effective. Future studies should examine best uses and methodologies for an ultraviolet disinfection approach.

Conclusions

Here we have presented an in-depth review of the creation and implementation of a novel, social VR-based intervention for an underserved, rare disease group. We have demonstrated feasibility through participation and retention and described pain points in implementation including the need for appropriate review committees, intrahospital network infrastructure, and disinfection needs.

These results and experiences have given us confidence to expand the trial to additional centers throughout the United States. The greater number of patients in more diverse populations with cancer will allow us to better assess feasibility in non–English-speaking populations, rural populations, and populations with low socioeconomic status. The expanded numbers will also offer greater power to identify effects on fear, anxiety, depression, resilience, and feelings of connectedness. In addition, we have started groups with the Yale Gender clinic, enrolling transgender and gender-diverse patients to examine the intervention's effects on such measures as gender dysphoria, psychological flexibility, and self-esteem.

As immersive technologies and opportunities for innovative telehealth models emerge, it will be important to find their appropriate places within the clinical landscape. Populations with rare diseases seeking peer-based social support appear to be a viable and enthusiastic group with which to start.
