DCEs offer an efficient means of assessing preferences and priorities for intervention-related attributes [50], which can guide intervention design and packaging to encourage uptake, engagement, and maintenance among the intended users. DCE participants are shown a series of choice sets juxtaposing ≥2 different hypothetical scenarios. Each scenario comprises intervention attributes, further defined by a number of levels, which are randomly combined to create hypothetical intervention alternatives. Participants are asked to choose the single preferred alternative for each choice set presented, recognizing the trade-offs between the desirable or undesirable characteristics of each. Through repetition of this process over several choice sets representing many possible combinations of attribute variations, investigators can identify which attributes and attribute levels participants value the most. Latent class multinomial logit regression is used to estimate utilities, which are measures of preference for levels within attributes. Positive utility values indicate greater preference.

DCE Survey Design

The aforementioned focus groups informed the team's selection of four attributes: (1) type of ART, (2) service location or mode, (3) adherence support, and (4) rewards. The latter 3 were alternative-specific attributes defined according to the type of ART (daily oral or LAI). Focusing on 3 implementation outcomes identified by Proctor et al [51] as salient during the adoption phase of an innovation-decision process, we also included the brief (4-item) *acceptability of intervention measure*

(AIM) on the provider and patient survey and the *intervention appropriateness measure* (IAM) and the *feasibility of intervention measure* (FIM) on the provider survey [52]. Contextual items at the end of the patient survey covered prior awareness of LAI ART and any experience with LAI ART, and contextual items at the end of the provider survey covered the length of time delivering MCM and vignettes about hypothetical patients as potential candidates for LAI ART.

Survey Recruitment

Eligibility for the patient DCE survey required being aged ≥18 years and enrolled in RWPA MCM services at any of the 6 partnering agencies. As with the focus groups, contact attempts for patient recruitment were conducted through MCM program staff at the partnering agencies. Eligibility for the provider DCE survey required having an RWPA MCM care team job role (ie, case manager or care coordinator, patient navigator or community health worker, program administrator with duties beyond clerical or data support, or prescribing provider). Given the target of 200 participants per survey (patient or provider) and the availability of fewer than 50 eligible providers at the 6 partner agencies, all 29 RWPA MCM programs were engaged for the provider survey. We offered the provider survey in English and the patient survey in English, Spanish, and Haitian Creole.

Patient Survey Participants and Preliminary Results

From June 2022 through January 2023, 201 NY RWPA MCM patients with a median age of 54 years (IQR 42-62) and a median MCM enrollment of 31 months (IQR 11-45) completed the DCE. Most patients (183/201, 91%) were Black or Latinx, and 39.3% (79/201) identified as women. Three-quarters (151/201, 75.1%) self-reported perfect adherence to daily oral ART. A two-group latent class analysis identified a smaller subset of patients with a strong preference for daily oral ART and a larger subset preferring LAI ART. Both groups preferred higher value monetary incentives and transportation to primary care or injection appointments over other rewards or supports for adherence. At the time of the survey, 85.6% (172/201) of the participants reported taking daily oral ART. About half of the participants (104/201) indicated that they had heard of LAI ART before taking the survey, but only 4.5% (9/201) reported having tried it.

Provider Survey Participants

From July 2022 through January 2023, 177 NY RWPA MCM staff members completed the DCE. Most provider participants identified as women (127/177, 71.8%), were aged 40 to 59 years (92/177, 52%), and had been providing RWPA MCM services for >2 years (124/177, 70.1%). The largest racial or ethnic group among the participating staff was Latinx or Hispanic (73/177, 41.2%), followed by non-Hispanic Black or African American (50/177, 28.2%), and non-Hispanic White (32/177, 18.1%). The most frequent job types were patient navigator (68/177, 38.4%), case manager or care coordinator (46/177, 26%), program director (33/177, 18.6%), and prescribing provider (21/177, 11.9%). As of the end of 2023, data from the provider DCE survey were in the early analysis stage.

Advisory Board

After receiving notice of the grant award (April 2021), the study team convened an AB for input in July 2021; February, May, and November 2022; and January, April, and August 2023. AB members, who consult on study tools, implementation, results interpretation, and dissemination, include clinical and nonclinical direct-service providers and administrators (from all 6 partnering provider agencies and a seventh interested MCM agency); Health Department staff; external researchers; and members of the HIV Health and Human Services Planning Council of NY (RWPA community planning body). In the January and April 2023 meetings, AB members provided critical input on the tools for inclusion in the pilot, including feedback on the content and visual design of draft versions.

Pilot Testing of ART Regimen Decision-Making Supports

Selection and Design of Tools to Be Piloted

The third aim and phase of this study has focused on the synthesis and application of findings from aims 1 and 2 to develop LAI ART implementation tools and pilot test them with partnering agencies while gathering data to inform tool refinement for future research and scale-up. Tools were developed in consultation with the MCM program staff and other AB members familiar with MCM service settings, MCM patient needs, or decision-support processes. The selection and design of tools for the pilot study were guided by a combination of focus group findings, AB input, and preliminary patient DCE results. In addition to indirectly informing tool development by highlighting the attributes for inclusion in the DCEs, focus group findings and AB input directly influenced the study team's decision to develop patient-facing educational materials. The latter decision stemmed from the focus group participants' emphasis on the need for clearer messaging about LAI ART and AB members' requests for materials that could be reviewed by patients on their own. AB members called attention to a general lack of patient-facing materials about LAI ART beyond the drug manufacturer's consumer-directed materials, which partnering program staff viewed as unrelatable for many of their patients. Finally, the AB advocated for including a patient-facing video to present and compare ART regimen options in an engaging and entertaining medium while minimizing the time required during MCM visits for ART regimen-related education and decision-making processes.

The limited familiarity of patient DCE participants with LAI ART reinforced the need for clear, patient-facing educational materials describing LAI ART and directly comparing it with daily oral ART. Divergent patient preferences for daily oral versus LAI ART suggested a difference in perception between LAI ART phase 3 clinical trial participants and patients seen in our safety-net MCM program settings, which may reflect some of the patient-level factors limiting LAI ART uptake in practice. The mixed reception of LAI ART in the DCE reinforced the potential value of a decision-support tool to assist patients in weighing the advantages and disadvantages of available regimen types and assessing the fit of each option with their individual preferences, needs, challenges, and strengths as well as considering programmatic resources (such as transportation)

that could reduce perceived barriers to treatment success. The study team developed a patient-provider ART regimen decision aid using the Ottawa Decision Support Framework [53] and tailored the tool to suit the RWPA MCM program context, the focus on ART regimen decisions, and the AB's emphasis on brevity and accessibility.

Pilot Trial Design

Primary data collection for the pilot has entailed brief provider surveys and semistructured provider interviews drawing upon the CFIR to assess factors (barriers and facilitators) for pilot tool implementation. In addition, we intend to use the provider interviews and program reporting on pilot enrollment and service delivery to evaluate pilot implementation outcomes, drawing upon RE-AIM measures: reach (types and numbers of patients enrolled), effectiveness (preliminary effects on LAI ART uptake and concordance between treatment plan pursued and patient choice as recorded on the decision aid), adoption (documentation of specific tools' use), implementation (alignment of reported tool use with study condition and guidance on tool use), and maintenance (ART adherence). This pilot study was designed as a nonrandomized, 2-arm trial of newly developed tools with ≥180 RWPA MCM patients. It was structured to allow comparison of an intervention arm including both patient education materials and the decision aid (*decision-aid arm*) with an intervention arm including only the patient education materials and usual care approaches (whatever agencies may already be doing) for ART regimen decision-making (*education-only arm*).

Study Setting and Participants

The pilot test was conducted at the 6 partnering RWPA MCM agencies. The characteristics and study arm assignments of the 6 agencies are summarized in Multimedia Appendix 1. Cluster (agency-level) assignment was used for this study to minimize crossover between intervention conditions and avert the logistical and ethical dilemmas posed by assignment strategies that require providers to administer, maintain, and track different investigator-assigned intervention conditions within a single patient caseload [54-56]. *Provider eligibility:* Pilot-related primary data collection was limited to English-speaking adults responsible for overseeing or delivering RWPA MCM services or prescribing ART for MCM patients at a partnering agency. At each agency, 1 administrative staff member (eg, program director) and 1 direct-service provider (eg, case manager, patient navigator, or prescriber) was engaged to participate in implementation-related data collection through brief surveys and semistructured interviews. *Patient eligibility:* Patients were enrolled in a partnering NY RWPA MCM program, aged ≥18 years, and able to understand materials in English or Spanish. Patient eligibility for an LAI ART prescription could not be directly assessed by the study team and could be assessed differently by different providers or third-party payers; it could also change over time with FDA label indications. However, the study team communicated to partnering programs that patients should not be included in the pilot if they had known or suspected resistance to cabotegravir or rilpivirine, as this was a contraindication for LAI ART available as of the start of this pilot study (CABENUVA). On the basis of AB feedback that translating pilot materials to Spanish without translating to Haitian Creole would be viewed as inequitable, and given a lack of remaining time or resources to provide translations for tools (including audio for the video) in 3 languages, the pilot study was launched with only English-language tool versions.

Intervention Conditions

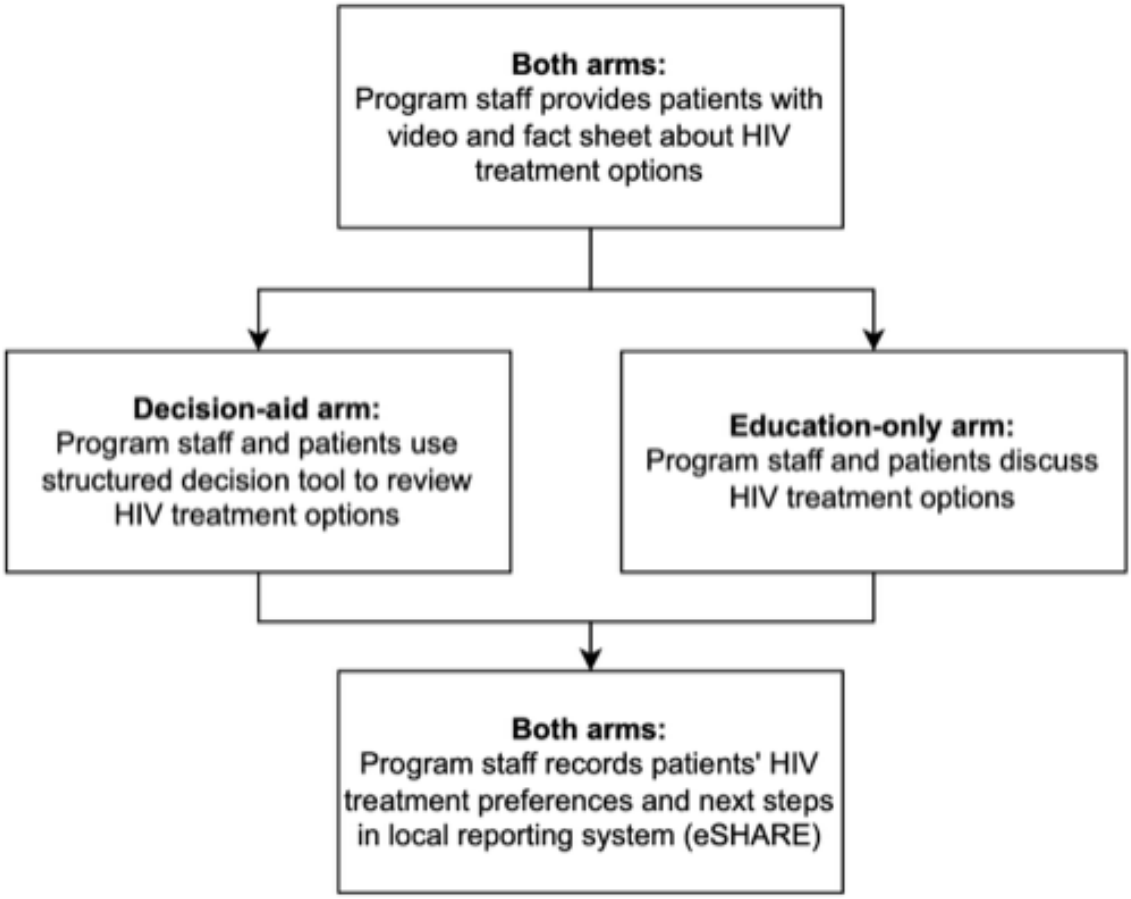
Education-Only Arm

Participants received informational materials (including a fact sheet covering *frequently asked questions* [Multimedia Appendix 2] and a short video [Multimedia Appendix 3]) on their HIV treatment options and related support service options. These materials provide a comparison of the risks and benefits of LAI and oral ART regimens, set expectations about clinic visits, present information about side effects, and include additional resources to assist patients in preparing to discuss HIV treatment and support options with their care coordinator and prescribing provider. All materials are at or below an eighth-grade reading level, use graphics to bolster understanding for different levels of health literacy, and follow accessibility guidelines for font choice and size. Participants receiving this intervention were offered these materials by a care coordinator or patient navigator and were encouraged to review the materials on their own; they could also go over the materials with staff during an MCM program visit.

Decision-Aid Arm

Before or during an MCM visit, participants received informational materials (described in *Education-Only Arm* section) on HIV treatment types and related support service options. During an MCM visit, the participant and patient navigator or care coordinator reviewed the shared decision aid (Multimedia Appendix 4) to weigh the participant's treatment options and their fit to the participant's interests, needs, assets, and constraints. The tool facilitates and records patient-provider agreement on a treatment plan to be integrated into the broader MCM care plan signed by both the patient and provider. Figure 1 illustrates the 2 intervention conditions and the workflow for each.

Figure 1. Intervention arms and workflows for the 2-arm pilot trial. eSHARE: Electronic System for HIV/AIDS Research and Evaluation.



Nonrandom Assignment

We used purposive sampling to assign 3 of the 6 partnering RWPA MCM agencies to the decision-aid arm (which included the educational tools) and 3 to the education-only arm. Specifically, we ensured representation of at least 2 different agency types and MCM program sizes in each arm.

Blinding

Owing to the need to engage service providers in the intervention through study team–led activities (eg, orientation to the project-specific educational materials or the decision aid), study arm assignments were transparent to agency staff and study team members (though not to patients).

Data Collection and Management

Aim 3 (pilot testing) involved repeated primary data collection with 2 providers at each of the 6 partnering agencies and use of secondary data on pilot participants, service delivery, and outcomes. In aim 3 pilot interviews with the implementing providers, oral informed consent was obtained in advance of the interview session by phone or videoconference. The interviews were audio-recorded and transcribed for coding in Dedoose. Aim 3 provider survey data were collected and managed using the NYC Health Department REDCap (Research Electronic Data Capture; Vanderbilt University) server, a web-based application for designing and managing surveys. The REDCap survey data will be analyzed using R (version 4.3.2; R Foundation for Statistical Computing).

Patient data for the pilot are being drawn from the local RWPA data system, the Electronic System for HIV/AIDS Research and Evaluation (eSHARE), in the form of provider-reported enrollments, services, patient characteristics, assessed needs, regimen types, and adherence data required for fee-for-service reimbursement in NY RWPA MCM contracts. eSHARE has been updated by the NYC Health Department to include pilot tools so that partnering MCM agencies could enter pilot activities along with (and as distinct from) other MCM services. No patients were enrolled in the RWPA MCM programs solely for the pilot; rather, patients already enrolled in MCM could be eligible to receive pilot-related services (ART regimen-related information and decision support with the tools developed for the project), along with the array of other MCM services. All patient- and service-level data are protected according to the Centers for Disease Control and Prevention's physical and electronic data security and confidentiality policies [57]. Health Department staff extract and clean eSHARE data monthly, clean and freeze surveillance data sets quarterly, and conduct matches of the program to surveillance data semiannually. The deterministic matching algorithm has been described previously [58]. Through matching with surveillance data, patients are assigned a unique record number used to deduplicate data sets, which are stripped of personal identifiers before analysis.

Study Outcomes

LAI Uptake (Primary Outcome)

The primary outcome is defined as the proportion of pilot participants who start LAI ART (whether initiating ART, transitioning from a prior regimen, or transitioning from a period of nonuse of ART). The denominator includes patients not already on LAI ART at the start of the pilot trial, and the numerator includes any of those in the denominator who began LAI ART during the trial. Using program-reported (eSHARE) data on regimen type, uptake will be measured continuously for up to 9 months (the duration of the pilot trial). *Concordance:* This outcome is defined as the proportion of participants whose intent (as documented via the decision aid) is carried through in terms of their subsequent treatment (self-administered daily oral ART, LAI ART, or some intermediate step such as directly observed therapy to meet the current FDA label requirement for viral suppression). Using eSHARE data on decision aid responses and subsequent regimen type or services related to ART adherence, concordance will be measured from the date of decision aid completion for up to 9 months. *LAI maintenance:* LAI maintenance is defined in terms of adherence to LAI ART, specifically the time from LAI initiation to first deviation from the injection schedule, among trial participants initiating LAI ART during the trial. A deviation includes any injection >1 week ahead of or 1 week after the treatment target date, where the injection target date depends on whether the prescribed regimen is monthly or bimonthly. Using eSHARE data on ART regimen type and adherence (as well as case closure owing to death), maintenance will be measured from the first report of LAI ART to the first reported deviation from the injection schedule or date of death from any cause, whichever comes first, assessed for up to 9 months from the first injection or up to 8 months of follow-up injections (counting from the first possible deviation from a scheduled follow-up injection).

Other Measures

To understand the influences on implementation, we assess provider-perceived acceptability, appropriateness, and feasibility of the tools at 3 points in the pilot: baseline, 4-5 months (midpoint), and 9 months (end of the pilot). Specifically, the provider survey includes the 4-item scales (AIM, IAM, and FIM) that were used in the provider DCE survey [52]. However, for the pilot survey, these 3 measures specifically refer to the pilot tools being implemented. The baseline and midpoint assessments also include a brief measure of organizational readiness for implementing change (ORIC), which captures commitment to change (5 items) and perceived efficacy to change (7 items) [59] based on the theory of organizational readiness for change [60]. As the ORIC measure is anticipatory, it is not part of the final assessment. The semistructured midpoint and end-of-pilot interviews elicit providers' experiences of the piloted tools, including barriers, facilitators, and suggested refinements. Interviews will lend context to the ORIC, AIM, IAM, and FIM results and guide tool refinements.

Sample Size, Data Analysis, and Power Analysis

The original target was to enroll 180 patients or 30 (on average) per partner agency. As of mid-November 2023, 205 patients were enrolled. Using eSHARE data, we will describe trial participant demographics (eg, gender, age, race or ethnicity, income, and housing status) overall and by intervention arm. We will compare LAI ART uptake and, among those starting LAI ART, adherence by intervention arm, to assess the effects of the fuller package with the decision aid versus education alone. We will use log binomial regression to estimate risk ratios for uptake and adherence by intervention arm with generalized estimating equations and a small sample correction (owing to the small number of clusters) to maintain the type I error rate while accounting for clustering by site. To the extent possible given our sample size, we will adjust for potential confounders captured in eSHARE.

The brief provider survey measures will be analyzed through a comparison of responses on the same measures over time (eg, to assess change in perceived feasibility), as well as comparison of responses by intervention arm, agency type, and participant role. AIM, IAM, FIM, and ORIC scores will also be analyzed in relation to the levels of pilot service delivery as documented in eSHARE. To understand the potential for sustainability and scale-up, we will explore qualitative provider interview themes related to the acceptability and feasibility of the intervention. Qualitative and quantitative analyses will be integrated by examining thematic patterns reflecting RE-AIM and CFIR implementation constructs as they explain observed implementation outcomes [61].

Our pilot was designed to assess implementation of the newly developed tools and inform tool refinements. Data from the pilot will be used to generate estimates of LAI ART uptake that can, in turn, inform sample size and power calculations for a larger, controlled study of the refined tools' implementation and treatment outcomes. Accordingly, data from the pilot study will be used to estimate the proportion of patients who start LAI ART and, among those initiating, the proportion who maintain LAI ART. With the original target of 180 patients (now exceeded), we will be able to estimate LAI uptake with precision (95% CI) with the levels of uptake described in Table 2.

Assuming that half of the people who initiate LAI ART maintain it at 9 months, we will have the abovementioned precision estimates for the scenario of 50% LAI ART maintenance across a range of different levels of LAI ART uptake.

Table 2. 95% CIs for long-acting injectable (LAI) antiretroviral therapy (ART) uptake among pilot participants overall and maintenance estimates for those who start on LAI ART under LAI uptake percent assumptions.

LAI ART uptake, (%)	LAI ART uptake, 95% CI	LAI ART maintenance at 50%, 95% CI
5	2.7-9.2	22.7-77.4
10	6.4-15.2	29.0-71.0
15	10.5-20.9	32.4-67.7
20	14.8-26.4	34.5-65.5
30	23.8-37.0	37.0-62.9
40	33.1-47.3	38.8-61.3
50	42.8-57.3	39.9-60.1

Ethical Considerations

This study was approved by the NYC Department of Health and Mental Hygiene IRB (protocol 20-096) and registered with ClinicalTrials.gov (Identifier NCT05833542, preresults). The pilot trial was granted a waiver of patient informed consent in accordance with the pre-2018 requirements set forth in 45 CFR 46.116(d) based on its reliance on secondary data analysis. Any changes to trial eligibility criteria, outcome measures, or analysis plans would be mutually agreed upon between the principal investigators, vetted with the AB, and submitted to the IRB as protocol modifications.

Informed consent was obtained from each participant before their participation in primary data collection: focus groups, DCE surveys, provider pilot interviews, or provider pilot surveys. No individual incentive was offered for provider pilot interviews or provider pilot surveys. Each focus group participant and each DCE survey participant received a US $25 gift card.

The primary data collected for this study are stored on secured servers without participant names or other personal identifiers. Study records can be linked to individual participants only by study team members, who retain a separate key linking study identifiers to other identifiers (eg, eSHARE identifier codes). Patient names are stored in the most secured environment, accessible only to NYC Health Department staff authorized to view names and only during a time-limited, secured session in Citrix, which prohibits access to the internet, email, portable media such as flash drives, or printers. All records used in secondary analyses are also stripped of personal identifiers before their inclusion in data sets for analysis.

Results

The study was funded in late April 2021 and received official IRB approval in May 2021 under protocol 20-096. Focus groups were conducted in late 2021 and DCE data collection took place between June 2022 and January 2023. Patient education and patient-provider decision aid tools were developed by May 2023, and the trial continued through January 2024. Complete outcome data are expected by October 2024 and will be submitted for publication by December 2024. Study results will be reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) extension to cluster randomized trials and disseminated through scientific conferences, peer-reviewed publications, and meetings with local stakeholders. The investigators have also been sharing this work with colleagues in other jurisdictions and will disseminate the findings via the Ending the Epidemic Dashboard website.

Discussion

Overview

As a biomedical advance that untethers HIV viral suppression from the requirement for daily medication adherence, LAI ART could greatly increase the opportunities for health, survival, transmission prevention, and health equity. However, realizing that potential will depend on reaching those who have difficulty achieving or maintaining viral suppression on daily oral ART regimens. In addition, at this relatively early stage of LAI ART availability through third-party payers, there is little information on how acceptable, appropriate, or feasible this treatment option may be for low-income, predominantly Black and Latinx patients and their HIV service providers. This study is designed to yield insights and field-tested strategies to help optimize the public health impact of LAI ART, with particular attention to the patient groups underrepresented in clinical trials, disproportionately burdened by HIV-related morbidity and mortality, and most able to benefit from gaining access to alternatives to daily oral ART. On the basis of the focus group participants' and AB members' calls for clear patient-facing information and findings of limited LAI ART familiarity and divergent ART regimen-type preferences among patient DCE participants, we prioritized the development and testing of a patient-facing fact sheet and educational video, along with a patient-provider decision aid to guide conversations about treatment options and related supports.

Limitations and Strengths

Agencies were purposively assigned to pilot intervention conditions (with the intent of balancing the characteristics of agencies represented in each condition) rather than through randomization. Additional limitations include a lack of blinding (of agencies, providers, or investigators) to the agencies' assignments and a lack of control over agencies', providers', or patients' exposure to other initiatives or interventions that may affect the outcome. We are aware of at least 1 other NY-based pilot test of LAI-related support strategies [62], as well as a NY State Department of Health clinical quality improvement committee focused on identifying and sharing LAI ART–related resources and best practices. However, the

other NY-based pilot does not directly involve any of the agencies engaged in this trial. To our knowledge, our study is the first and only study to explicitly focus on the integration of LAI ART regimen options in RWPA or other RWHAP MCM service settings and the first to develop patient-directed LAI ART education materials or a patient-provider ART decision aid for use in an RWPA service population.

As with other HIV care quality improvement activities led by the NYC Health Department, agency participation is voluntary, meaning that agencies in the pilot could implement their assigned intervention condition incompletely or decline to implement. To address this limitation, we are tracking multiple implementation measures.

Conclusions

The United States National HIV/AIDS Strategy and National Institutes of Health have called for implementation science to produce evidence-based models of care [63,64]. Reviews of HIV care continuum research have also noted the need for practice-based evidence to inform program and policy development [65-67]. The implementation science design of this study has been selected to facilitate rapid research-to-practice translation of any LAI ART educational or decision-support tools that are found to be acceptable, feasible, and appropriate to these service settings and that show preliminary evidence of patient benefit. Through a robust academic-government-provider partnership, products from this study will be incorporated into local HIV services planning and delivery, as well as into future research.

Acknowledgments

This project was supported by the National Institutes of Health (NIH), grant number R34 MH 126809 (Project Officer Teri Senn), and by the Health Resources and Services Administration (HRSA), grant number H89HA00015 (Project Officer Axel Reyes). The authors would like to thank the 6 partnering provider agencies: State University of New York Downstate Health Sciences University (lead contacts: Lori Hurley and Antoinette Davis), La Casa de Salud (lead contacts: Mohammed Aldhuraibi and Pedro Gonzalez), Together Our Unity Can Health (lead contacts: Julian Palmer and Memunatu Attah-Issah), Open Door Family Medical Centers (lead contacts: Karin Palencia-Lua and José Miranda), Council on Adoptable Children (lead contacts: Denise Barrera and Katie Rivera), and Sun River Health (lead contacts: Aldonza Milian and Lisa Reid). This study also benefited from the support of other Ryan White Part A MCM service providers, Ryan White Part A participants, the HIV Health and Human Services Planning Council of New York, New York City Health Department HIV Care and Treatment Program leadership and quality management staff (Guadalupe Dominguez Plummer, Gina Gambone, Frances Silva, Grace Herndon, and Jacqueline Graham), and the Einstein-Rockefeller-CUNY Center for AIDS Research. The authors are indebted to Jennifer Carmona and Aimee Campbell, who provided early input critical to the grant proposal and the planning of the trial reported here. Finally, the authors would like to recognize the contributions of our other AB members and study team members (including Honoria Guarino, Will You, Chunki Fong, and Javier Lopez-Rios) to the larger Assessing Perceptions and Preferences Around Long-acting Injectables (APPLI) study and specifically the qualitative components and DCEs that guided the development of tools for pilot testing in the study's clinical trial phase. Generative AI (eg, ChatGPT) was not used in the ideation or in the writing process of this protocol. The content of this manuscript is solely the responsibility of the authors and does not necessarily reflect the official views of the funding agencies supporting this project. The NIH and HRSA are not involved in the study design, conduct, or products, or in the decision to submit this work for publication. The cited personal communication from ViiV Healthcare, indicating approximately 20,000 people in the US (including Puerto Rico) on CABENUVA, is based on an estimate derived from the use of information under license from the following IQVIA information service: National Custom Patient with National Longitudinal Patient (LRx) for the period ending 2023-09-29. IQVIA expressly reserves all rights, including rights of copying, distribution, and republication.

Data Availability

The full institutional review board protocol and statistical code will be made available upon request. The NY State Public Health Law prohibits the study team from releasing a public use data set containing information tending to identify the participants in its research. The NYC Health Department staff retain sole custody of study data sets and designated staff are available to answer any inquiries. Any questions or requests for additional information can be emailed to the study contact person.

Authors' Contributions

MKI is the health department (NYC Department of Health and Mental Hygiene [DOHMH]) principal investigator and led the conception of the overall study and the writing of the R34 proposal. RZ (City University of New York [CUNY]) reviewed and edited all drafts of the grant proposal, led the analyses on aim 2 of the larger study, and contributed substantively to the preparation of the manuscript. TA (DOHMH) supervised the DOHMH analysts' work on aims 1 and 3 of the larger study and contributed substantively to the study design and analysis plan. MP (DOHMH) and CE (DOHMH) conducted qualitative data collection for aim 1 and aim 3 and conducted qualitative analyses for aim 1. SGK (CUNY) and MMP (University of California, San Francisco [UCSF]) contributed substantively to the grant proposal and participated in ongoing planning. EAK (CUNY) contributed to the grant proposal and analysis plan and advised on study implementation. RZ (CUNY), TA (DOHMH), MP (DOHMH), and CE (DOHMH) prepared data, facilitated intervention implementation, participated in ongoing planning, and contributed to

communication with service providers and other stakeholders while managing other aspects of the larger study. DN is the university-based, lead agency (CUNY) principal investigator and shares responsibility for the conceptualization and oversight of the overall study and this trial, serves as the primary contact with the grant funding agency, supervises CUNY team members on the grant, and guides dissemination. MKI drafted the manuscript, and all authors (MKI, RZ, TA, MP, CE, SGK, MMP, EAK, and DN) revised it for critically important intellectual content and provided the final approval of the manuscript.

Conflicts of Interest

The authors have reported only federal government grants to their institutions for this work. For work beyond this project, DN has received consulting fees from Gilead Sciences, Inc and Abbvie, Inc, and RZ, SGK, and DN have received research grant funding from Pfizer to their institution.

Abstract

Background: The COVID-19 pandemic has sharpened the focus on health care safety and quality, underscoring the importance of using standardized metrics such as the *International Classification of Diseases, Tenth Revision* (*ICD-10*). In this regard, the *ICD-10* cluster Y62-Y69 serves as a proxy assessment of safety and quality in health care systems, allowing researchers to evaluate medical misadventures. Thus far, extensive research and reports support the need for more attention to safety and quality in health care. The study aims to leverage the pandemic's unique challenges to explore health care safety and quality trends during prepandemic, intrapandemic, and postpandemic phases, using the *ICD-10* cluster Y62-Y69 as a key tool for their evaluation.

Objective: This research aims to perform a comprehensive retrospective analysis of incidence rates associated with *ICD-10* cluster Y62-Y69, capturing both linear and nonlinear trends across prepandemic, intrapandemic, and postpandemic phases over an 8-year span. Therefore, it seeks to understand how these trends inform health care safety and quality improvements, policy, and future research.

Methods: This study uses the extensive data available through the TriNetX platform, using an observational, retrospective design and applying curve-fitting analyses and quadratic models to comprehend the relationships between incidence rates over an 8-year span (from 2015 to 2023). These techniques will enable the identification of nuanced trends in the data, facilitating a deeper understanding of the impacts of the COVID-19 pandemic on medical misadventures. The anticipated results aim to outline complex patterns in health care safety and quality during the COVID-19 pandemic, using global real-world data for robust and generalizable conclusions. This study will explore significant shifts in health care practices and outcomes, with a special focus

on geographical variations and key clinical conditions in cardiovascular and oncological care, ensuring a comprehensive analysis of the pandemic's impact across different regions and medical fields.

Results: This study is currently in the data collection phase, with funding secured in November 2023 through the Ricerca Corrente scheme of the Italian Ministry of Health. Data collection via the TriNetX platform is anticipated to be completed in May 2024, covering an 8-year period from January 2015 to December 2023. This dataset spans pre-pandemic, intra-pandemic, and early post-pandemic phases, enabling a comprehensive analysis of trends in medical misadventures using the ICD-10 cluster Y62-Y69. The final analytics are anticipated to be completed by June 2024. The study's findings aim to provide actionable insights for enhancing healthcare safety and quality, reflecting on the pandemic's transformative impact on global healthcare systems.

Conclusions: This study is anticipated to contribute significantly to health care safety and quality literature. It will provide actionable insights for health care professionals, policy makers, and researchers. It will highlight critical areas for intervention and funding to enhance health care safety and quality globally by examining the incidence rates of medical misadventures before, during, and after the pandemic. In addition, the use of global real-world data enhances the study's strength by providing a practical view of health care safety and quality, paving the way for initiatives that are informed by data and tailored to specific contexts worldwide. This approach ensures the findings are applicable and actionable across different health care settings, contributing significantly to the global understanding and improvement of health care safety and quality.

KEYWORDS

COVID-19; curve-fitting analyses; health care quality; health care safety; International Classification of Diseases, Tenth Revision; ICD-10; incidence rates; safety; TriNetX

Introduction

A wealth of scholarly research and empirical data underscores the imperative of prioritizing safety and quality in health care [1,2]. Seminal studies in the last 3 decades, such as the Canadian Adverse Events Study and the Harvard Medical Practice Study, have highlighted the rates of adverse events in health care settings, which led to severe, sometimes fatal, consequences for patients [3,4]. Moreover, research conducted in various international contexts has emphasized the necessity of rigorous safety protocols and the urgent need for continuous quality improvement plans [5-7]. The criticality of safety and quality in health care is not merely a theoretical construct but is supported by extensive research, governmental reports, and real-world implications [8]. Ensuring that safety and quality are at the forefront of health care delivery is pivotal for enhancing patient outcomes, reducing costs, and optimizing the effectiveness and efficiency of health care systems globally [9].

The COVID-19 pandemic has served as a watershed moment in the global health care landscape, profoundly influencing safety culture and catalyzing a renewed emphasis on quality improvement plans [10]. The unprecedented strain on health care systems worldwide has necessitated rapid adaptations in safety protocols, resource allocation, and patient care strategies. The pandemic has exposed vulnerabilities in existing health care infrastructures, compelling institutions to reevaluate and fortify their safety measures [11]. For instance, the critical importance of infection control has been magnified, leading to more stringent guidelines for personal protective equipment use, sanitation, and patient isolation [12]. Moreover, the pandemic has accelerated the adoption of telemedicine, which presents its own set of quality and safety considerations. The COVID-19 pandemic has also underscored the importance of data-driven approaches to safety and quality, as health care providers increasingly rely on real-time analytics to make informed decisions in a rapidly changing environment and use data to monitor improvements [13]. In essence, the COVID-19 pandemic has acted as a catalyst for a paradigm shift in health care safety culture, making the continuous improvement of quality not just an institutional goal but a global imperative.

In this evolving landscape of health care safety and quality improvement, the potential use of the *International Classification of Diseases, Tenth Revision* (*ICD-10*) has gained significant attention [14]. *ICD-10* serves as a standardized coding system for diagnosing a wide array of medical conditions, thereby facilitating precise communication among health care providers and enabling robust data collection for research and policy development [15]. This standardization has further enabled the use of expansive data sets for retrospective analyses, thereby contributing to targeted quality improvement initiatives. For instance, platforms such as TriNetX leverage the *ICD-10* coding system to facilitate data-driven decision-making, offering health care institutions invaluable insights into areas requiring intervention or optimization [16]. Consequently, the *ICD-10* framework stands as a pivotal instrument in elevating the culture of safety and the data needed to guide quality improvement plans, particularly in the intricate health care landscape shaped by the ongoing COVID-19 pandemic.

Within the framework of *ICD-10*, the cluster Y62-Y69, designated for "Misadventures to patients during surgical and medical care," serves as a critical proxy for assessing patient safety and quality of care [17]. This particular cluster comprises an array of diagnostic codes that encapsulate a diverse spectrum of medical misadventures, ranging from lapses in sterile precautions to inaccuracies in dosage administration and contamination of medical or biological substances. Using these nuanced codes enables health care practitioners and academic researchers to undertake focused analyses to augment the

standard of medical care. Critically, this categorization facilitates pinpointing potential vulnerabilities in existing safety protocols, thus providing empirically based insights that can be harnessed for the advancement of quality improvement strategies to improve safety.

In light of the urgent need to enhance safety and quality in health care, a comprehensive analysis focusing on the *ICD-10* cluster Y62-Y69 could offer invaluable insights. This research protocol articulates a methodical framework for examining longitudinal trends in the incidence rates associated with this specific cluster. Using the TriNetX platform, the study will encompass an 8-year period and use curve-fitting analyses. The choice of an 8-year time frame for this study serves multiple analytical purposes. First, it provides a sufficient number of data points to establish a robust trendline prior to the onset of the COVID-19 pandemic. These baseline data are crucial for understanding the pre-existing patterns and vulnerabilities in health care safety and quality, as captured by the *ICD-10* cluster Y62-Y69. Second, including data during the pandemic allows for an in-depth examination of how the health care systems adapted their safety protocols and quality improvement plans in response to the unprecedented challenges posed by COVID-19. Finally, extending the study into the postpandemic context offers a timely opportunity to assess the current state of health care safety and quality, including any lasting impacts or improvements catalyzed by the pandemic experience. Therefore, the 8-year span is methodologically sound and contextually relevant, enabling a comprehensive analysis that covers prepandemic, pandemic, and postpandemic phases.

This study aims to describe not only the linear trajectories of these rates but also the dynamics of their rate of change over time. This analytical focus has particular relevance in the context of health care systems' responses to the COVID-19 pandemic, a transformative event that has indelibly impacted global health care. The protocol specifies the analytical methodologies to be deployed, identifies the data repositories for consultation, and outlines the statistical models for rigorous data interpretation. Ultimately, this research protocol aims to provide a robust analytical framework capable of generating empirically substantiated findings regarding the past and current state of safety. The findings are designed to inform targeted interventions for the advancement of health care safety and quality.

Methods

Study Design

This study will adopt an observational, retrospective design, adhering to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines. This is a big data study, leveraging the extensive and diverse data sets available within the TriNetX platform to provide a comprehensive analysis. The Gantt Chart for research activities presents a 6-month project timeline, where the initial 3 months are allocated to retrieving data. This is followed by a period of analysis spanning 2 months. Concurrently, starting in the third month and continuing through to the sixth month, a total of 3 months is devoted to meta-elaboration and scientific writing.

Setting and Data Source

Data will be extracted from the TriNetX platform, a global health research network that provides real-time access to clinical data. The platform's big data capabilities enable the analysis of large, complex data sets, thereby enhancing the robustness and generalizability of the study findings.

This retrospective analysis will be done using TriNetX, a global health research network providing a deidentified data set of electronic medical records regarding demographics, diagnoses, procedures, medications, laboratory values, genomics, and visits. This network comprises routinely collected, aggregated clinical data from around 130 million patients attending 107 health care institutions in 16 countries, with data spanning from 2008 to 2023.

Data include both inpatient and outpatient care. Clinical information is collected using widespread standard terminologies, such as Systematized Nomenclature of Medicine, Logical Observation Identifiers Names and Codes, and *ICD-10*. TriNetX is certified to the International Organization for Standardization 27001:2013 standard and maintains an Information Security Management System to ensure the protection of the health care data it has access to and to meet the requirements of the Health Insurance Portability and Accountability Act (HIPAA) Security Rule.

The cohort for the study includes all patients aged 0 to 89 years old who underwent any *ICD-10-Clinical Modification* diagnosis during the period of observation. The *ICD-10-Clinical Modification* cluster Y62-Y69, which represents "Misadventures to patients during surgical and medical care," has been identified as the outcome of the analysis. The analysis of the incidence rate of the outcome in the years between 2016 and 2023 (4 years before and 4 years after the pandemic) will be conducted globally and for specific geographic areas: North America (United States); Latin America; Europe, Middle East, and Africa; and Asia-Pacific. This analysis will use the corresponding collaborative networks within TriNetX. TriNetX offers natural language processing capabilities, which use machine learning technology from Averbis (located in Freiburg in Breisgau, Germany) to search free text from clinical charts and other records specifically for the geographical areas in the United States.

The analysis will be applied to an oncological cohort and one with cardiovascular diseases to validate the results obtained in the initial phase of the research. The oncological cohort was determined using any *ICD-10* codes related to neoplasms (C00-D49). In contrast, the cardiovascular cohort was identified using codes related to Diseases of the Circulatory System (I00-I99).

The findings will be reported according to the STROBE guideline. One of the primary goals of STROBE is to ensure a clear and transparent account of the reporting of methods and results.

Study Period

The analysis will encompass 8 years of data, now divided into 3 distinct phases to align with the key periods of the COVID-19

pandemic: from 2018 to 2019 (prepandemic phase), from 2020 to May 2023 (intrapandemic phase, aligning with the federal COVID-19 public health emergency declaration period), and from June 2023 to the end of 2023 (early postpandemic phase). This division allows for a precise examination of health care safety and quality trends during the prepandemic phase, the active pandemic phase as defined by the federal public health emergency declaration, and the immediate aftermath of the pandemic. This approach aims to provide a more detailed and contextually relevant understanding of the varying impacts of the COVID-19 pandemic, thus offering a comprehensive view of the health care landscape and its adaptation during these critical periods.

Variables of Interest

This study's primary variables of interest are the incidence rates associated with the *ICD-10* cluster Y62-Y69, a specific set of diagnostic codes designated for capturing "Misadventures to patients during surgical and medical care" [17]. This cluster is of particular importance as it serves as a critical proxy for assessing the safety and quality of health care delivery. It encompasses a wide range of medical misadventures, including but not limited to lapses in sterile precautions, inaccuracies in dosage administration, and contamination of medical or biological substances. Analyzing the incidence rates will enable a comprehensive evaluation of the health care system's performance in minimizing medical misadventures and informing targeted interventions for quality improvement and safety enhancement [18]. The limitations of these data are the self-reporting nature of documenting the "misadventures," with the potential for underreporting.

The incidence rate, which measures the rate of new or first-time cases, is calculated using a time-sensitive approach. The denominator for the incidence rate is the product of the number of patients in the incidence proportion denominator and the number of days covered by the time interval. This ensures that the incidence rate provides a dynamic view of how safety and quality are evolving over time. Importantly, the study also incorporates a "lookback period" to exclude patients who have experienced the event of interest prior to the study period, thereby focusing only on new cases.

Incidence rates are subject to stringent criteria, including demographic matching and time window overlaps, to ensure that the data are accurate and meaningful for targeted interventions. Furthermore, the study acknowledges the potential impact of date shifting by health care organizations to protect patient health information and takes this into consideration in the analysis.

Statistical Analysis

The primary aim of the forthcoming statistical analysis will be to decipher the linear and nonlinear trajectories of incidence rates, with a particular focus on understanding their rate of change over time. Special attention will be dedicated to evaluating the impact of the COVID-19 pandemic on these health care metrics.

The linchpin of the analytical strategy will be the application of curve-fitting analyses [19]. This advanced technique will enable researchers to construct models that elucidate the intricate relationships between the rates and the temporal variables. Specifically, polynomial regression models, including quadratic models, will be used to capture the complexity of the data trends. Quadratic models will be particularly useful for capturing nonlinear trends in the data. These models will be formulated based on the equation $y = ax^2 + bx + c$, where y represents the incidence rate; x represents time; and a, b, and c are coefficients to be estimated. The quadratic term ax^2 will allow us to understand the curvature in the data, providing insights into acceleration or deceleration trends over time. Model diagnostics, such as residual analysis and goodness-of-fit tests, will be conducted to ensure the appropriateness of the quadratic models.

Initially, curve-fitting analyses will be executed on an overall sample characterized by its extensive demographic and clinical diversity. Given the inherent heterogeneity of this sample, a rigorous validation process will be indispensable for confirming the generalizability and applicability of the observed trends.

A series of subgroup analyses will be undertaken to augment the robustness of the findings. These analyses will be stratified by various factors, including but not limited to geographic location. Data for these subgroup analyses will be sourced from the TriNetX network, which amalgamates health care data from a multitude of geographic regions. This approach will facilitate an assessment of the consistency of the observed trends across diverse subpopulations to bolster the external validity of the findings. Further stratification will be conducted based on prevalent epidemiological conditions in the fields of oncology and cardiovascular diseases. Within these conditions, specific groups identified with inclusion and exclusion criteria will be selected as they possess well-documented epidemiological profiles, serving as robust benchmarks for validation. Reperforming the curve-fitting analyses within these disease-specific cohorts will aim to corroborate the trends discerned in the overall sample.

Ethical Considerations

Human Subject Research Ethics Review and Approvals

The study uses data from the TriNetX network, which adheres to international and national data protection and privacy laws, including the HIPAA in the United States and the General Data Protection Regulation in the European Union. These compliance standards ensure that the data are reliably sourced and managed ethically. Each health care organization participating in the TriNetX network is committed to strict ethical standards, including obtaining informed consent for primary data collection with provisions for secondary analysis. Therefore, the study protocol has been approved by the institutional review board of Policlinico San Donato within the Ricerca Corrente funding scheme, affirming adherence to ethical standards and contribution to health care research. No external ethical committee review was deemed necessary due to the aggregated nature of the information, emphasizing the study's compliance with privacy and data protection principles inherent in its observational and secondary data analysis approach.

Informed Consent for Secondary Analysis

The study involves secondary analysis of anonymized data sets obtained from organizations within the TriNetX network. It is important to note that the original informed consent obtained by these organizations (or their respective institutional review boards) allows for secondary analysis without requiring additional consent. This approach ensures that the use of the data respects and upholds the original consent and ethical approvals.

Privacy and Confidentiality Protection

The data included in the study, derived from the TriNetX platform, are aggregated to ensure that individual patient data are not directly used. This aggregation process, in conjunction with the initial ethical compliance by each participating health care organization, guarantees the protection of privacy and confidentiality. The data used in the research are anonymous and deidentified, following strict data protection principles.

Compensation

Compensation is not applicable in the study as it revolves around the secondary analysis of existing anonymized data sets. There is no direct participant interaction, so compensation for participants is not applicable.

Image and Supplementary Material Identification

No individual participants or user identification is possible in any images included in the manuscript or supplementary materials. The study design protects the privacy and anonymity of all individuals involved.

Anticipated Findings

The anticipated results of this comprehensive analysis focusing on the *ICD-10* cluster Y62-Y69 are expected to provide valuable insights into the safety and quality of health care delivery over the study period, spanning prepandemic, intrapandemic, and early postpandemic phases.

Regarding the incidence rates associated with the *ICD-10* cluster Y62-Y69, we anticipate that our analysis will reveal trends and patterns that can be attributed to various factors, including changes in safety protocols, resource allocation, and health care practices during the COVID-19 pandemic. Given the unprecedented challenges and adaptations required by health care systems worldwide, it is reasonable to expect that the pandemic may have had a significant impact on these rates.

In the prepandemic phase, our analysis aims to establish a baseline for the incidence rates, offering insights into the existing vulnerabilities in health care safety and quality captured by the *ICD-10* cluster. This baseline data will be crucial for understanding the context in which subsequent changes occurred.

During the intrapandemic phase, we anticipate observing fluctuations and shifts in the incidence rates. These changes may be indicative of the health care system's responses to the challenges posed by the pandemic, including heightened infection control measures, changes in patient care protocols, and resource allocation adjustments. The pandemic's impact on safety and quality may be reflected in the data.

In the early postpandemic phase, we expect to see how health care systems have adapted and evolved in response to the pandemic's challenges. It is possible that some changes implemented during the pandemic may persist or lead to improvements in safety and quality.

Furthermore, our analysis will include stratified subgroup analyses, which may reveal variations in trends across different geographic regions and within specific disease cohorts (oncology and cardiovascular diseases). These subgroup analyses will help identify whether the observed trends are consistent across diverse populations and clinical contexts. This study aims to provide a nuanced understanding of how the COVID-19 pandemic has influenced safety and quality in health care, as reflected in the incidence rates of the *ICD-10* cluster Y62-Y69. These findings will inform targeted interventions and quality improvement strategies, contributing to the ongoing efforts to enhance health care safety and quality in a rapidly evolving health care landscape.

Results

Our research, supported by the Ricerca Corrente funding from the Italian Ministry of Health to IRCCS Policlinico San Donato (funds secured in November 2023), is currently advancing through the data collection stage. The compilation of data, facilitated by the global health research network TriNetX, is set to encapsulate a comprehensive 8-year timeframe extending from January 2015 to December 2023. This carefully curated dataset documents the healthcare landscape across three critical phases: before the COVID-19 pandemic (pre-pandemic), during the height of the pandemic (intra-pandemic), and the period following the emergency phase of the pandemic (early post-pandemic). Such temporal delineation is pivotal for our investigation into the trends and fluctuations in medical misadventures classified under the ICD-10 cluster Y62-Y69, offering a lens through which to view the nuances of healthcare safety and quality across different global healthcare contexts.

With data collection anticipated to be completed by May 2024, and final analysis expected by June 2024, our study is on track to fulfill its objective of dissecting the intricate patterns of medical misadventures during a period marked by unprecedented global health challenges. The results are anticipated to equip healthcare professionals, policymakers, and stakeholders with the insights necessary to fortify healthcare systems against future adversities, thereby enhancing the overall safety and quality of care delivered to patients worldwide

Discussion

Principal Findings

The primary expectation of this study is to elucidate the linear and nonlinear trajectories of incidence rates associated with the *ICD-10* cluster Y62-Y69 over time. Through the application of curve-fitting analyses, specifically quadratic models, we anticipate revealing intricate patterns in the data that may not be discernible through simpler linear models.

In the context of the COVID-19 pandemic, we expect to observe significant fluctuations in these rates, potentially manifesting

as spikes or declines corresponding to various phases of the pandemic. These observations will be critical for understanding the pandemic's impact on health care safety and quality, particularly in medical misadventures. Furthermore, examining the postpandemic response to these rates will be of particular interest. These results will provide insights into the resilience and adaptability of health care systems in returning to prepandemic safety and quality levels or possibly achieving even better standards.

Upon conducting subgroup analyses, we expect that the trends observed in the overall sample will be validated in specific subpopulations. These subpopulations will be stratified by geographic location and specific epidemiological conditions within oncology and cardiovascular diseases. The validation of trends across these diverse subpopulations will lend greater credibility and generalizability to our findings.

Moreover, we anticipate that our stringent data selection criteria for validating the overall models will yield accurate and meaningful results. These results are expected to inform targeted interventions to improve the safety and quality of health care delivery, fulfilling the study's ultimate objective.

However, it is essential to acknowledge the limitations that may arise from the study. These could include potential biases in the original data documentation and collection and the challenges associated with interpreting complex statistical models. One specific limitation is the retrospective nature of the study, which may introduce recall bias and limit the ability to establish causal relationships. Retrospective studies often rely on existing records and data, which may not have been collected for research purposes, affecting the data's quality and completeness. In addition, despite the application of data selection criteria, the possibility of unmeasured or residual confounding factors cannot be entirely excluded. These factors might influence the observed associations and outcomes. This limitation is characteristic of retrospective studies and should be considered when interpreting our findings. Furthermore, we acknowledge the challenges associated with analyzing data from broad and heterogeneous geographic areas such as Europe, the Middle East, Africa, and Asia-Pacific. The diversity in health care systems, practices, and patient populations across these regions may limit the uniformity and specific applicability of our findings. This variation is important when interpreting our results and their implications in these diverse settings. We recognize this as a limitation of our study and suggest caution in generalizing the findings uniformly across these broad geographic areas.

Despite these limitations, the strength of this study lies in its use of global real-world big data. The TriNetX network provides a rich data set that captures a broad range of demographic and clinical variables, enhancing the study's generalizability and applicability. The use of real-world data allows for a contemporary understanding of medical misadventures, as it reflects on the complexities and variabilities inherent in everyday health care settings. This aspect is a significant advantage over controlled clinical trials, which often operate under idealized conditions that may not be representative of the real world.

Future research will focus on addressing these limitations and possibly using other advanced statistical techniques for a more in-depth analysis. For instance, machine learning algorithms could be used to identify hidden patterns and relationships in the data, providing a more comprehensive understanding of the factors influencing medical misadventures. In line with our future research directions, we aim to delve deeper into specific indicators like complications, side effects, mortality, and morbidity in subsequent studies. These indicators, when analyzed in homogeneous subgroups of patients with and without the presence of the *ICD-10* cluster Y62-Y69, could provide critical insights into the impact of medical misadventures on patient outcomes. This focus will augment our current understanding of relevant safety-related patterns and guide targeted interventions to mitigate such occurrences in health care settings.

Conclusions

The upcoming study is poised to offer a multifaceted exploration of the incidence rates associated with medical misadventures, as defined by the *ICD-10* cluster Y62-Y69. The research is designed to use advanced statistical models, such as quadratic equations, to capture both linear and nonlinear trends over time. This approach will be particularly illuminating in the context of the pre–, intra–, and post–COVID-19 pandemic analyses, a period in history that has introduced unique challenges and disruptions to health care systems globally. Global real-world data stand as a significant strength, offering a more pragmatic view of health care safety and quality that can typically be achieved through controlled clinical trials or other primary studies. The study's findings are anticipated to be of considerable value to health care professionals, policy makers, and researchers alike. The results will not only shed light on the current state of medical misadventures but also provide actionable insights for targeted interventions aimed at improving health care safety and quality.

Abstract

Background: Hodgkin lymphoma (HL) occurs at young ages, with the highest incidence between 20 and 40 years. While cure rates have improved to 80%-90% over the past decades, survivors of HL are at substantial risk of late treatment–related complications, such as cardiovascular diseases, breast cancer, severe infections, and hypothyroidism. To reduce morbidity and mortality from late treatment effects, the Dutch Better care after lymphoma, Evaluation of long-term Treatment Effects and screening Recommendations (BETER) consortium developed a survivorship care program for 5-year survivors of HL that includes risk-based screening for and treatment of (risk factors for) late adverse events. Even though several cancer survivorship care programs have been established worldwide, there is a lack of knowledge about their effectiveness in clinical practice.

Objective: The Improving Nationwide Survivorship care Infrastructure and Guidelines after Hodgkin lymphoma Treatment (INSIGHT) study evaluates whether Dutch BETER survivorship care for survivors of HL decreases survivors' burden of disease from late adverse events after HL treatment and associated health care costs and improves their quality of life.

Methods: The INSIGHT study is a multicenter retrospective cohort study with a quasi-experimental design and prospective follow-up, embedded in the national BETER survivorship care infrastructure. The first BETER clinics started in 2013-2016 and several other centers started or will start BETER clinics in 2019-2024. This allows us to compare survivors who did and those who did not receive BETER survivorship care in the last decade. Survivors in the intervention group are matched to controls (n=450 per group) based on sex, age at diagnosis (±5 years), age in 2013 (±5 years), and treatment characteristics. The primary outcome is the burden of disease in disability-adjusted life years from cardiovascular disease, breast cancer, severe infections, and hypothyroidism. In a cost-effectiveness analysis, we will assess the cost of BETER survivorship care per averted or gained disability-adjusted life year and quality-adjusted life year. Secondary outcomes are BETER clinic attendance, adherence to screening guidelines, and knowledge and distress about late effects among survivors of HL. Study data are collected from a survivor survey, a general practitioner survey, medical records, and through linkages with national disease registries.

Results: The study was funded in November 2020 and approved by the institutional review board of the Netherlands Cancer Institute in July 2021. We expect to finalize recruitment by October 2024, data collection by early 2025, and data analysis by May 2025.

Conclusions: INSIGHT is the first evaluation of a comprehensive survivorship program using real-world data; it will result in new information on the (cost-)effectiveness of survivorship care in survivors of HL in clinical practice. The results of this study will be used to improve the BETER program where necessary and contribute to more effective evidence-based long-term survivorship care for lymphoma survivors.

research design; Hodgkin lymphoma; late effects of cancer treatment; survivorship care; screening; cost-effectiveness analysis

Introduction

Cardiovascular diseases (CVDs) and second malignancies, especially breast cancer, are well-known late complications of Hodgkin lymphoma (HL) treatment. The risks of CVD and breast cancer are highest in survivors of HL treated with chest radiotherapy with or without anthracycline-based chemotherapy [1-8]. In addition, survivors of HL may also face other late treatment effects such as severe infections, associated with (functional) asplenia [3,9], and hypothyroidism after neck radiotherapy [10,11]. Although improved chemotherapy and radiotherapy regimens have increased HL cure rates to 80%-90% over the past decades, the aforementioned treatment-related complications have led to excess morbidity and mortality in survivors of HL [3,4,12-14].

CVD risk is 4-6 times higher in survivors of HL treated in 1965-1995 than in the general population, with up to 50% cumulative CVD incidence 40 years after HL treatment [7]. Female survivors of HL who received chest radiotherapy in the aforementioned period have a 5 times higher breast cancer risk than women in the general population, with a 19% cumulative incidence 30 years after treatment [2]. In addition, infectious disease mortality in survivors of HL treated in 1965-2000 increased 8-fold compared to the general population [3]. Moreover, 25 years after HL treatment, the cumulative incidence of (subclinical) hypothyroidism was 44% in survivors treated between 1961 and 1989 [9]. Individual late treatment–related complication risks depend on the characteristics of patients and HL treatment (radiotherapy location, dose and volume, chemotherapy type and dose, and whether or not splenectomy was performed) and are expected to be lower in more recent treatment years as a result of improved radiotherapy techniques [2,3,5,7,9].

In 2009, the Dutch “Better care after lymphoma, Evaluation of long-term Treatment Effects and screening Recommendations” (BETER) consortium, a collaboration between hemato-oncologists, radiation oncologists, nurse practitioners, epidemiologists, a general practitioner (GP), and patient representatives, was established. While HL generally occurs at a young age (with the highest incidence between 20 and 40 years) and survivors have a long life expectancy where they can develop late effects, structured survivorship care for adult survivors of HL was lacking. Structured survivorship care may lead to the early detection of (risk factors for) late adverse events, enabling timely intervention, possibly leading to a lower burden of disease due to late effects and better quality of life in survivors of HL [15,16]. Therefore, the BETER consortium developed a nationwide infrastructure of outpatient clinics where 5-year survivors of HL are screened for late adverse effects of lymphoma treatment according to nationally approved screening guidelines. Recommendations in the guidelines were based on the available scientific evidence in survivors of HL, and, if this evidence was absent, in other high-risk populations (eg, *BRCA* mutation carriers for breast cancer screening recommendations) or on expert consensus [17,18].

In 2013-2016, the first BETER clinics started inviting 5-year survivors of HL for risk-based screening for late treatment–related complications. Of note, setting up a BETER clinic requires a substantial effort, that is, identification and tracing of patients and setting up local infrastructure, including consulting specialists such as cardiologists [17]. Therefore, several Dutch lymphoma treatment centers were only able to start or will start inviting survivors of HL for survivorship care in 2019-2024.

Other cancer survivorship care programs, especially for survivors of childhood cancer (often also including survivors of childhood HL), have been established in several countries worldwide. However, there is a lack of knowledge about their effectiveness in clinical practice. Studies that evaluated the yield of late events in these programs, almost exclusively concerned with CVD and breast cancer screening results, lacked a comparison group or used hypothetical cohorts or simulation models to estimate the potential health benefits from structured survivorship care [19-25]. The effect of the implementation of cancer survivorship programs on survivors’ burden of disease, quality of life, and cost-effectiveness has never been assessed using real-world data. Therefore, in the Improving Nationwide Survivorship care Infrastructure and Guidelines after Hodgkin lymphoma Treatment (INSIGHT) study, we aim to assess whether BETER survivorship care leads to reduced burden of disease from late adverse events after HL treatment, lower health care costs, better quality of life, and reduced health-related productivity losses compared to the absence of structured survivorship care.

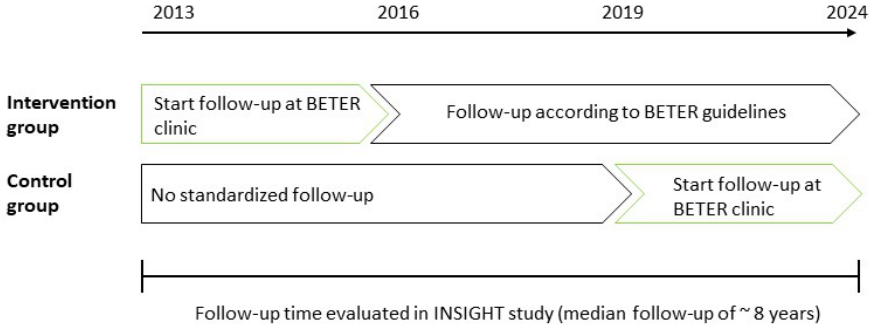
Methods

Design

The INSIGHT study is a retrospective cohort study with a quasi-experimental design and prospective follow-up, embedded in the national BETER survivorship care infrastructure. The first BETER clinics started in 2013-2016 and the number of centers participating in the BETER program increased over the last few years; several centers started or will start a BETER

clinic in 2019-2024. This provides the unique opportunity to evaluate the effectiveness of BETER survivorship care by comparing survivors who did and did not receive BETER survivorship care over the past 6-10 years (expected median follow-up of ~8 years). The intervention group will consist of 450 survivors of HL who were invited to first visit a BETER clinic in 2013-2016. The control group will consist of a matched group of 450 survivors of HL who were eligible for BETER survivorship care as of 2013-2016 but were not invited because they were treated in a lymphoma treatment center not starting a BETER clinic until 2019-2024 (Figure 1).

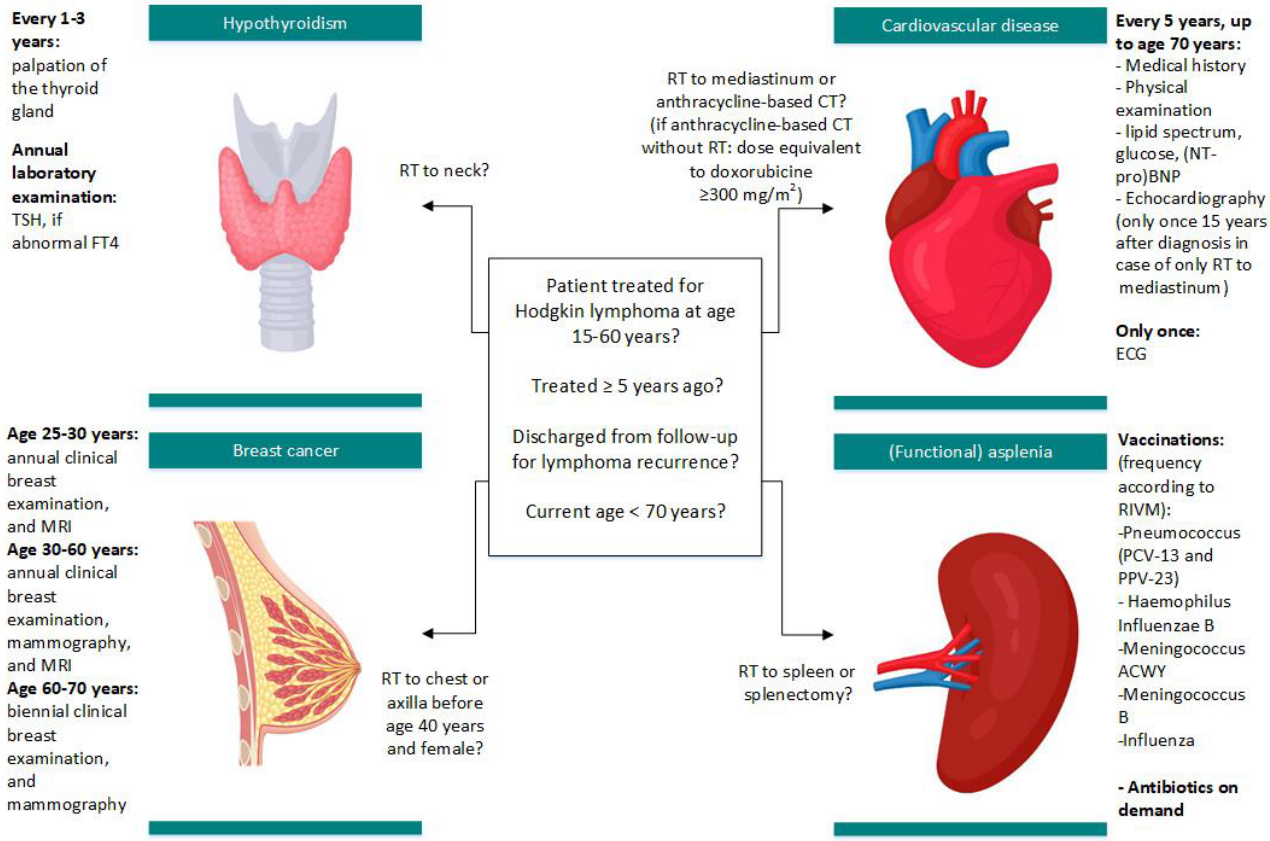
Figure 1. Schematic overview of the INSIGHT cohort study follow-up period among 5-year survivors of Hodgkin lymphoma in the Netherlands. BETER: Better care after lymphoma, Evaluation of long-term Treatment Effects and screening Recommendations.



Study Population

According to the BETER guidelines, survivors of HL are eligible for survivorship care after completion of regular surveillance for HL recurrence (5 years after treatment), if they were 15-60 years at HL diagnosis, and are currently younger than 70 years of age. Figure 2 [17,18,26] shows a simplified overview of BETER eligibility criteria and the screening guidelines [17,18]. Survivors who do not have sufficient understanding of the Dutch language to complete the study survey, have developed an HL relapse during follow-up, whose vital status (and if alive current address) could not be verified, or who live abroad are excluded from the INSIGHT study.

Figure 2. Simplified overview of BETER screening guidelines for 5-year survivors of Hodgkin lymphoma in the Netherlands [17, 18] and guideline asplenia from the National Institute for Public Health and the Environment (RIVM) [26]. CT: chemotherapy; ECG: electrocardiogram; FT4: free thyroxine; MRI: magnetic resonance imaging; (NTpro-)BNP: (N-terminal pro–)B-type natriuretic peptide; RIVM: National Institute for Public Health and the Environment, RT: radiotherapy; TSH: thyroid stimulating hormone.



The study participants in the control group are matched to patients in the intervention group based on the following survivor characteristics: sex, age at diagnosis (±5 years), and age in 2013 (±5 years) and the following treatment

characteristics associated with increased risk of CVD, breast cancer, hypothyroidism, and (functional) asplenia: chest radiotherapy (yes or no), neck radiotherapy (yes or no), spleen radiotherapy or splenectomy (yes or no), and anthracycline-based chemotherapy (yes or no). Controls are selected from the comprehensive database of the previously established retrospective cohort of lymphoma survivors treated in participating BETER centers between 1965 and 2012. This database contains information on basic survivor characteristics and detailed treatment data [17].

Outcomes

The primary outcomes of this study are the burden of disease (in disability-adjusted life years [DALYs]) from CVD including associated risk factors (Table S1 in Multimedia Appendix 1 [17,27-30]), breast cancer, severe infections (defined as fatal or requiring hospitalization) and hypothyroidism, the associated health care costs, and quality of life. In a cost-effectiveness analysis, the cost of BETER survivorship care will be weighed against averted or gained DALYs and quality-adjusted life years (QALYs). In order to assess indirect costs in both groups, health-related productivity losses and overall health care use will be calculated. Furthermore, the incidence rates (including stage and time since HL diagnosis) for the (risk factors for) late adverse events of interest (screen detected or nonscreen detected) will be compared between the intervention and control group.

The secondary outcomes of this study are BETER clinic nonattendance, guideline adherence, and knowledge and distress about late effects among survivors. Both the intervention and control group include survivors who attended the BETER clinic (attenders) and survivors who were invited for BETER survivorship care but chose to not attend (nonattenders). We will describe the reasons for nonattendance to BETER survivorship care and assess possible associations of nonattendance with socioeconomic status, health status, and other patient characteristics. This subanalysis will allow us to place our main study findings in perspective and possibly even improve future attendance rates. Survivors' socioeconomic status will be derived from their zip code based on data from Statistics Netherlands [31]. We assess the BETER clinicians' adherence to the guidelines by comparing the screening diagnostics that were performed in clinical practice to those that are recommended in the BETER guidelines. Finally, we will assess survivors' knowledge about the risk of late complications (risk perception) in both groups and investigate whether this knowledge comes with increased or decreased distress about their risk of late complications.

Follow-Up

For the intervention group, follow-up starts at the first BETER visit (or BETER clinic invitation date for nonattenders) and ends at the study inclusion of its matched control in 2019-2024 or at date of death, whichever comes first. For the control group, follow-up starts at the date their matched intervention group survivor started follow-up and ends at their first BETER visit (or BETER clinic invitation date for nonattenders), or, if earlier, at death. All study data will be stored for at least 20 years. This enables prospective follow-up of our cohort in order to study the long-term effects of screening on the incidence of late adverse events and the associated burden of disease.

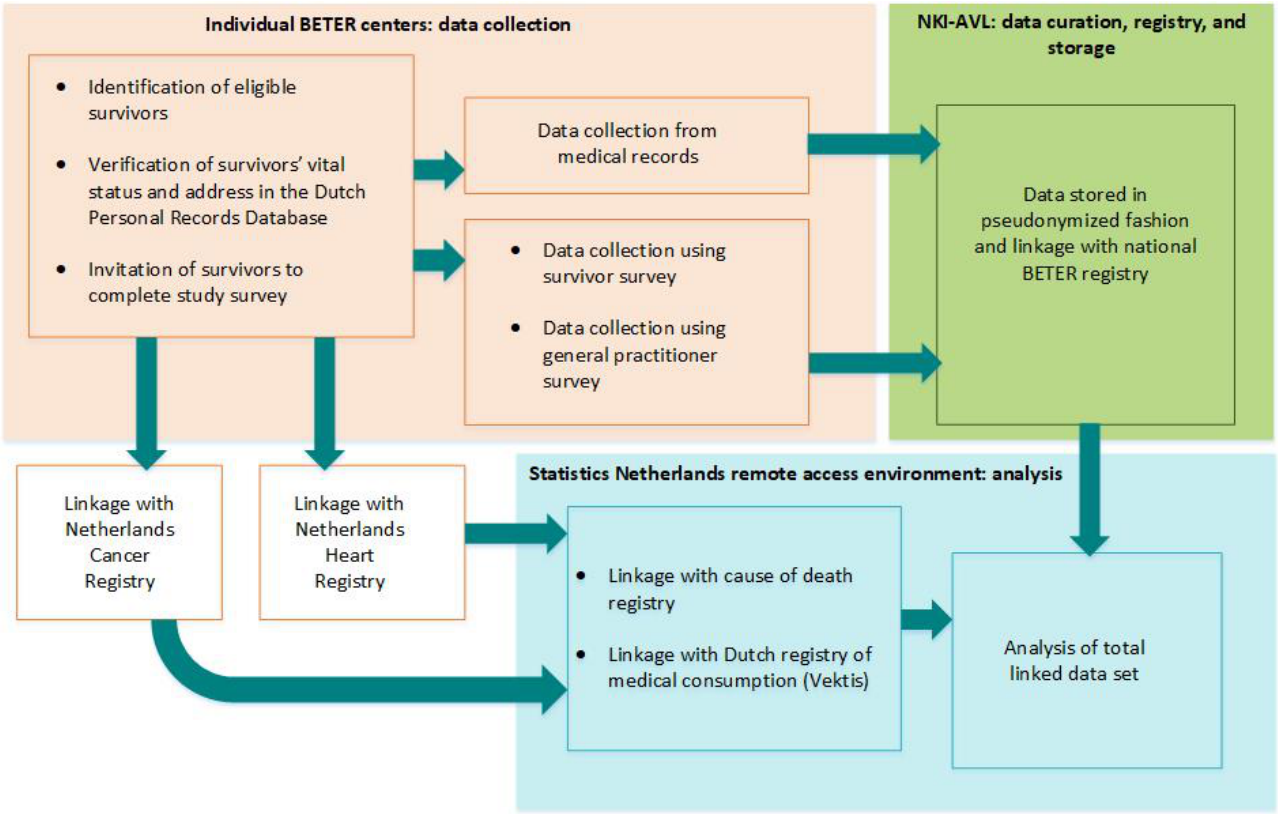
Recruitment and Informed Consent Procedure

For the detailed recruitment and informed consent procedure, refer to the detailed informed consent procedure section in Multimedia Appendix 1. In brief, in intervention centers, study patients are identified and linked to the national Personal Records Database to verify survivors' vital status and current address. Subsequently, eligible survivors are invited for study participation by their (former) treating radiation oncologist or hematologist. In control centers, survivors who match an intervention group survivor are selected from the previously established cohort of survivors of HL from that specific center (Design section) [17]. Matched controls who are alive and do not experience adverse health outcomes in an advanced stage (eg, metastatic breast cancer or end-stage heart failure) are invited to the BETER clinic. After the invitation for BETER survivorship care, these controls are invited for study participation using the same procedures as for the intervention group. Survivors who do not respond to the study invitation will receive reminders; nonattenders receive 1 reminder approximately 4 weeks after the initial invitation and attenders receive 2 reminders after approximately 4 and 8 weeks, respectively. Survivors who died during follow-up are included without informed consent.

Data Collection

Basic survivor characteristics and detailed treatment information for the included survivors are extracted from the comprehensive database of lymphoma survivors treated in participating BETER centers between 1965 and 2012 [17]. For the INSIGHT study, we collect additional data from multiple sources: medical records, a survivor survey, a GP survey, and national registries. We provide explanations on each of the data collection procedures in the upcoming sections Medical Records, Survivor Survey, GP Survey, and Linkage With National Registries and in Figure 3.

Figure 3. Data collection procedures for the INSIGHT cohort study at individual BETER survivorship care clinics for 5-year survivors of Hodgkin lymphoma in the Netherlands and planned linkages with national disease registries. BETER: Better care after lymphoma, Evaluation of long-term Treatment Effects and screening Recommendations; NKI-AVL: The Netherlands Cancer Institute.



Medical Records

For attenders of the BETER clinics in the intervention group, complete follow-up data from the BETER clinic (ie, performed screening tests, results, diagnoses, and subsequent treatments) are collected from the medical records. For attenders in the control group, the date of the first BETER visit and the date of the last regular radiation oncology or hemato-oncology outpatient clinic visit are collected.

Survivor Survey

For attenders of the BETER clinics, the survivor survey includes, among others, the following standardized questionnaires: the EQ-5D-5L questionnaire yields utilities used to calculate QALYs, the 36-Item Short Form Health Survey is used to cross-sectionally assess the quality of life, and the Institute for Medical Technology Assessment Productivity Cost questionnaire is used to assess health-related productivity losses [32-34]. Textbox 1 shows an overview of the total study survey components for attenders of BETER care. The expected survey completion time for attenders of BETER care is 20-55 minutes depending on medical history. Nonattenders of the BETER clinics are asked to complete a survey that contains the following components: (1) a questionnaire assessing reasons to not attend a BETER clinic and possible screening or treatment for late effects elsewhere, (2) a short questionnaire on their current health status and lifestyle, and (3) the 6-item adapted version of the Cancer Worry Scale to determine distress associated with the increased risk of late effects [35]. The expected survey completion time for nonattenders is 10-25 minutes. Attenders in the intervention and control group receive the same survey; the same applies to the nonattenders in the intervention and control group.

Textbox 1. Overview of Improving Nationwide Survivorship care Infrastructure and Guidelines after Hodgkin lymphoma Treatment cohort study survey components for 5-year survivors of Hodgkin lymphoma who attended survivorship care at different Better care after lymphoma, Evaluation of long-term Treatment Effects and screening Recommendations (BETER) centers in the Netherlands. The survey is completed by study participants at enrollment in the period 2021-2024.

- EQ-5D-5L questionnaire (a standardized questionnaire that yields utilities used for calculating quality-adjusted life years)
- 36-Item Short Form Health Survey (standardized quality of life questionnaire)
- Institute for Medical Technology Assessment Productivity Cost Questionnaire (standardized health-related productivity losses questionnaire)
- Medical consumption (including general practitioner care, hospital care, physiotherapist, psychologist, and psychiatrist consultations)
- Knowledge about late adverse effects
- Satisfaction with BETER care and perception of benefit and burdensomeness of BETER care
- 6-item adapted Dutch version of the Cancer Worry Scale to determine distress about late adverse effects
- Current health status (diagnoses of possible late effects, medication use, and lifestyle). These questions are only included when the last BETER clinic visit was > 6 months ago

GP Survey

Each survivor's GP is approached by the survivor's former treating radiation oncologist or hematologist with a request to provide information for the INSIGHT study. Each GP receives a short paper survey enquiring about the survivor's medical history of (risk factors for) CVD, severe infections, vaccination status, hypothyroidism, and, if applicable, cause of death. The GP receives 2 reminders in case of nonresponse.

Linkage With National Registries

For all survivors included in the study (intervention and control group), we will obtain information on the incidence of clinical events of interest through linkage with disease registries. Information on breast cancer diagnoses will be obtained from Netherlands Cancer Registry, information on cardiac interventions and disease episodes will be obtained from the Netherlands Heart Registry, information on hospital admissions for CVD and serious infections and total medical consumption will be obtained from the Dutch health care costs registration (Vektis), and for those who died during follow-up cause of death will be obtained from Statistics Netherlands [36-39]. Furthermore, linkage with the national BETER registry data, containing BETER questionnaire data, will be performed. The BETER questionnaire is completed by survivors before their first BETER visit and contains extensive questions about current health, medical history, and lifestyle, which helps health care providers focus on actual symptoms of late adverse effects and lifestyle during the consultation [17]. The questionnaire answers are registered in the national BETER registry for research into late effects of lymphoma treatment upon survivor's written informed consent [17]. Due to the privacy regulations of Statistics Netherlands, the final linked data set can only be accessed and analyzed in the protected remote environment of Statistics Netherlands.

Ethical Considerations

The study protocol was approved by the institutional review board of the Netherlands Cancer Institute (IRB21-115), and we complied with local ethical approval guidelines at all participating sites. Survivors who opted out of the use of their medical data for the INSIGHT study, or medical research in general, are excluded from the study (refer to the detailed informed consent procedure section in Multimedia Appendix 1). Participating survivors did not receive financial compensation. Patient-identifying information is pseudonymized at the participating sites before storage at the Netherlands Cancer Institute and before data analysis in the Statistics Netherlands remote access environment.

Statistical Analysis

Burden of Disease and Secondary Outcomes

DALYs for the conditions of interest are calculated as the sum of the "years of life lost" (YLL) due to premature mortality and the "years lost due to disability" (YLD) for people living with the condition: DALY=YLL+YLD. The YLL is calculated by the number of deaths multiplied by the standard life expectancy at the age at which death occurs. Standard life expectancy in the Netherlands is available from Statistic Netherlands [40]. To estimate YLD during the follow-up period, the number of cases in that period will be multiplied by the average duration of the disease and a weight factor (disability weight) that reflects the severity of the disease on a scale from 0 (perfect health) to 1 (dead). Disability weights are extracted from the Global Burden of Disease Study 2019 or the most recent Global or preferably Dutch disability weight studies [41].

For continuous outcomes (eg, DALYs and health-related quality of life), multiple linear regression analysis will be used to study differences between the intervention and the control group. Important confounders will be controlled for by matching survivors in the intervention group to survivors in the control group based on patient and treatment characteristics, see Study population section. The influence of other potential confounders (eg, BETER hospital or socioeconomic status) on the regression coefficients will be examined, and these will be included in the model when associated with a ≥10% change in the regression coefficient.

For count data (eg, the incidence of late adverse events), negative binomial regression analysis or Poisson regression analysis (depending on the distribution of the data) will be used. To analyze the time between HL diagnosis and diagnosis of late adverse events, competing risk regression methods will be used, with death treated as a competing risk.

Missing data will be handled by multiple imputation when data are missing (completely) at random. Data analysis will be performed in R and RStudio software (The R Foundation).

Sample Size Calculation

The complete sample size calculation including detailed substantiation can be found in the Detailed sample size calculation section in Multimedia Appendix 1. In brief, in an intention-to-treat analysis, taking a BETER clinic attendance rate of 65% into account (A Nijdam, unpublished data, 2016), the expected difference between the intervention and the control group is 0.40 acquired DALY over a follow-up period of 5 years (our expected median follow-up is longer). With a 2-sided significance level of .05 and 80% power to detect a difference of 0.20 SD (small effect size) and larger, we need 393 patients in each study arm. When we take a 15% loss to follow-up and incomplete data into account, we need 452 patients in each study arm.

Cost-Effectiveness Analysis

To compare direct and indirect health care costs between the intervention and the control group, the Dutch health care costs registration (Vektis) and the handbook of costing studies from the Dutch National Health Care Institute (ZorgInstituut) will be used [39,42]. The effects of BETER survivorship care in comparison to the absence of standardized follow-up will be expressed in costs/DALY and costs/QALY. QALYs are derived by health state utilities. A utility is a standardized score between 0 and 1, with 0 reflecting death and 1 perfect health, measured by the EQ-5D-5L questionnaire [33]. The cost-effectiveness analysis will be performed using a discrete event simulation, where we will incorporate several screening strategies. A discrete event simulation analysis on the patient level will be used to simulate the sequences of events that occur as a continuous process over time and to calculate the mean associated costs and QALYs [43]. Uncertainty around the results will be quantified using nonparametric bootstrapping and cost-effectiveness acceptability curves. These curves will show whether BETER survivorship care is cost-effective or not for various values of the Dutch society's willingness to pay for 1 QALY. A budget impact analysis will be performed to estimate the 5-year financial consequences of the implementation of BETER survivorship care in the Dutch health care system. The following factors will be accounted for in the budget impact analysis: screening costs, the potential number of survivors of HL eligible for screening, and the costs of treatment of late adverse events.

Results

The study was funded in November 2020 and approved by the institutional review board of the Netherlands Cancer Institute in July 2021. The first survivor was included in November 2021, and by November 2023, a total of 445 survivors were included in the study intervention group, and 34 survivors were included in the control group. We expect to finalize recruitment by October 2024, data collection by early 2025, and data analysis by May 2025.

Discussion

Principal Findings

BETER is an internationally unique comprehensive infrastructure for adult oncology survivorship care. The INSIGHT study evaluates the effect of the implementation of BETER survivorship care for survivors of HL on survivors' burden of disease from late adverse events, associated health care costs, and quality of life. It will result in important new information on the (cost-)effectiveness of survivorship care in survivors of HL in clinical practice. With our study results, we will be able to evaluate current BETER screening guidelines and adapt them accordingly, if indicated [17,18]. These study results can therefore be used to improve the BETER survivorship care infrastructure and contribute to more effective evidence-based long-term survivorship care for survivors of HL. Moreover, some results could possibly be extrapolated to other cancer survivors (eg, survivors of breast cancer treated with anthracyclines). Importantly, the knowledge gained in this study can be used to better inform survivors of HL about the possible benefits of screening.

If our study demonstrates the cost-effectiveness of BETER survivorship care, we expect that more hospitals in the Netherlands will be motivated to reallocate resources to overcome the organizational hurdles to implement survivorship care according to the BETER guidelines, thus improving implementation of BETER care.

Taking into account the increasing number of cancer diagnoses, improving survival rates, and increasing health care costs, it is essential to ensure that BETER survivorship care is feasible and cost-effective in the long term. If we are able to identify diagnostic tests that have little added value in terms of diagnostic yield and clinical benefit, we will look into leaving them out in future BETER guidelines. Our results may demonstrate that additional diagnostics not recommended in the guidelines, which do not contribute to the cost-effectiveness of BETER survivorship care, are routinely performed. Also, we may observe that survivors are recalled for surveillance more frequently than advised in the guidelines. We can then provide this feedback to the centers in question, as it is not only important to reduce costs but also to make sure we do not overmedicalize survivors of HL.

Strengths and Limitations

An important strength of this study is the quasi-experimental design, which takes advantage of the situation in which BETER care has been gradually implemented in different lymphoma treatment centers in the Netherlands over the past decade. This provides the unique opportunity to study the added value of BETER survivorship care by comparing survivors who did receive such care over the past 6-10 years with a matched comparison group that did not, thereby minimizing the risk of bias in our observational study. A second strength of this study is the comprehensive data collection on the incidence rates of late adverse events from multiple sources: survivors, survivors' medical records, survivors' GPs (and if necessary medical specialists), and national disease registries. This allows us to verify our data, in order to overcome uncertainties and selection

bias related to patient-reported outcomes and potential missing data, for example, due to failed linkages. Third, very importantly, this study design provided us with a representative study population. As we have identified the entire cohort of 5-year survivors who were treated for HL in the centers participating in BETER, we can also include survivors who died during follow-up [17]. Moreover, we also include the data of survivors who did not respond to the invitation to visit the BETER clinic and those who did not respond to our INSIGHT study invitations. The only survivors not included in our study are those who explicitly objected to the use of their data for the INSIGHT study or medical research in general (expected 2%-7%). Including nonattenders of BETER care in this study enables us to accurately assess the total number of survivors eligible for BETER care and perform the cost-effectiveness analysis from a societal perspective of the Netherlands.

The first limitation of our analysis of patient-reported outcomes such as quality of life and risk perceptions is that our results can be affected by selection bias, as we expect 60%-70% of survivors to complete our study survey. A second limitation may be that our sample size calculation is based on a cumulative difference in the burden of disease of CVD, breast cancer, severe infections, and hypothyroidism. Therefore, we may have limited power to perform subanalyses of parts of the disease-specific screening guidelines separately. A third limitation is that we could only follow survivors treated for HL from 1971 to 2011 who were screened for late adverse events from 2013 onward. As late adverse events of interest may have already developed before the start of the BETER screening program in a substantial proportion of the included survivors, we may underestimate the yield and potential benefit of screening. Finally, the expected study follow-up of approximately 8 years may not be sufficient to accumulate enough events of interest to be able to detect a significant difference in the burden of disease between the groups. Therefore, we plan to prospectively follow our cohort and repeat linkages with disease registries after 5-10 years.

Comparison With Prior Work

The INSIGHT study is not only the first evaluation of survivorship care provided at BETER clinics but also the first cost-effectiveness study of structured cancer survivorship care worldwide that uses real-world data and focuses on multiple types of screening. Previous studies performed on survivors of HL and childhood cancer reported on the screening yield of 1 type of screening, lacked a valid comparison group, or used simulations models or hypothetical cohorts to study its cost-effectiveness [19-25,44].

For example, the study by Chow et al [23] reported on underdiagnosis and undertreatment of hypertension, hypercholesterolemia, and diabetes in adult survivors of childhood cancer at high risk of premature CVD in the United States Childhood Cancer Survivor Study cohort and compared the prevalence rates to the general population [23]. Furthermore, in the St. Jude Lifetime Cohort study of childhood cancer survivors, Armstrong et al [24] and Palmer et al [25] evaluated echocardiographic detection rates of impaired left ventricular ejection fraction and diastolic dysfunction, respectively [24,25]. Howell et al [44] described breast cancer cases detected in the United Kingdom national GP mammography screening program for survivors of HL and compared the findings (eg, stage) to breast cancer cases diagnosed in the general population. Although these studies provide valuable information, the results do not demonstrate the incremental value of screening due to the lack of a valid comparison group.

Chen et al [21] evaluated lipid screening and statin therapy in a hypothetical cohort of 30-year-old 5-year survivors of HL treated with chest irradiation. The authors compared no screening with screening at 1-, 3-, 5-, or 7-year intervals and used Markov models to calculate life expectancy, quality-adjusted life expectancy, and lifetime cost. Wong et al [20] simulated life histories using Markov health states to assess the effect of the implementation of echocardiographic screening followed by angiotensin-converting enzyme inhibitor and β-blocker therapy in survivors of childhood cancer on cost-effectiveness, life expectancy, QALYs, and the cumulative incidence of heart failure 30 years after a cancer diagnosis. An important limitation of the above-mentioned studies is that the actual efficacy of statins, angiotensin-converting enzyme inhibitors, and β-blockers in survivors of HL and childhood cancer is unknown and therefore had to be estimated based on assumptions. Furzer et al [22] used simulation models to evaluate the cost utility of 8 different breast cancer screening strategies for survivors of HL treated with chest radiotherapy, with annual magnetic resonance imaging and mammography from age 25 years onward as a reference (no comparison to population screening only). A limitation of this study is that model assumptions about the efficacy of breast cancer screening at young ages were mostly based on *BRCA1/2* mutation carriers, who are known to have different breast cancer tumor characteristics than other women [45].

The German Hodgkin lymphoma study group described the yield of hypothyroidism with thyroid-stimulating hormone screening in survivors of HL (median time since treatment 6 years, median follow-up of 70 months, IQR 12-243 months) [11]. Our study will examine the efficacy of thyroid-stimulating hormone screening after longer time intervals since HL treatment and will also provide longer follow-up after the start of screening. To our knowledge, no studies describing health gains from vaccinations or prescription of on-demand antibiotics in (functional) asplenic survivors of HL have been published. The current BETER afunctional spleen guideline is based on knowledge about patients who had a splenectomy for other indications and on the known increased mortality from infectious disease after spleen irradiation in survivors of HL [3,9,17,18,26]. This study will provide the opportunity to compare incidences of severe infections among survivors of HL who did and did not receive the recommended vaccinations and antibiotics.

Little is known about the effect of survivorship care on survivors' knowledge about late adverse effects and possible distress about these risks. Signorelli et al [46] performed a systematic review and described that attenders of survivorship care (compared to nonattenders) demonstrated increased knowledge about their treatment and diagnosis, and although not significantly, attenders tended to report more distress associated with the risk of late effects [46]. With our study, we can identify areas of insufficient risk perception in survivors of

HL attending the Dutch survivorship program, with the aim of improving risk communication by BETER health care providers.

Conclusions

INSIGHT is the first evaluation of (cost-)effectiveness of structured cancer survivorship care for survivors of HL based on real-world data. It will result in new knowledge on the (cost-)effectiveness of survivorship care in lymphoma survivors in clinical practice. The results are expected to contribute to more effective evidence-based long-term lymphoma survivorship care and could also be of interest to other survivorship programs.

Acknowledgments

This research was supported by the Netherlands Organization for Health Research and Development (ZonMw; grant number 10330022010009) and an institutional grant from the Dutch Cancer Society and the Dutch Ministry of Health, Welfare and Sport. The INSIGHT study is conducted in close collaboration with the Erasmus Medical Center (CPM Janus and C So-Osman), University Medical Center Utrecht (RJ de Weijer and R Oostvogels), Haaglanden Medical Center (SS Gommers and LCJ te Boome), Amsterdam University Medical Center (JM Zijlstra, MJ Kersten, and LA Daniëls), Verbeeten Institute (MGA Schippers and KMS Verschueren), Amphia hospital (RS Boersma), Leiden University Medical Center (SE Rademakers), University Medical Center Groningen (FG Stedema and WJ Plattel), Haga hospital (R van Os and LH Böhmer), Catharina hospital (M van den Berg and MR Nijziel), Meander Medical Center (AC Kroeze, AW Snijder, and JC Regelink), Gelre hospitals (M Kappert, LS Strobbe, ES Eerenberg, and K Dollenkamp), Máxima MC (HAM van Beek and HS de Lil) and Rijnstate hospital (W Deenik). We refer to the consortium website for the full list of participating BETER hospitals and clinicians [47].

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

EMJL participated in the study design and drafted this manuscript. BMPA, FEvL, and AN designed the study and supervised the drafting of this manuscript. JMZ and VPR participated in the study design and critically reviewed the manuscript. All authors read and approved the final manuscript and take full accountability for its content.

Conflicts of Interest

BMPA reports reimbursement costs for an oral presentation at the International Symposium on Hodgkin Lymphoma (2022) in Cologne, Germany.

Abstract

Background: Nursing-sensitive events (NSEs) are common, accounting for up to 77% of adverse events in hospitalized patients (eg, fall-related harm, pressure ulcers, and health care–associated infections). NSEs lead to adverse patient outcomes and impose an economic burden on hospitals due to increased medical costs through a prolonged hospital stay and additional medical procedures. To reduce NSEs and ensure high-quality nursing care, appropriate nurse staffing levels are needed. Although the link between nurse staffing and NSEs has been described in many studies, appropriate nurse staffing levels are lacking. Existing studies describe constant staffing exposure at the unit or hospital level without assessing patient-level exposure to nurse staffing during the hospital stay. Few studies have assessed nurse staffing and patient outcomes using a single-center longitudinal design, with limited generalizability. There is a need for multicenter longitudinal studies with improved potential for generalizing the association between individual nurse staffing levels and NSEs.

Objective: This study aimed (1) to determine the prevalence, preventability, type, and severity of NSEs; (2) to describe individual patient-level nurse staffing exposure across hospitals; (3) to assess the effect of nurse staffing on NSEs in patients; and (4) to identify thresholds of safe nurse staffing levels and test them against NSEs in hospitalized patients.

Methods: This international multicenter study uses a longitudinal and observational research design; it involves 4 countries (Switzerland, Sweden, Germany, and Iran), with participation from 14 hospitals and 61 medical, surgery, and mixed units. The 16-week observation period will collect NSEs using systematic retrospective record reviews. A total of 3680 patient admissions will be reviewed, with 60 randomly selected admissions per unit. To be included, patients must have been hospitalized for at least 48 hours. Nurse staffing data (ie, the number of nurses and their education level) will be collected daily for each shift to assess

the association between NSEs and individual nurse staffing levels. Additionally, hospital data (ie, type, teaching status, and ownership) and unit data (ie, service line and number of beds) will be collected.

Results: As of January 2024, the verification process for the plausibility and comprehensibility of patients' and nurse staffing data is underway across all 4 countries. Data analyses are planned to be completed by spring 2024, with the first results expected to be published in late 2024.

Conclusions: This study will provide comprehensive information on NSEs, including their prevalence, preventability, type, and severity, across countries. Moreover, it seeks to enhance understanding of NSE mechanisms and the potential impact of nurse staffing on these events. We will evaluate within- and between-hospital variability to identify productive strategies to ensure safe nurse staffing levels, thereby reducing NSEs in hospitalized patients. The TAILR (Nursing-Sensitive Events and Their Association With Individual Nurse Staffing Levels) study will focus on the optimization of scarce staffing resources.

Introduction

Overview

The link between patient outcomes and adequate nurse staffing levels has been extensively studied internationally over the last 2 decades. To avoid negative patient outcomes, such as adverse events, adequate staffing levels and combinations of skills and grades are needed. In hospital settings, up to 77% of adverse events are attributed to nursing care [1]. Nursing-sensitive events (NSEs) are part of adverse events that are specifically affected, caused, and influenced by the processes or structures of nursing care, though nursing is not exclusively responsible [2]. Examples of NSEs are hospital-acquired urinary tract infections, pressure ulcers, pneumonia, or deep venous thrombosis [3]. NSEs may be accompanied by additional monitoring or treatment [4]. Compared to studies on adverse events and their characteristics, few studies include all types of NSEs and their prevalence, preventability, and severity [5]. A recently published study exploring NSEs in home care settings found that 73% of the NSEs were preventable, and approximately 37% resulted in temporary harm that required additional health care resources [6]. In addition to the burden on the patient, NSEs generate high medical costs by necessitating additional monitoring or treatment [5,7]. Different methods to identify and assess NSEs are available. Currently, there is no gold standard for identifying and assessing NSEs. However, retrospective record review (RRR) methods, such as the Global Trigger Tool [5] and the Harvard Medical Practice Study methodology [8], seem most promising. Compared to other methods (eg, critical incident reporting systems and patient safety indicators), record review facilitates the detection of more adverse events, thereby minimizing the underreporting of NSEs [9]. To prevent and reduce NSEs and ensure quality nursing care, appropriate nurse staffing levels are needed [8,10]. Nurse staffing refers to the number and qualifications of nurses relative to the care demands of patients, often expressed as staffing levels (eg, nurse-to-patient ratios), skill mix (ie, the composition of the nursing team in terms of qualifications), and grade mix (ie, educational levels of the nursing team) [9]. Providing optimal nurse staffing levels has been a challenge for health care systems worldwide. Having too few nurses increases the risk of NSEs and decreases the quality of care (F Gratwohl, N Grossmann, S Musy, and M Simon, unpublished data, September 2018) [11,12]; it also increases the risk of nurse burnout and job dissatisfaction, which impedes the recruitment and maintenance of the nursing workforce [13]. Evidence suggests that the occurrence of negative patient outcomes is related to staffing [14], but there is a lack of systematic reviews focusing on different types of NSE.

Despite studies that substantiated the link between nurse staffing and NSEs [14-16], operational and methodological challenges have limited the practical impact of this research. Typically, staffing studies describe only constant staffing exposure at the unit or hospital level without assessing individual patient-level exposure to nurse staffing during the hospital stay [17]. Methodological challenges include the omission of important variables (eg, shift patterns, skill mix, and patient turnover) [10,16]; common method variance (ie, dependent and independent variables derived from the same survey of nurses); and simultaneity, which refers to common-cause variables affecting both staffing and outcomes, such as patient severity [16]. Only a few studies have assessed nurse staffing and patient outcomes using a longitudinal study design [10,15,18], and most of these studies were single-center studies; there is a lack of multicenter or international studies allowing generalizability. Therefore, there is a need for multicenter longitudinal studies of the association between individual patient-level exposure to nurse staffing and all types of NSEs, with improved potential for generalization.

To advance the field, there is a strong need to determine the optimal intervention strategies for nurse staffing levels required to reduce the risk of NSEs. This study is the first step in generating data aimed at structuring and planning future intervention strategies.

Objectives

The overall aim of the TAILR (Nursing-Sensitive Events and Their Association With Individual Nurse Staffing Levels) study is to investigate the association between NSEs and individual nurse staffing levels. The specific aims are as follows:

1. To determine the prevalence, preventability, type, and severity of NSEs across sites using structured RRR methodology
2. To describe individual patient-level nurse staffing across hospitals
3. To describe the effect of nurse staffing on NSEs in hospitalized patients
4. To determine thresholds of safe nurse staffing levels and test them against NSEs in hospitalized patients

Methods

Design

TAILR is an international multicenter study with a longitudinal and observational research design, running from 2021 to 2025. Altogether, 4 countries are participating in the study: Switzerland, Sweden, Germany, and Iran. Those countries make up the international TAILR consortium. Except for Switzerland, all data will be collected within the TAILR study. For Switzerland, data from the CroWiS (Crowd Working in der Schweiz) study will be used for data collection and analyses. CroWiS is a multimethod study with the overall aim of investigating the effect of temporary nurses in Switzerland [19].

Setting and Sample

For the different countries, different numbers of hospitals and units are included in the TAILR study. The numbers of participating hospitals and units range from 1 to 4 hospitals and 4 to 21 units, depending on the country. Across all countries, 4 medical, surgical, or mixed units for each hospital are participating in the study, which is a total of 11 hospitals and 49 units. The study also includes acute care hospitals providing elective care. The inclusion criteria for units are as follows: they must have at least 10 patient beds and are either medical or surgical. Units with elevated levels of care, such as intensive or intermediate care, will be excluded, as these units have higher levels of staffing. In Sweden, 1 of the 4 hospitals is a pediatric hospital that is part of a university hospital providing adult care as well. For this pediatric hospital in the TAILR study, 9 units will be included. For pediatric care, neonatal care units will be included, but these data will be analyzed separately in the pediatric cohort. Table 1 shows the setting and sample information for each country.

During the 16-week observation period, 60 admissions will be randomly selected from all eligible admissions per unit and will be reviewed. For adult care, patients ≥18 years of age will be included. For pediatric care, no inclusion criteria for age will be applied. All patients must be hospitalized for at least 48 hours at a TAILR unit, and the admission record must be closed. The stay in the TAILR unit ends after patients have been discharged, when the length of stay exceeds 14 days or when patients are transferred from the TAILR unit for more than 12 hours. If the patient has a length of stay >14 days, the data collection ends at the end of day 14. If a patient is readmitted, this admission is considered a new admission.

Table 1. Number of hospitals, units, and patients, along with shift system information, including the number of shifts for each country and in total.

Country and hospital	Hospital, n	Units, n	Shifts per day, n	Patient admission, n	Number of shifts, n	
					Weekday	Weekend
Germany						
Acute adult care hospital	3	12	3-14	720	Minimum 2880	Minimum 1152
Iran						
Acute adult care hospital	1	4	3	240	1152	192
Sweden						
Acute adult care hospital	3	12	3	720	2880	1152
Pediatric care hospital	1	9	3	560	2160	864
Total	4	21	N/A[a]	1280	5040	2016
Switzerland						
Acute adult care hospital	3	12	3	720	2880	1152
All countries						
Acute adult care hospital	10	40	N/A	2400	Minimum 9792	Minimum 3648

Total	11	49	N/A	2960	Minimum 11,952	Minimum 4512

[a]N/A: not applicable.

Variables and Measurements

Patient Characteristics and NSEs

Patient characteristics (eg, age and sex), clinically relevant variables (eg, primary diagnosis and patient-based workload for activities of daily living), and NSEs will be collected from patient records using systematic RRR, inspired by commonly used RRR methods. For the collection of the type of NSEs, we will use a set of predefined events (eg, deficiencies in drug management, deterioration of vital signs, health care–associated

infections, gastrointestinal impairment, pain, and pressure ulcer) based on a literature review [3,5,6,20]. Furthermore, there is an option to enter "other" NSEs in the patient record, which allows all types of NSEs to be included. In addition to the type of NSE, preventability, severity, timing, origin, and potential contributing causes will be assessed per NSE. For severity, a slightly modified version of the National Coordinating Council for Medication Error Reporting and Prevention will be used, ranging from "An event that reached the patient but did not cause harm" to "Contributed or resulted in the patient's death."

Staffing Assessment

The shift-level nurse staffing data of the participating units will be collected using routine data or data from unit schedules depending on the hospital. For each day and each shift during the observation period of 16 weeks, each registered nurse (RN), specialist RN, nurse with an associate nursing degree (AND), unqualified helper, and student or trainee directly involved in patient care on the unit will be considered in the staffing assessment. Informal caregivers will be excluded. The assessment also includes whether the staff member is a temporary worker on the unit. We define "temporary" as a staff member deployed from a different unit than the target TAILR unit, a hospital pool, or an external agency. We will not differentiate between temporary nurses who only work for a single or few shifts and nurses who are deployed for weeks or months. To identify shifts with missing nurses, we will clarify whether the number of staff on this shift was as planned or not. If not, the missing number of nurses stratified by nursing degree will be entered.

Patient Counts and Turnovers

To assess the workload of nurses in relation to patient turnover, routine data regarding the number of patients, discharges, admissions, and transfers will be collected. Moreover, we will assess the number of out-of-specialty patients to account for additional workload for nurses.

Unit Survey

The study-specific 26-item unit survey assesses the organizational characteristics of the participating units, such as size (bed count) and service line. Additionally, data about the used care system and the used system to describe nursing care demands, workload, or patient acuity will be part of the unit questionnaire.

Hospital Survey

The study-specific hospital survey (8 items) will be used to collect hospital-level characteristics and statistics, such as ownership status (eg, private, not-for-profit, and public) and type (ie, district, general, and teaching hospital), as well as regulation, financing, and provision of the hospital.

Survey Translation and Validity Testing

The study manual, surveys, and assessments were developed in English. For Germany and Iran, they were translated into German and Farsi (Persian), respectively. Using a modified Brislin protocol, a systematic translation process was conducted [21]. After translation, an expert panel review of bilingual clinical and research nurses fluent in each target language reviewed each item in terms of cultural adaptations. To ensure comprehensibility and to check for response patterns, the entire German and Farsi versions of the NSE assessment sheet were pilot tested with nurses of varying educational levels. For all language versions, adaptations were made, as necessary, for wording and clarity.

Data Collection

The data observation period started in 2022. The data collection covers an observation period of 16 weeks at each hospital, but the start dates for hospital enrollment will be staggered between and within countries. We opted for this stepwise approach to ensure proper supervision and optimal use of resources during the data collection process, considering unit availability. Data will be collected digitally or with paper and pencil.

In Sweden and Switzerland, the random sampling of 60 admissions per unit will be carried out at the end of the 16-week observation period. In Germany and Iran, to use the available data collection resources, a random sampling of 15 admissions for each unit occurred 4 times with an interval of 4 weeks. Therefore, the number of included admissions in Germany and Iran is the same as those in the other participating countries, that is, 60 admissions per unit within 16 weeks of observation. Data will be collected by the internal RNs of the corresponding hospital or RNs who have experience working in the corresponding hospital. All data collectors will receive standardized education with the study manual, PowerPoint presentations, test examples, test records, and discussion sessions. For data quality control, an RN experienced in research for comprehensibility and plausibility will monitor the entered data.

The shift-level staffing assessments will be collected every day (from Monday to Sunday) for every shift (ie, morning, afternoon, night, and intermediated shifts). In Germany and Iran, data will be entered directly into a cloud-based electronic data capture platform by the ward manager of the TAILR unit, a hospital internal RN or a research team member. All data collectors for staffing assessment will receive a 3-hour education session with test entries and discussion sessions. In Sweden, shift data will be generated automatically by the corresponding hospital staffing system. In Switzerland, staffing data will be manually extracted from hospital staffing systems and entered into a secure web platform by members of the research team.

The hospital- and unit-level surveys will be conducted retrospectively after the main data collection. Data will be collected using routine data. If no routine data are available, interviews between TAILR country-specific research group members, unit managers, and hospital managers will be conducted.

Data will be stored in a cloud-based database, with a server in the Netherlands, that complies with the European Union General Data Protection Regulation. Access to the platform is restricted to the TAILR research group members and data collectors at specific sites.

Sample Size

We used 3 hospitals as the basis for sample size considerations. Assuming the same NSE rate of 36.4% as in a Swedish study [5], a sample size of 720 (95% CI 33.3%-39.5%) patients is expected (aim 1). A simulation (500 iterations per cell) of a 3-level generalized linear mixed model with a count variable for each shift above a low staffing threshold, with 15% of patients exposed to 1 or more shifts, was performed. We set the random effects at the unit and hospital level to 0.1, indicating an intraclass correlation coefficient (ICC) of 0.03. Based on an odds ratio of 1.10 and a sample of 60 patients per 4 units in 3 hospitals, the power was 100%. With a lower odds ratio of 1.07, representing the smallest effect of interest for a sample of 60 patients per 4 units in 3 hospitals, the power was still 0.91. As the ICC is unknown, we also assessed ICCs of 0, 0.06, and 0.15, resulting in the power ranging from 90% to 100% for both effect sizes, with a sample of 720 patients. Reducing the number of units to 3 per site, the total sample size was reduced to 540, with the power dropping to 70%-96%, depending on the specification. As the weights will only be known after the study has been conducted [22], this power calculation is based on a generalized linear mixed model without inverse probability weighting.

Data Analysis

Aim 1

A descriptive analysis of the prevalence, preventability, types, and severity of NSEs will be carried out. We will calculate the frequencies and percentages with 95% CIs for NSE type, severity, and preventability. We will calculate the prevalence of NSEs per 1000 patient days and 100 patient admissions. To determine the quality of the review process, we will assess interrater reliability between 2 primary reviewers from a random sample of every tenth of the admissions via the Cohen kappa (κ) coefficient for review stage 1. Agreement between reviewers is defined as (1) agreement on the presence of potential NSEs by calculating Cohen kappa and (2) agreement on the number of NSEs by calculating the weighted Cohen kappa, where high disagreement corresponds to high weights.

Aim 2

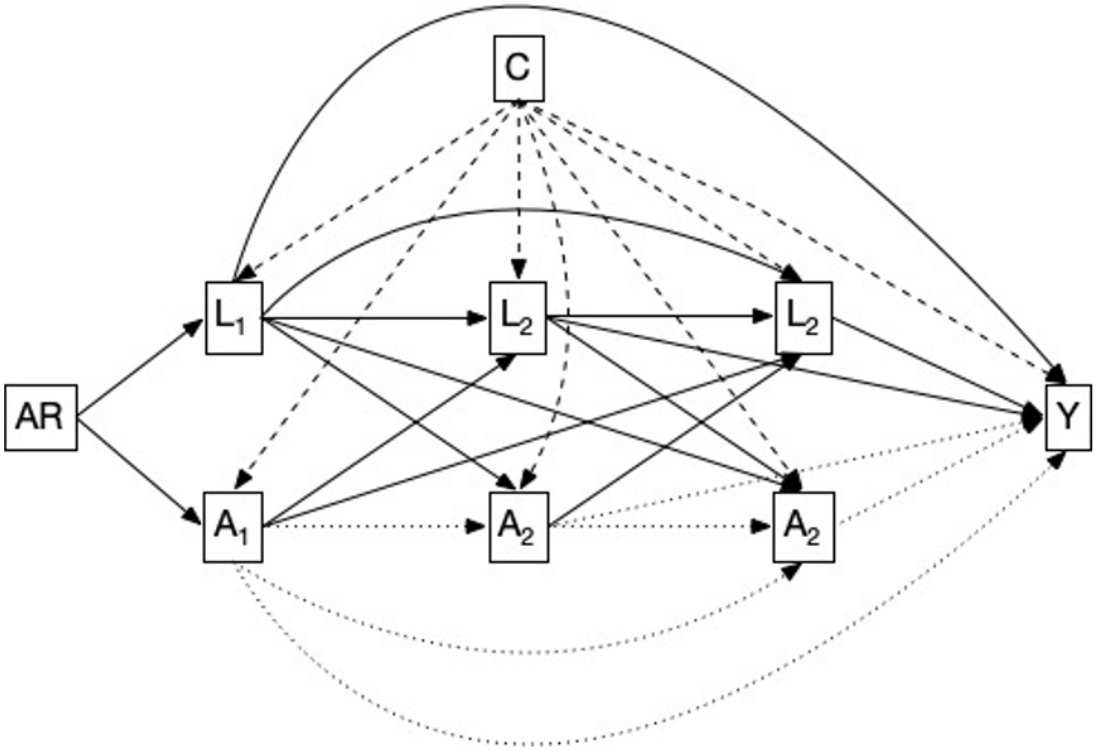
In the first step, a descriptive analysis of the numbers of patients and nurses and the patient-to-nurse ratios for different staff categories (eg, RNs, specialist RNs, nurses with ANDs, and unqualified staff) over time will be conducted. Extreme staffing shifts will be defined as those with 50% more or fewer patients per nurse for each unit based on the shift median.

In the second step, the workload will be modeled with the observed-over-expected (O/E) estimator. The O/E estimator is the observed number of nurse staff on a shift divided by the expected number of nurse staff based on the shift, patient, and unit characteristics; the O/E estimator is an extension of the adjusted staffing measure we used in a previous study [23]. For the O/E estimator, we will predict the number of different staff groups (eg, RNs, nurses with ANDs, and unqualified staff) with a multivariate generalized linear model of the Poisson family, with separate models for each unit. This model will take patient characteristics; primary and secondary diagnoses; shifts; and the number of patients, admissions, transfers, and discharges into account. The observed number of nurse staff per shift will be divided by the expected value derived from the multivariate generalized linear model. The O/E estimator will then be used to describe the staffing variability over time for each patient. Furthermore, the coefficients of the model will allow us to compare units, hospitals, and countries in terms of their nurse staffing provision.

Aim 3

We will evaluate the suspected causative effect of nurse staffing on selected NSEs using a directed acyclic graph describing the hypothesized mechanism over time (Figure 1). Directed acyclic graphs describe a set of time-invariant individual-level confounders, such as age (A) or sex (C), time-variant confounders, such as patient severity on a given shift ($L_{1...n}$); and the time-variant exposure variable of the O/E estimator for nurse staffing ($A_{1...n}$). The minimal adjustment set also includes the admission reason, which determines the unit to which a patient is admitted. To estimate the causal effects, 3 conditions need to be met. The first condition is the "exchangeability assumption." An uncontrolled variable that influences exposure and outcome would violate this assumption. As the supply side (ie, the available nurse staffing resources) is determined by the unit type and relatively fixed rosters, the exposure is primarily driven by the volatility of the demand side (ie, the patients admitted to the unit). Therefore, within units, the exchangeability assumption for the exposure should hold. Indeed, occupancy might influence patient admissions or discharges, potentially creating a backdoor path. We will, therefore, consider occupancy as a variable in a sensitivity analysis. Second, the "positivity" assumption is met by the design, as individual exposure to high- or low-staffed shifts occurs continuously throughout the index admission. We will use descriptive analysis to confirm this assumption. Last, the "consistency assumption" requires that the level of exposure is identical for all patients. Although consistency is provided in the way the exposure is operationalized, the nursing staff will allocate available time between patients according to their needs within shifts. The severity measure will partially account for this. We will use nurse activity data, which are available for some sites, to explore this issue. To estimate a causal effect of nurse staffing exposure on each NSE of interest, we will construct a marginal structural model using inverse probability weighting [24]. According to VanderWeele et al [25], a marginal structural model can assess the joint effects of time-varying exposure. To calculate the weights, we will use the R package "ipw" [26]. To fit the model, we will use a generalized mixed model of the binomial family with the lme4 package in R software (version R-4.3.3; R Foundation for Statistical Computing) [27].

Figure 1. Directed acyclic graph of the staffing and nursing-sensitive events The graph describes a set of time-invariant individual-level confounders, such as age (A) or sex (C); time-variant confounders, such as patient severity on a given shift ($L_{1...n}$); and the time-variant exposure variable of the observed-over-expected estimator for nurse staffing ($A_{1...n}$). The minimal adjustment set also includes the admission reason (AR), which determines the unit to which a patient is admitted. Y: outcome.



Aim 4

To help optimize and predict the necessary nursing staffing needs in hospitals to decrease NSEs, we will develop a simulation using the simmer package in R software. Simmer is a discrete-event simulation (DES) and automation software. DES is a flexible, computer-based modeling methodology characterized by the ability to simulate dynamic behaviors of complex systems and interactions between individuals, populations, and their environments. Compared with aggregate models without interaction, such as decision trees or Markov models, a DES can be more advantageous as an operational research technique to model complex systems at the individual level instead of the cohort level. After we have developed the DES model, we will test it against various data elements from our observational study, including the hospital bed size, number of nursing staff, patient flow structure, nursing practices, and NSEs. The process flow will be translated into a DES model, which will allow us to determine and validate the thresholds of safe nurse staffing levels.

Ethical Considerations

The TAILR study is compliant with the legal and ethical guidelines of the applicable federal, clinical (including participating hospitals), and academic partners (ie, universities and universities of applied sciences). Ethical approval for the proposed study has already been obtained according to national regulations (Germany [Ethik-Kommission Hochschule für Gesundheit, University of Applied Sciences Bochum]: 210602; Sweden [Swedish Ethical Review Authority]: TAILR.SE: 2021-04962; Iran [Ethics Committee of Kashan University of Medical Sciences]: TAILR.IR: IR.KAUMS.REC.1398.032; and Switzerland [Ethikkommission Nordwest- und Zentralschweiz]: CroWiS BASEC 2022-01121).

The study will follow all ethical standards of research conduct outlined in the Declaration of Helsinki and the General Data Protection Regulation for European countries. The project team will handle the patient- and unit-level staffing data with confidentiality. Each patient record included in the record review will receive a unique identification number, and the data in a cloud-based database will be pseudonymized. Participant names will not be disclosed. The published study data will be anonymous, and therefore, there will be no identification of individual participants. The study participants received no compensation.

Results

As of January 2024, the checking of plausibility and comprehensibility of patients' and nurse staffing data is ongoing in all 4 countries. Data analyses are planned to be completed by spring 2024, with the first results expected to be published in late 2024.

Discussion

This paper describes the study protocol for the TAILR study. TAILR is an international multicenter study with a longitudinal and observational design that will consider within- and between-hospital variability to identify productive and urgently needed strategies to ensure safe nurse staffing levels to reduce NSEs. More concretely, TAILR will provide important building

blocks to address and overcome a critical patient safety issue, that is, the lack of staffing guidance in national health policy and at local organizational levels. TAILR provides a unique opportunity to better understand the mechanisms of NSEs and the potential impact of nurse staffing on NSEs. Collecting data on nurse staffing and its association with NSEs in multiple countries, the TAILR study aims to provide a new perspective on optimal nurse staffing levels in hospitals and a unique innovative template for the evaluation of the association between NSEs in patients and individual nurse staffing levels within the international context. This study addresses a gap in current research, as emphasized by repeated calls for research to inform health policies on safe nurse staffing levels [15,28]. This need has been increased due to the COVID-19 pandemic and the increasing pressures to develop and maintain the nursing workforce in the participating countries as well as other countries [29].

TAILR will act as a model for nurse-led improvement strategies for safe staffing within different countries. First, for the participating hospitals, TAILR will create transparency by providing comparative data. Moreover, we will be able to identify hospital structures and processes that facilitate and challenge safe nurse staffing. By conducting workshops with the participating hospitals and stakeholders, the best practices will be identified and described to create applicable solutions based on the study results. Second, based on the workshops with hospitals and stakeholders, TAILR will provide data to develop recommendations that provide cornerstones for safe staffing policies in a country-specific context. Beyond mandatory minimum nurse staffing levels, TAILR will provide highly granular data to describe operational gaps in nurse staffing, which remain undetected in aggregate analysis. Potential safe staffing policies must consider the service line and patient acuity as well as hospital-specific factors, such as nurse pools, clear distribution of nursing and nonnursing tasks between nurses with different educational backgrounds, and the systematic assessment and monitoring of nurse staffing and NSEs. Third, the international TAILR study will create research outputs for the participating countries as well as other countries. For (inter)national stakeholders and the members of the international TAILR consortium, the study results will enable the definition of global quality improvement strategies.

Acknowledgments

We would like to thank all data collectors as well as the hospital and unit coordinators and unit managers.

Abstract

Background: Cancer is a life-threatening, stressful event, particularly for young adults due to delays and disruptions in their developmental transitions. Cancer treatment can also cause adverse long-term effects, chronic conditions, psychological issues, and decreased quality of life (QoL) among young adults. Despite numerous health benefits of health behaviors (eg, physical activity, healthy eating, no smoking, no alcohol use, and quality sleep), young adult cancer survivors report poor health behavior profiles. Determining the associations of stress (either cancer-specific or day-to-day stress), health behaviors, and QoL as young adult survivors transition to survivorship is key to understanding and enhancing these survivors' health. It is also crucial to note that the effects of stress on health behaviors and QoL may manifest on a shorter time scale (eg, daily within-person level). Moreover, given that stress spills over into romantic relationships, it is important to identify the role of spouses or partners (hereafter partners) in these survivors' health behaviors and QoL.

Objective: This study aims to investigate associations between stress, health behaviors, and QoL at both within- and between-person levels during the transition to survivorship in young adult cancer survivors and their partners, to identify the extent to which young adult survivors' and their partners' stress facilitates or hinders their own and each other's health behaviors and QoL.

Methods: We aim to enroll 150 young adults (aged 25-39 years at the time of cancer diagnosis) who have recently completed cancer treatment, along with their partners. We will conduct a prospective longitudinal study using a measurement burst design. Participants (ie, survivors and their partners) will complete a daily web-based survey for 7 consecutive days (a "burst") 9 times over 2 years, with the bursts spaced 3 months apart. Participants will self-report their stress, health behaviors, and QoL. Additionally, participants will be asked to wear an accelerometer to assess their physical activity and sleep during the burst period. Finally, dietary intake (24-hour diet recalls) will be assessed during each burst via telephone by research staff.

Results: Participant enrollment began in January 2022. Recruitment and data collection are expected to conclude by December 2024 and December 2026, respectively.

Conclusions: To the best of our knowledge, this will be the first study that determines the interdependence of health behaviors and QoL of young adult cancer survivors and their partners at both within- and between-person levels. This study is unique in its focus on the transition to cancer survivorship and its use of a measurement burst design. Results will guide the creation of a developmentally appropriate dyadic psychosocial or behavioral intervention that improves both young adult survivors' and their partners' health behaviors and QoL and potentially their physical health.

Introduction

Overview

Each year, more than 80,000 adolescents and young adults (aged 15-39 years) are newly diagnosed with cancer in the United States [1], and cancer is the leading cause of disease-related death among adolescents and young adults [2]. Mortality rates in adolescent and young adult patients with cancer have decreased over the past decade, and the 5-year relative survival rate for adolescent and young adult patients with cancer is 85.5% [3]. However, this high relative survival rate may mask the true burden of cancer among adolescent and young adult survivors. Although cancer and its treatment can be a traumatic event for any individual, it may be particularly so for adolescents and young adults because cancer can cause delays and disruptions in their successful developmental transitions across various domains of life: biological or physical (eg, cancer can cause hair loss, infertility, and weight change), psychological (eg, lack of control over life and disruption in progress toward life goals), educational or occupational (eg, disruption in education and unemployment), social or relationship (eg, problems in relationship with significant other and interference with plans for having children), and financial (eg, large debt and bankruptcy) [4-13]. Cancer and its treatment can also cause adverse long-term effects among adolescents and young adults (eg, premature or accelerated aging, cardiotoxicity, and second malignant neoplasms) [14,15] and heightened risk of chronic conditions (eg, cardiovascular disease, hypertension, diabetes, and asthma) [14,16,17], psychological issues (eg, depressive symptoms and fear of cancer recurrence), and lower quality of life (QoL) among adolescents and young adults compared with their peers without cancer [14,18].

Interest in and calls for research on adolescent and young adult cancer survivors have dramatically increased since 2006 when the Adolescent and Young Adult Oncology Progress Review Group published a report about the state of the science regarding cancer among adolescents and young adults [19]. However, adolescents and young adults affected by cancer still have vast unmet health care needs, including psychosocial care needs [7,20-23], and remain an understudied subgroup of patients with cancer. In addition, adolescent and young adult cancer survivors are often considered a single entity, and much of the existing data comes from studies that grouped adolescents and young adults together, although individuals in this age range may face different developmental tasks. Thus, the proposed study focuses on young adult survivors who were diagnosed with cancer at 25 to 39 years old [24], whose primary source of support is more likely to be romantic partners, whereas pediatric and adolescent survivors are more likely to depend on their parents. Due to a lack of existing studies specific to young adult survivors, the literature review below is based on studies among adolescent and young adult survivors.

Stress and Health Behaviors Among Young Adult Survivors

Overview

Strong evidence exists that engaging in healthy behaviors (eg, physical activity, low sedentary behavior, healthy eating, no smoking, no alcohol use, and quality sleep) is critical for cancer survivors' health, as it reduces the likelihood of cardiotoxicity, development of secondary cancers, cancer recurrence, and cancer-specific and all-cause mortality [25-28] and improves QoL [26,29]. However, young adult survivors report poor health behavior profiles. Specifically, young adult survivors report higher rates of unhealthy eating than their peers without cancer [14,16,30], and 26% of young adult survivors versus 18% of their peers without cancer report current smoking [14,16,30]. In addition, 50% to 90% of young adult survivors report at least some alcohol use [30], and 31% of young adult survivors report no leisure-time physical activity [14]. Further, approximately 40% of young adult survivors report experiencing sleep issues (eg, trouble falling or staying asleep in the previous week), and those who report difficulties with sleep also indicate higher levels of psychological distress [31].

While stress can substantially influence negative health outcomes [32] and poor health behaviors [33-35], it remains an understudied factor for young adult survivors' health behaviors. At present, almost nothing is known regarding the association between stress and health behaviors among young adult survivors. To better understand the association between stress and health behaviors in this survivor population, there are three crucial factors to be considered: (1) the transition from active treatment to survivorship; (2) interdependence between survivors and family caregivers, especially partners; and (3) within-person variabilities in stress and health behaviors.

Transition From Active Treatment to Survivorship

Transitioning from active treatment to posttreatment care is critical to cancer survivors' long-term health. However, the transition is challenging because survivors are often lost to systematic follow-up, and opportunities to effectively intervene are missed [36]. Many people finish their primary cancer treatment being unaware of their heightened health risks and are ill-prepared to manage their future health care needs [36]. In particular, young adult survivors struggle with the transition; with the abrupt cessation of intensive support (feelings of abandonment); and with challenges regarding returning to work, study, and social or recreational activities, which is complicated by ongoing disease or treatment impacts and a collective dearth of knowledge and resources on how to cope with these challenges during this time [37]. Thus, beyond cancer or treatment-specific stress (eg, symptom burden and concerns about cancer recurrence), stress regarding postcancer life adjustment needs to be addressed to better understand young adults' survivorship outcomes.

Interdependence Between Survivors and Their Partners

Cancer is often considered a "we-disease" [38]; survivors and their families tend to react to cancer as an interdependent system in which they influence each other's health. As an example of this interdependence, stress experienced by a cancer survivor or by their spouse or partner (hereafter partner) can affect the QoL of the other person in the relationship [38,39]. Beyond cancer care demands and stressors shared with the survivor (eg, concerns about cancer recurrence or progression), partners of survivors may encounter various stressors in their everyday lives (eg, work deadlines and social obligations) that can spill over into the relationship. Thus, neglect of partners' stress and coping and failure to include partners in young adult survivorship interventions may provide only a partial understanding of QoL and the challenges of the transition to survivorship among young adult survivors who have partners. However, to date, to the best of our knowledge, none of the existing interventions developed for and tested among young adult survivors to enhance their psychosocial outcomes (eg, QoL and psychological symptoms) have targeted survivor-partner dyads [40].

Within-Person Variabilities in Stress and Health Behaviors

Although previous studies have significantly advanced our understanding of cancer survivorship issues among young adults, most of these studies were cross-sectional and therefore could not capture potential dynamic changes in stress, health behaviors, and QoL during the transition to survivorship. While a few prospective longitudinal studies in young adult survivors exist [41-44], assessment intervals tend to range between 6 and 12 months and assume that stress, health behaviors, and QoL are fairly stable in the short term. However, evidence indicates that an individual's stress and health behaviors may vary across days of a week [45-53], which may further explain reported short-term (eg, daily) within-person variations in QoL [54]. Moreover, within-person variations in stress, health behaviors, and QoL may exist in survivor-partner dyads [45,46]. Thus, global, aggregated measures of stress, health behaviors, and QoL at the between-person level or over longer time scales at the within-person level (eg, "How much were you stressed out in the *last week*?"; "How much did you drink alcohol in the *past month*?"; and "How was your overall QoL in the *past year*?") may fail to reveal subtle and dynamic changes in stress, health behaviors, and QoL that can occur over shorter time scales (eg, daily intervals) [55].

A measurement burst design can assess both the between- and within-person processes in stress, health behaviors, and QoL. The design incorporates bursts of intensive repeated assessment within a relatively short period of time (eg, daily) that are repeated longitudinally, over more widely spaced intervals (eg, every 3 months), which will enable us to investigate the interaction of within-person processes that transpire over different time intervals [56,57]. However, to date, no published studies have investigated the extent to which young adult survivors and their partners facilitate or hinder each other's short- and long-term adjustment during the transition to survivorship using the measurement burst design.

This Study

Overview

The overarching purpose of this study is to investigate associations between stress, health behaviors, and QoL at both within-person and between-person levels over the transition to survivorship in young adult survivors and their partners to identify the extent to which young adult survivors' and their partners' stress facilitates or hinders their own and each other's health behaviors and QoL. To examine both within-person and between-person changes, we will implement a measurement burst design [56,57], in which participants will be asked to complete a daily survey for 7 consecutive days (a "burst") 9 times over 2 years, with the bursts spaced 3 months apart. Thus, there will be 3 levels: day, burst (3-month interval), and person. We have the following specific aims.

Aim 1

Aim 1 is to determine the within-person effects of stress on health behaviors at both day and burst levels. We hypothesize that on days or during bursts when stress is high, individuals are more likely to report physical inactivity, unhealthy eating, poor sleep quality, smoking (current smokers only), or alcohol use (current drinkers only). We also hypothesize that on days or during bursts when partners' stress is high, survivors are more likely to report these unhealthy behaviors, and vice versa.

Aim 2

Aim 2 is to determine the within-person, day-level, and burst-level effects of stress on QoL and the effects of health behaviors on QoL. We hypothesize that individual's QoL will be high on days or during bursts when their stress is low, when they perform physical activity, and when their sleep quality is good. We also hypothesize that on days or during bursts when partners' stress is low, when partners perform physical activity, and when partners' sleep quality is good, survivors are more likely to report high QoL, and vice versa.

Exploratory Aims

The two exploratory aims are as follows: (1) identifying 2-way cross-level interaction effects between day- or burst-level and person-level stress on health behaviors and QoL—in other words, we will examine whether the extent to which individuals' day- or burst-level stress influences their health behaviors and whether QoL is stable or varies depending on their average person-level stress; and (2) identifying 2-way cross-level interaction effects between day- or burst-level stress and person-level stable factors (eg, sex, race, age at diagnosis, and type of cancer) on health behaviors and QoL—that is, we will examine whether the extent to which individuals' day- or burst-level stress influences their health behaviors and whether QoL is stable or varies depending on their person-level factors.

Methods

Participants and Procedures

We aim to enroll 150 young adult survivors and their partners (ie, 300 individuals). Cancer survivors will be eligible if they (1) were diagnosed with cancer for the first time (ie, no previous history of cancer); (2) were a young adult (aged 25-39 years) at the time of diagnosis; (3) are within 3 months after the completion of treatment (eg, surgery, chemotherapy, and radiation therapy) with curative intent; (4) have no further planned cancer treatment (surgery, chemotherapy, radiation therapy, and immunotherapy) except for hormone therapy; and (5) have a valid phone number and email address. Survivors will be excluded if they (1) do not have significant others and (2) are unable to read, write, or speak English. Partners will be eligible if they (1) are aged ≥18 years; (2) are spouses or romantic partners (either married or not) cohabitating with the young adult survivor; (3) self-identify as the current primary caregivers of the young adult survivors; (4) are able to read, write, and speak English; and (5) have a valid phone number and email address.

During the study period, partners may change (because of separation, divorce, etc). If so, the current (ie, newly identified) partner (identified by the survivor, if applicable) will be contacted after permission is obtained from the survivor, and if interested and eligible, will be enrolled upon providing informed consent. We will record these changes in the dyads. If a member of a dyad drops out of the study, the other member will be asked to complete the study to investigate survivors' or partners' changes in stress, health behaviors, and QoL. If a survivor's cancer recurs during the 2-year study period, the dyad (ie, both the survivor and their partner) will be withdrawn from the study.

Cancer survivors will be recruited at The University of Texas MD Anderson Cancer Center. Potentially eligible survivors will be initially identified by research staff via electronic health records and will be contacted via telephone. Only those who are interested in the study will be further screened. If the survivor is eligible and interested, we will obtain the contact information of their partner for the partner's eligibility screening. If the partner is eligible and interested, the survivor-partner dyad will provide consent remotely via teleconferencing (eg, Zoom). We will also contact young adult cancer support groups and organizations through their websites and social media platforms to recruit non–MD Anderson cancer survivors. Interested individuals can submit a study interest form, and our research staff will contact them for phone screening.

All study procedures will be conducted remotely. After signed electronic consent forms are obtained, both survivors and partners will be asked to individually complete a baseline assessment in the form of a survey questionnaire via Research Electronic Data Capture (REDCap; Vanderbilt University), a secure, web-based app with controlled access designed to support data capture for research studies. This retrospective survey includes demographics, health status, stress, health behaviors, and QoL and will take approximately 1 hour to complete.

The daily survey will also be designed with REDCap, and the first daily survey period (ie, burst) will start within 10 days after completing the baseline survey. All participants will receive a survey link at 6 PM once per day for 7 consecutive days via their email; the brief 5-minute survey can be completed on the participant's electronic device (computer and smartphone). Survivors and partners will receive separate links and be asked to complete their daily reports in the evenings (before going to sleep) regarding stress, health behaviors, and QoL. Survivors and partners will be asked to complete assessments separately. Each survey link will be valid for only 12 hours. Thus, participants will not be able to submit data for a given day early, but they will be able to provide it the next early morning (until 6 AM). Regardless of when data are provided (that evening or the next morning), the questions will be specific to the person's experiences on the day the survey link is received.

During the burst, both survivors and partners will be asked to wear a blinded accelerometer (ActiGraph GT9X Link) on their nondominant wrist for 7 days and to engage in their daily routines as normal. The accelerometer with a prepaid envelope will be sent to the participants' residential address. After wearing the accelerometer for 7 days, participants will return the device using the envelope. Moreover, participants will be asked to choose 2 days (a day to recall a weekday's diet and another day to recall a weekend day's diet) over the 7 days when they are available for a dietary assessment (the Automated Self-Administered 24-hour Dietary Assessment Tool [58]). Participants will be told that research staff will call them on the selected days or times for the assessment.

Before each 7-day daily assessment period, participants will be asked to complete a retrospective survey similar to the baseline survey. We will mail out the accelerometer (with the prepaid envelope) in advance so that participants can wear the accelerometer and begin the 7-day daily survey without delays once they complete the retrospective survey.

Measures

Retrospective Survey Measures

Demographic and Medical Factors and Other Descriptive Factors and Covariates

Both survivors and partners will be asked about demographic (eg, sex, age, level of education and income, and marital or

relationship status) and health and health care information (eg, existing comorbidities, health insurance, and height and weight to calculate BMI). Tumor characteristics will be obtained from self-report and medical records (for MD Anderson patients). Financial toxicity will be assessed with the Comprehensive Score for Financial Toxicity instrument [59], which consists of 12 items scored on a 5-point Likert scale and reveals high internal consistency and test-retest reliability (Cronbach α=.90) in patients with cancer. Financial toxicity will be assessed for both survivors and partners. For partners, the caregiving burden will be assessed with the short form of the Zarit Burden Inventory, a 12-item measure [60], which is validated among cancer caregivers [61]. Each question is scored on a 5-point Likert scale from 0 (never) to 4 (almost always). High scores represent a higher burden.

Stress

All participants will be asked to identify the most stressful event in the past 30 days (open-ended question). Then, the 4-item Perceived Stress Scale [62] will be administered; participants will rate each item from 0 (never) to 4 (very often).

Health Behaviors

For both survivors and partners, self-reported physical activity will be assessed with the Godin Leisure-Time Questionnaire [63], a brief measure assessing aerobic exercise, which is widely used in diverse populations including those with cancer [64]. In addition, we will assess strength exercise (eg, weight lifting and circuit training) with 1 item from the Health Information National Trends Survey [65]. Smoking will be assessed with items adapted from the Patient-Reported Outcomes Measurement Information System (PROMIS) Smoking Initiative [66] and the Health Information National Trends Survey [65], which include smoking behaviors (eg, "Have you smoked at least 100 cigarettes in your entire life?" [yes/no]; if yes, "How old were you when you first started smoking?"; and "Have you ever used an e-cigarette, even one or two times?" [yes/no]). Alcohol use will be assessed with 2 items from the Alcohol Use Disorders Identification Test–Consumption [67] asking about alcohol use frequency and quantity. Eating behaviors will be assessed with the validated, National Cancer Institute Diet History Questionnaire-III, which consists of 135 food and beverage line items and 26 dietary supplement questions [68]. Sleep will be assessed with the Pittsburgh Sleep Quality Index [69], an 18-item self-rated questionnaire that assesses the quality of sleep and sleep disturbances.

Relationship

Relationship will be assessed with 1 item measuring transformation of motivation [70] (indicating motivation for disease management is transformed from self-centered [eg, cancer is my/your problem] to relationship-centered [eg, cancer is our problem]) and with the 5-item Emotional Intimacy Scale, which showed good internal consistency (0.88) and test-retest reliability (0.85) [71].

QoL Measurement

For young adult survivors, we will use the 30-item satisfaction scale from the Late Adolescence and Young Adulthood Survivorship-Related Quality of Life (LAYA-SRQL) [72]. The LAYA-SRQL measure comprises 10 domains, including existential/spirituality, coping, relationship, dependence, vitality, health care, education/career, fertility, intimacy/sexuality, and cognition/memory. Participants can endorse "not applicable" if any item is not relevant to them. To reduce participants' burden, we will use 11 items (ie, approximately 1 item per domain). In addition, both survivors' and partners' QoL will be assessed with the 10-item PROMIS–global health (measuring physical function, pain, fatigue, emotional distress, and social health) [73] so that we can compare the level of QoL between survivors and partners.

Daily Survey Measures

Both survivors and partners will report the following.

Stress

Stress will be assessed by adapting a measure of daily recording of coping with everyday stressful events [74]. Specifically, participants will be asked to report the most stressful event or issue of the day in their own words. Then, the level of distress will be assessed with 1 item asking, "On a scale from 1 to 100 (where 100 is the maximum distress that you could imagine and 1 is a minor annoyance), how stressful would you rate this problem or situation?"

Health Behaviors

The objective level of physical activity will be assessed with the accelerometer, which has strong reliability and validity [75]. Participants will wear a blinded accelerometer on their nondominant wrist for 7 days to assess typical physical activity. The Godin Leisure-Time Questionnaire [63] and the strength exercise item [65] will be asked to assess self-reported physical activity. Dietary intake will be assessed via telephone (from research staff) on 2 preselected days with the Automated Self-Administered 24-hour Dietary Assessment Tool [58], which produces a healthy eating index. The accelerometer will also objectively assess sleep (eg, total sleep time, sleep percentage, and wake after sleep onset). Thus, subjective sleep quality (over the last night) will be assessed with 1 item ("How would you rate your last night's sleep quality overall?") adapted from the Pittsburgh Sleep Quality Index [69]. Daily smoking (yes or no) will be assessed only among current smokers. Daily alcohol use (yes or no) and number of drinks will be assessed only among current drinkers. All of these self-reported measures will be assessed among both survivors and partners, adapting the aforementioned measures with the stem "TODAY, ..."

Relationship

The aforementioned 1 item measuring transformation of motivation [70] and 3 items from the Emotional Intimacy Scale [71] will be assessed with the reference "TODAY."

QoL Measurement

We will assess survivors' QoL with the same 11 items from the LAYA-SRQL. Survivors will be asked to answer each item with the stem "Please indicate the extent to which you are satisfied with this aspect of your life TODAY." Participants can endorse "not applicable" if any item is not relevant to them. For both survivors and partners, the PROMIS-global health

measure (4 items) [76] will also be assessed with the reference "TODAY."

Analytic Plans

We will first conduct extensive descriptive analyses of the retrospective and daily surveys over the 2-year period. Descriptive statistics, for example, means, SDs, and ranges for continuous measures, as well as frequencies and proportions for categorical variables, for the time-varying variables, will be calculated for each burst and for the 2-year period as a whole. Those of the baseline, person-level stable variables (eg, sex) will be calculated once. Preliminary bivariate analyses of the time-varying variables (eg, stress, health behaviors, and QoL) will be performed using within- and between-person correlations between them for each burst and for the 2-year period as a whole. Both correlations between an individual's own variables (eg, individuals' own stress and their health behaviors) and correlations between partners' and survivors' variables (eg, partners' stress and survivors' health behaviors) will be calculated.

For the aims of this study, we will design and fit mixed-effects multilevel models that adapt to the correlation structures of the underlying data process. For continuous (or near-continuous) outcomes (physical activity, eating behaviors, sleep, and QoL), linear mixed-effects models will be considered first, but depending on the distributional properties of the outcome (eg, skewed and censored), generalized linear mixed-effects models with proper distributions such as gamma or censored normal distribution and link functions such as log link will be used accordingly. For categorical outcomes (smoking and alcohol use), a logistic link function and binomial distribution will be used to build mixed-effects logistic regression models. All the models will be multilevel, incorporating burst-level trends, general day-to-day trends (centered), and deviations from the overall mean and day-to-day trends specific to burst (level 2) and to person (level 3) using random effects. Predictors will include survivors' and partners' day-to-day variables (person-burst-centered) to estimate within-person effects at level 1 and their burst-level variables (person-centered) to estimate within-person effects at level 2 (eg, the effect of day- or burst-level stress on health behaviors in Aim 1 and the effect of day- or burst-level health behaviors on QoL in Aim 2), their person-level (averaged) variables to estimate between-person effects at level 3, and a role variable to differentiate survivors' and caregivers' effects in each of those individuals' own effects and partners' effects using interaction terms. For the exploratory aims, 2-way interaction terms between the person-level variables (eg, person-level stress) and the day- or burst-level variables (eg, daily fluctuations of stress), as well as between-level stable demographic and clinical factors and the day- or bust-level variables, will be added to assess moderations for the individuals' day- or burst-level effects. Three-way interaction terms with the role variable added will be used to differentially evaluate each of those 2-way interactions for survivors and partners.

Within this modeling framework, the components of the aims can be estimated and evaluated. For Aim 1, various components of stress will be related to concurrent health behaviors, both within and between individuals and across survivors and partners. The effect of interest is the association between stress components and individual health behaviors (at the burst level and the day level within bursts). Smoking and alcohol use will each be assessed as an indicator of behavior (with a logistic link) and a magnitude of behavior (excluding nonsmokers and nondrinkers, respectively). Linear relationships will be tested, and if model diagnostics indicate a nonlinear fit, a smooth nonlinear association will be assessed. A similar construction will be considered for Aim 2, relating components of stress to QoL and components of behavior to QoL at the burst level and the day level within bursts. Similarly, for the exploratory aim, the effects of interest will be interactions of day- or burst-level stress and aggregate-scale person-level stress or person-level stable factors. For each model, there is a possibility of nonignorable dropout or mortality. To address issues of missingness, we will assume that loss to follow-up is missing at random. Within this context and under a small number of assumptions, the missingness due to death or dropout becomes missing at random and ignorable given the context of the model. The mixed-effects structure, in particular, is robust to many patterns of random missingness. With respect to mortality, we will implement the principal stratification approach [77], wherein participants are weighted by their propensity to survive the study period.

Sample Size and Power Calculation

Assuming a 20% rate of dropout, we expect to have at least 120 dyads complete the study. Most of our assessments will be measured by correlation. With 120 dyads, we expect to have at least 80% power to detect relationships with a partial R^2 of at least 0.26, which is a medium-large effect. A similar construction shows that the 80% detectable level of the partial F is 0.06, which is a small-to-medium effect. The partial F statistic is a scaled version of the partial F statistic in a nested analysis of variance comparison; the scaling factor is the ratio of the numerator's and the denominator's degrees of freedom [78]. As the modeling structure and relative effect sizes (and confidence bounds) will be of primary interest, we will not incorporate a multiple testing structure until the correlation between test statistics can be carefully assessed (which allows for less conservative testing criteria). The R library *pwr* was used in the calculation of these effect sizes.

Ethical Considerations

This study was approved by MD Anderson's institutional review board (Protocol 2021-0165). Written informed consent will be obtained from all participants. Study participant research data, which will be obtained for purposes of statistical analysis and scientific reporting, will not include the participant's contact or identifying information. Rather, individual participants and their research data will be identified by a unique study identification number. Participants will receive gift cards as compensation for their time and participation. Each participant will receive up to a US $35 gift card to complete a 7-day daily survey and wear an accelerometer (ie, US $5 gift card per day). Of the 7 days, participants must complete surveys and wear the accelerometer for at least 3 days to receive the compensation. Participants will also receive an additional US $15 gift card for

completing both nutritional assessments and receive a US $40 gift card for each retrospective survey that they complete.

Results

We are currently recruiting participants, having initiated recruitment in January 2022. Recruitment and data collection are expected to conclude by December 2024 and December 2026, respectively. We expect to submit the main study results for publication in 2027.

Discussion

The aim of the proposed study is to investigate associations between stress, health behaviors, and QoL at both within- and between-person levels over the transition to survivorship in young adult survivors and their partners. To date, much is unknown regarding associations between stress, health behaviors, and QoL among young adult survivors. In particular, to the best of our knowledge, there is currently no existing study that investigates these associations among both young adult survivors and their partners. This will also be the first study that determines the interdependence of health behaviors and QoL between young adult survivors and partners, exploring how their stress levels may either facilitate or hinder their own and each other's health behaviors and QoL over the transition to survivorship.

This study has a few limitations. First, recruiting survivor-partner dyads, particularly survivors within a restricted age range (25-39 years old), can be a challenge. We will thoroughly review the recruitment progress, study refusal reasons, and work on addressing enrollment barriers. Second, participants' compliance may be a concern in this intensive longitudinal study. Over the course of the study, we will carefully monitor survey responses and consider reducing the number of retrospective or daily assessments if noncompliance is salient. Finally, this study addresses stress, health behaviors, and QoL of young adult survivors who have partners. Thus, the results of this study may not be generalized to all young adult survivors.

Despite these limitations, this study is novel and promises to generate new knowledge. Specifically, using a sophisticated research design—measurement burst—this study will allow assessment of both within- and between-person level changes in those variables and their relationships [56,57]. If the results of this study could reveal whether and on what time scales higher stress levels or certain types of stressors are associated with unhealthy behaviors and poor QoL, interventions such as just-in-time adaptive intervention [79] might be considered based on the findings. The focus on the transition to survivorship is another strength. By following up with the survivors over the course of 2 years after the completion of their cancer treatment, we can identify the time points when stress, health behaviors, and QoL begin to change (increase or decrease) during the transition. This information will help us target the right time to intervene for this understudied survivor group. Furthermore, the proposed study seeks to shift current individual-focused research in young adult survivors to relationship-focused exploration as it focuses on both survivors and their partners. Thus, the results of this study may guide the creation of a developmentally appropriate couple-based psychosocial or behavioral intervention that improves both young adult survivors' and their partners' QoL.

Acknowledgments

The authors thank Project Koru and Stupid Cancer for their support in the participant recruitment. The authors also thank Sarah Bronson, scientific editor, Research Medical Library, for editing this article. This work was supported by the Department of Defense (W81XWH-21-1-0184).

Data Availability

The data sets generated during this study are not publicly available because they include sensitive information but are available from the corresponding author on reasonable request.

Abstract

Background: The increasing number of requests for help for acutely ill patients and their management is a major problem in the health systems of many countries, but especially in Germany. Rescue coordination centers and ambulances in Germany are increasingly overloaded. As a result, rides as a part of rescue operations have been increasing in length for years, yet a relevant proportion of these operations represent low-acuity calls (LACs). The basic objective of this pilot study is the quantitative analysis of the potential misuse of requests to the rescue control center. Indications for alternative treatment options and how to handle these treatment options in nonacute, non–life-threatening health conditions, such as minor injuries or minor infectious diseases, will be assessed. The identification of these LACs is vital in order to prevent health care resources in emergency medical care becoming inadequate.

Objective: The overarching goal of this study is to determine the percentage of unnecessary rescue missions on site and subsequently to obtain an impression of the paramedics' assessment of alternative treatment options or alternative methods of rescue transportation.

Methods: This will be an exploratory, noninterventional, cross-sectional study with a quantitative approach. The study is multicentric, with 21 ambulances in 12 different locations. The data for this study were collected via a questionnaire, newly developed for this study, for rescue personnel. Additionally, secondary data from the responsible control center will be linked and processed in an initial descriptive analysis. This descriptive analysis will form the basis for a subsequent variance analysis.

Results: Data collection started as projected on September 18, 2023, and was ongoing until end of November 2023. We expect the documentation of several thousand rescue operations. We expect the following study results: (1) many unnecessary rescue operations, (2) immediate on-site assessment of correct care and treatment, and (3) patients' reasons for calling a rescue coordination center.

Conclusions: To our knowledge, this is the first observational study in which acute rescue operations are recorded on site. The focus of this study is on the trained paramedics' assessment of whether rescue operations are necessary or not. Additionally, alternative treatments, such as out-of-hours care service or primary care service, are shown for each individual case. The study also intends to cover the question of which factors are relevant and statistically significantly connected to the misuse of ambulances.

KEYWORDS

emergency medical service; EMS; ambulance misuse; low-acuity calls; emergency department; paramedics; rescue operations

Introduction

The number of outpatient medical treatment cases in Germany has been showing an upward trend for years [1]. Additionally, the number of rescue operations in emergency medical service (EMS) shows a continuous annual increase of about 5%, amounting to almost 16.5 million emergency ambulance and emergency missions in the 2016-2017 observation period [2-5]. This increase can also be observed in the number of rescue operations performed by the ambulance service and is similar in most European countries, as well as in the United States and Australia [6-9]. The steady increase can only partly be accounted for by demographic developments or geographical peculiarities [10,11]. Rather, a not inconsiderable proportion of EMS operations and the resulting transports to an emergency department (ED) do not seem to be indicated from a medical point of view [12-14].

In Germany, patients with minor ailments should generally be treated in medical on-call service centers out of hours when their own general practitioner (GP) is not available. GPs and specialists are obliged to work in medical on-call services; in some regions this is only out of hours, while in other regions it is 24 hours, 7 days a week. The medical on-call services are regulated by the Association of Statutory Health Insurance Physicians, that is, they are self-administered. Everybody, whether seriously or only slightly ill, can consult the ED as well as clinics and the EMS. EDs are also responsible for, preferably, emergency care but also for all other acute patient concerns. [15]. In addition to a lack of professional assessment on the part of those seeking help and ignorance of the responsibilities of the existing emergency and acute patient care structures [16,17], a variety of factors can lead to the EMS and ambulance service being alerted in nonurgent cases. Apart from the possibility of low-threshold and timely care by the ambulance service, these also include the patient-specific perception of their urgency as well as a personal need for safety [18]. Other circumstances that occasionally lead to avoidable requests for ambulance service include nursing home patients with ambulatory care–sensitive conditions, older people with many comorbidities not receiving timely outpatient consultation appointments, and people with mental health problems or somatoform disorders requiring psychological care [19-25].

The increased and undifferentiated use of the EMS means rising costs at the expense of social insurance [26] and a higher workload for emergency medical staff, who are exposed to an extremely high risk of burnout [27,28]. This also leads to overcrowded EDs and therefore to great difficulties treating patients efficiently and at a high quality outside of regular and scheduled consultations [29,30]. Besides this, the response time of the EMS tends to be more and more extended, and statutory provisions consequently cannot be observed [31,32]. Serious doubts concerning the capability of the EMS and the emergency medical system in general are being seen more and more in public debate in recent years.

German policy makers are now seriously addressing this issue after making some local short-term changes; for example, alert keywords have been restricted for ambulances on call. Recently, a German government commission proposed comprehensive modifications to the EMS. These call for extending the EMS's entitlement to services and fees for care and treatment of minor ailments on site, not just transportation (as before). The overall aim is to reorganize and expand the existing components of the EMS [33].

The aim of this prospective cross-sectional study is the quantitative analysis of unnecessary ambulance missions, in addition to the examination of indications for alternative care options in nonacute life-threatening situations instead of transport by the ambulance service to a hospital ED. Alternative health care options should be discussed to help improve care for acute patients and reduce the misuse of ambulances.

Methods

Aim

This study intends to quantify the fraction of low-acuity calls (LACs) in ambulance operations, focusing on alternative treatment options. For this purpose, the trial will evaluate how often EMS personnel rate a different, usually ambulatory treatment as being more suitable because a patient has a non–life-threatening health condition that does not require any urgent medical intervention. In addition, this study aims to identify and quantify the reasons why patients without a life-threatening medical condition or other medical indications are brought to an emergency room by ambulance instead of being transferred to a more suitable location for treatment. Therefore, the 2 main questions the study plans to cover are, first, what kind of treatment patients of the EMS need, if not emergency treatment and urgent conveyance to a hospital, and second, why patients may not receive adequate medical care. A quantitative approach is required to obtain an indication of the dimensions of these individual aspects, as there is usually no standardized documentation by the control center that goes beyond the point of "patient was taken to hospital/patient was referred to GP/refusal of transport/no patient was found," which represents only part of the actual situation. Furthermore, the study will collect and analyze data on operational statistics to determine if conditions like operation time, day of the week, accessibility to a GP, priority, and content of the alert (as set by the dispatcher in the control center) have an impact on the frequency of LAC operations. We will also evaluate socioeconomic factors, such as age and gender of the patient, as well as the impact of the operation area.

Design

The key feature of this exploratory, noninterventional, cross-sectional study is a web-based questionnaire (Table 1) for tablets or smartphones. In the first phase, each individual question on the web-based questionnaire was reviewed by an expert panel at the Department of General Medicine at Heidelberg University Hospital, and in the second phase, the questions were discussed with the heads of operations at the rescue coordination centers, as well as with selected paramedics. The focus was on the feasibility of this pilot study. When this study is rolled out (at large scale) there also will be analyses of interrater reliability.

Table 1. Questionnaire for ambulance crews on emergency cases.

Item	Content
Operation number	• (Free text)
Patient gender	• Male • Female • Gender-diverse
Patient age group (years)	• 18-24 • 25-39 • 40-59 • 60-64 • 65-79 • ≥80
Operation time on a weekend day or holiday[a]	• Yes/no
Operation time during main opening hours of general practitioner care[b]	• Yes/no
Classification of operation area (number of inhabitants)	• Metropolitan (>100,000) • Urban (30,000-100,000) • Suburban (10,000-30,000) • Rural (<10,000)
Working diagnosis	• (Free text)
Treatment or procedure performed (multiple choices possible)	• Being conveyed to a hospital • Referral to a general practitioner or medical on-call service • Continuance at home • Patient refused being conveyed • Therapeutic measures performed • (Free text)
Appropriate treatment or procedure (multiple choices possible; no choice possible)	• Being conveyed to a hospital autonomously • Calling on the medical on-call service autonomously • Consulting the general practitioner for further care • Exclusively counseling • Counseling by telephone possible • Social caretakership • Being conveyed by a patient transport ambulance • (Free text)
Reasons for being conveyed to a hospital without medical indication (multiple choices possible; no choice possible)	• Missed transportation opportunity by patient or relatives • Patient insists on being conveyed by ambulance • Social indication • House call by general practitioner or medical on-call service indicated but not provided • Medical on-call service not favored by patient • Insecurity of team leader • Language barrier • (Free text)

[a]As defined by the state in which the operation took place.

[b]Main opening hours were defined as Monday, Tuesday, and Thursday from 7 AM to 7 PM, and Wednesday and Friday from 7 AM to 2 PM.

The members of the expert panel determined which crucial dimensions of medical emergency treatments will be queried, including (1) working diagnosis, which is the assessment made on site by the ambulance crew with consideration of diagnostics that can be carried out preclinically; (2) procedures, including the ambulance crew's approach to counseling, treatment, patient transport, and referral to other caregivers; (3) adequacy of care, that is, the assessment of the most suitable form of care, which is carried out by the ambulance crew based on the situation on site; and (4) problems that arise, that is, the evaluation of possible reasons why patients are not directed to the form of care that has been assessed as being most suitable.

The training of the paramedics consists of 5 vital elements. The important questions for assessing their concerns about possible rescue operations (Textbox 1) are described in in-person lectures. The five *W* questions are integrated in the questionnaire and special training is provided.

Textbox 1. W questions and example cases.

***W* questions**

- Which typical use cases are presented?
- Who called? (Age and gender should be documented)
- Which concerns were stated? (Assessment of the emergency is an overarching goal of the study)
- When did the concerns occur? (Duration and assessment of the acute situation has to be included in the consideration)
- Where is the location? (Infrastructure, social environment, etc., should be documented)

Examples of possible rescue operation cases integrated into the training

- An ambulance is alerted with high priority because of high blood pressure and vertigo. On site, the crew can rule out current life-threatening conditions, only the blood pressure is slightly elevated beyond the patient's known level after an upsetting argument a few hours before. Anamnesis brings out that the patient is familiar with vertigo and does not have any new kinds of symptoms. So, the ambulance crew cannot find any indication for conveyance at this moment and offers the patient to stay at home unless new kinds of symptoms or decline of general condition occur. The patient prefers to do so, but his daughter presses him to "have a thorough checkup in hospital" and does not concede. The patient is conveyed to the nearest hospital. After the operation, the ambulance crew fills in the questionnaire, describes their working diagnosis as "slightly elevated blood pressure without further symptoms, known vertigo without current worsening" and picks "hospital conveyance" as performed procedure, "consulting the GP in the further course" as appropriate procedure and "patient insists on conveyance by ambulance" (which includes relatives) as reason for hospital conveyance without urgent medical indication.
- An ambulance is alerted under the heading "attendance operation for fire brigade". As there is no patient contact during the whole operation and therefore the operation is excluded from this study, the ambulance crew does not fill in the questionnaire.
- An ambulance and an emergency doctor's car are alerted with high priority because of acute chest pain. On site, the medical examination shows evidence for an acute myocardial infarction and the patient is quickly treated and conveyed to hospital for further treatment. After terminating the operation, the ambulance crew fills in the web-based questionnaire with the items 1-9 only, because they categorize their treatment as appropriate.
- An ambulance is alerted with low priority because of a headache on a Saturday. On site, they find a young woman who is healthy except for a cold that has been lasting for "already six days" accompanied by a sinusitis and a feeling of pressure in her head. The symptoms didn't change during the last days, and she was not satisfied by the advice of her GP and the request to await spontaneous recovery. The ambulance crew repeats the advice of the GP and recommends waiting and see and to contact the GP or alternatively the medical out-of-hours on-call service again if no improvement will occur. The patient insists on an immediate treatment, has never heard of the medical on-call service until now and claims not to be able to drive on her own, so the paramedics call the medical on-call service themselves and ask for a home call. After the operation, they fill in the web-based questionnaire, set their working diagnosis "headache associated with acute sinusitis", pick "referral to GP or medical on-call service" and "continuance at home" as performed procedure, "consulting the GP in the further course" and "exclusively counseling" as well as "counseling telephonically possible" as appropriate procedures and select "missing transportation opportunities by patient and relatives" and add "patient didn't know the medical on-call service" for reasons why the patient has not been directed to the appropriate caregiver straightforward.

We explained all phrases used in the questionnaire (Table 1) to precisely define the terms used. Examples for 2 terms are as follows: "social indication" means, for example, a single, immobile older person, a single mother, or a father of an ill child without his own car and without access to public transportation; "medical on-call service" means an on-call service in a suitable medical practice, self-managed by primary care physicians outside regular consultation hours or when a GP is not available.

The questionnaire will be completed once per operation by the ambulance crew, ideally in consultation with both or all 3 crew members and will represent the assessment of the most qualified crew member. The questionnaire can be filled in until the end of the operation.

The following types of operations are excluded: operations involving minor patients (aged <18 years), secondary transports or interhospital transfers, operations cancelled during the approach, operations with no patient found, provisional operations without a patient (eg, fire service operations), and operations in which the patient dies or is found dead on the incident scene. The inclusion and exclusion criteria are listed in Textbox 2.

Textbox 2. Inclusion and exclusion criteria for emergency case recording.

Inclusion criteria

- Minimum of 1 ambulance involved in the operation (type C according to EN 1789)
- Crew members were recruited and briefed

Exclusion criteria

- Provisional operation without patient (eg, fire service operations)
- Secondary transport/interhospital transfer
- Cancellation during approach
- Minor patients (aged <18 years)
- Patient dies or is found dead on incident scene
- No patient found

Setting

The study takes place in the whole area of responsibility of the integrated emergency control center of Ludwigshafen, Germany. This covers an area of about 1200 km^2 and represents a point of call for over 620,000 inhabitants in 6 administrative districts and independent cities. Its dispatchers answer more than 210,000 calls per year, which result in more than 140,000 EMS operations (average 380 per day) and around 11,000 operations of the fire service annually. The control center has at its disposal 21 ambulances in 12 different locations, as well as 8 emergency doctor's cars, 1 rescue helicopter, and up to 28 patient transport ambulances (figures obtained via oral communication with the management team of the integrated EMS control center of Ludwigshafen on August 29, 2023). The area of responsibility, with its 6 administrative districts and independent cities, includes the core city of Ludwigshafen as the metropolitan zone, a few cities classified as urban regions, several smaller, suburban towns, and several remote rural townships [34]. The classification of the operation areas used in this survey can be found in Table 2.

Table 2. Operation areas of emergency crews.

Operation area	Description
Overall	The area around Ludwigshafen, a city in the federal state of Rhineland-Pfalz, Germany
Metropolitan	The core region of Ludwigshafen
Urban	The cities Speyer, Neustadt, and Frankenthal, as well as the districts Ruchheim and Maudach of Ludwigshafen
Suburban	The cities Bad Dürkheim, Grünstadt, Schifferstadt, Haßloch, Böhl-Iggelheim, Limburgerhof, Mutterstadt, and Bobenheim-Roxheim
Rural	All townships with less than 10,000 inhabitants

Participant Recruitment

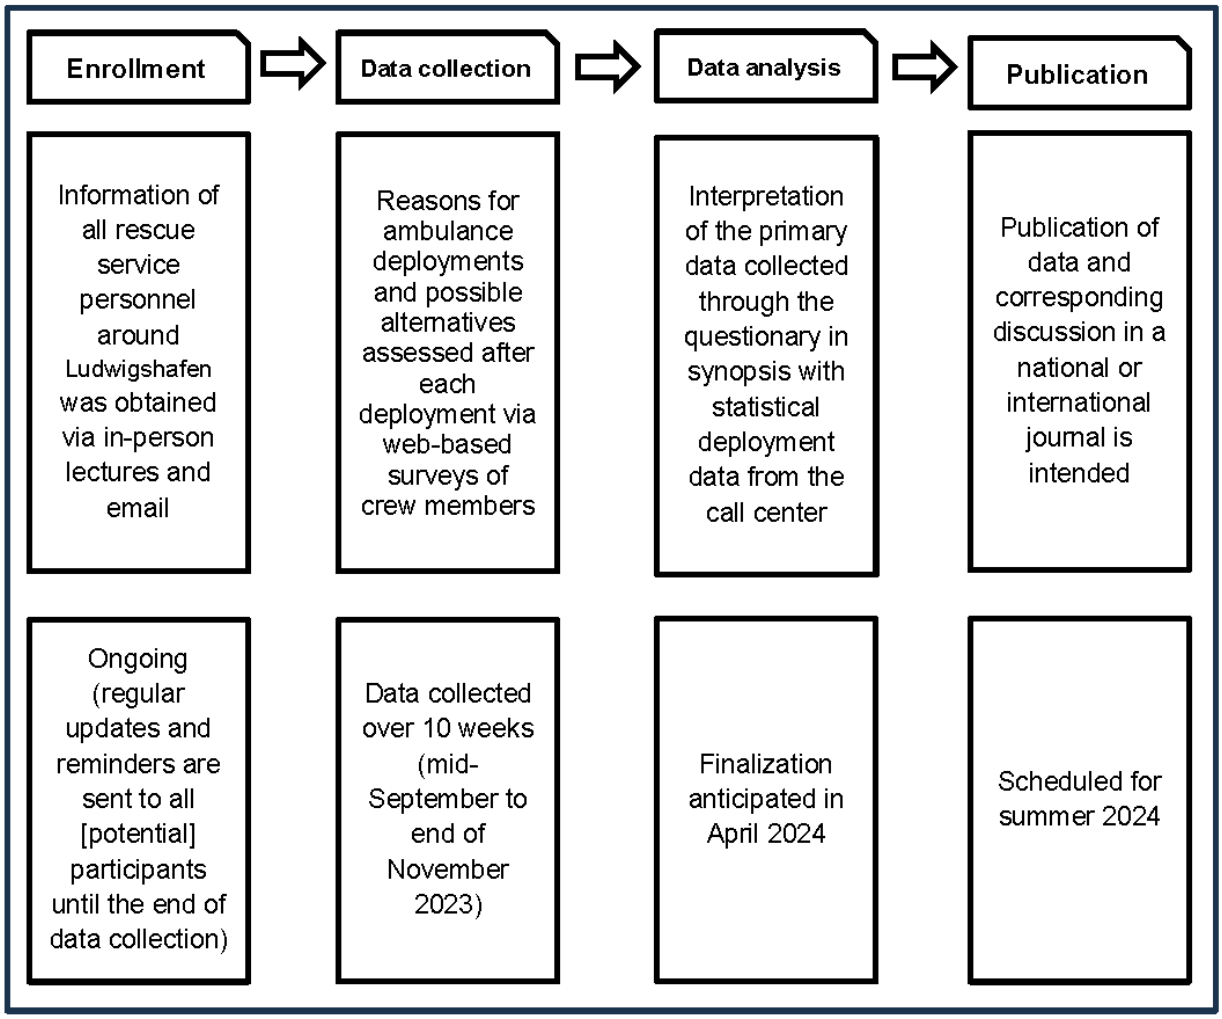
All ambulance crew members under the responsibility of the integrated emergency control center of Ludwigshafen will have access to voluntary participation in this study. LMN, a doctoral student, will run several information sessions integrated into conferences at the individual rescue stations. Additionally, a written invitation with information will be sent to every employee via an email distribution list on the internal communications devices of the quality management system. It will include a thorough description of the study content, clarifications concerning the questionnaire, an informed consent form, and a link and QR code supplying access to the web-based questionnaire. Consent will be obtained in the web-based questionnaire; further participation is only possible after providing informed consent.

Data Collection

During the 10-week period of data collection, access to the web-based questionnaire is available 24 hours a day, 7 days a week. The questionnaire is accessible via the link or QR code and can be filled in using a personal computer, tablet, or smartphone. The questionnaire website has been built exclusively for the study by the department conducting the study. The EMS personnel are encouraged to capture as many operations as possible during this period. The acquisition of the data sets is not bound to a certain time frame after the operations. Although the ambulance crew members must complete the questionnaire only after finishing an operation, the data sets only have to be completed within the period of data collection. The data set of each recorded ambulance operation is directly sent to a dedicated study server within the Department of General Practice and Health Services Research of the University Hospital Heidelberg via secure internet protocols. After closing of primary data collection, additional information and secondary data provided by the control center will be combined with each completely collected data set for interpretation. This comprises the time of day of the alert, the priority of the alert, the keywords of the alert, and a specific feedback code from the ambulance.

The scheduled course of the study is summarized in Figure 1.

Figure 1. Scheduled further course of study.



Research Staff

The research team consists of a doctoral student, several senior researchers, and a computer scientist employed at the Department of General Practice and Health Services Research of the University Hospital Heidelberg, Germany.

Data Management

Data management is performed by the data management team of the Department of General Practice and Health Services Research of the University Hospital Heidelberg. The secondary data are collected by the control center of Ludwigshafen and are unrelated to the described questionnaire; they are governed by their own data management team.

Each data set is directly sent to and filed on a dedicated study server in the Department of General Practice and Health Services Research of the University Hospital Heidelberg. This also applies to the required secondary data transferred from the control center. Data access is granted only to the research staff directly involved in data collection and analysis. There will be no passing on of the unprocessed data to any external institution. Additionally, secondary data from the responsible control center will be linked and processed in the initial descriptive analysis. This descriptive analysis will form the basis for the variance analysis (see Data Analysis section). Working diagnoses will be converted to *International Classification of Diseases, Tenth Edition* codes by a research physician. The free-text entries will be analyzed separately with qualitative methods to obtain a deeper insight into patients' motives for their behavior. Data storage and extraction will be performed with MySQL Community Server x64 (Oracle Corp).

Data Analysis

The two main outcomes for our analyses are the number and percentage of inappropriate emergency calls and the reasons for patients being conveyed to a hospital without a medical indication. This total numbers will be further subdivided according to the paramedics' assessments. Moreover, it is of interest if there are explanatory variables such as patient gender, patient age, operation area, and operation time in the data set that might be associated with inappropriate emergency calls or being conveyed to a hospital without a medical indication. This will be analyzed based on multivariable regression modeling [35]. To calculate frequencies, rates, and percentages, we will use the PROC SQL procedure in SAS (version 9.4, SAS

Institute). To perform the multivariable analyses, we will use the PROC GENMOD procedure in SAS. For qualitative analyses, we will use MAXQDA (version 24.1, VERBI Software).

Ethical Considerations

The ethics committee of the University of Heidelberg revised and approved this study on May 30, 2023 (S-250/2023). The trial has been developed and will be executed according to all relevant national and international rules and regulations under the Declaration of Helsinki (2013 version) and International Council for Harmonisation Good Clinical Practice (E6, R2) guidelines. Consent from all participants will be obtained in the web-based form, and access to the questionnaire will be granted only after approval. Protocol modifications are not scheduled and are not foreseeable; if the need for them arises, they will have to be approved by the ethics committee. In case of modifications, a new study protocol will be released to all study participants via an official email. Due to the anonymous collection of data, participants do not have the choice to opt out after completing the questionnaire. Furthermore, as the questionnaire is anonymous, there is no possibility of inferring the identity of the participant or any other personal information. There is also no way to identify the personal data of patients using the secondary operational data provided by the control center. There is no compensation, financial or otherwise, provided to participants.

Results

Data collection started as projected on September 18, 2023, and was ongoing until end of November 2023. We expect the documentation of several thousand rescue operations. We expect that many of these rescue operations will be unnecessary. Our intention is to train paramedics to give an immediate on-site evaluation of the correct care and treatment. We hope to identify patients' reasons for calling a rescue coordination center so that we can give recommendations in advance on where to find the appropriate treatment options.

Discussion

To the best of our knowledge, this is the first observational study in which acute rescue operations are being recorded on site in Germany. This study was initiated to show how many inappropriate rescue operations, such as those for minor injuries or minor infections, take place in a defined study period. The assessment of these LACs is carried out directly on site by trained rescue personnel and not later in the clinic. The assessment is therefore supplementary and can provide information on operations without the need for a referral, which is a main strength of this study. Another focus is on a preclinical assessment to determine suitable, diverse alternatives to transport by ambulance to an ED for patient conditions that do not require urgent treatment.

One major intent of our study is to complement previous work, which includes several retrospective clinical evaluations and many qualitative studies, such as interview studies, on reasons for calling the EMS in LAC situations as seen through the eyes of patients, as well as of caregivers (mostly EMS personnel), and what circumstances encourage these calls [36-38]. It is known from previous data that around 30% to 35% of all rescue service operations transporting patients to the ED are rated as inadequate and unnecessary [5-8], so a similar proportion of operations with preferred alternative care methods is expected. Most of these inadequate EMS operations involve patients whose health conditions are assessed as being able to be adequately treated by a GP or in general outpatient care [6], which is why there may be a significant difference in the number of primary care–sensitive EMS operations depending on the general availability of and access to general practices and medical out-of-hours care [17]. Additionally, we anticipate that a certain number of transportation operations by ambulance for LACs will take place because of missing transportation alternatives, which has been found to be a relevant reason for ambulance misuse in previous work [39,40]. Previous studies have shown differences in the use of emergency services between urban and rural populations [41], as well as between groups with differences in relevant socioeconomic factors, such as age and personal mobility [42], which may be confirmed in this study.

Several limitations of this study should be noted. The whole system of EMS and acute patient care is complex and includes many variables that cannot be examined in this study. For example, the control centers' process for receiving emergency calls and dispatching ambulances plays a major role during all ambulance operations and the management of acute patients. Assessments of patients' health condition by dispatchers, EMS personnel, and the patients themselves may greatly differ [43]. Misclassification can occur due to different assessment standards because there are usually no uniform classification criteria. There are approaches to harmonizing the triage and dispatching process, such as an intervention in out-of-hours care call centers in Germany that started in 2017 [44], but currently there exist no mandatory and coherent structures in emergency or rescue coordination centers.

In general, studies concerning the EMS in Germany deal with limited generalizability because of huge regional differences in standard operating procedures for treatment, equipment, staffing of rescue resources, and laws and regulations [45]. This is due to the federal structure in Germany and the accountability for civil protection lying mostly with the federal states or even autonomously with the local authorities [46].

Another limitation is the risk of bias. Operations that the ambulance crew rates as having been inappropriately dispatched are more likely to be captured than operations that fulfill the original functions of the EMS. Additionally, recall bias could occur if the questionnaire is not filled in soon after the end of an operation. Our intention was, in any case, to document all rescue operations regardless of urgency.

Nevertheless, the results of this cross-sectional pilot study may form the basis of further evaluations of possible interventions and pilot projects, the implementation of additional services in urgent care, support for change in the way patients are treated, and political change concerning urgent care in general.

Acknowledgments

The authors would like to thank Mr Frank Aluttis for the digital implementation of the questionnaire and the excellent support in all questions concerning the website and data management. Special thanks go to the employees of the rescue services involved in the organizational preparation for the study and to the heads of the control center of Ludwigshafen, Germany, for supporting the realization of the study. There has been no external financial funding in this study. The umbrella organization of the rescue service of Ludwigshafen, Rhineland-Palatinate, as well as the integrated control center of Ludwigshafen, did not support the conceptualization of the study and also provided no nonmaterial or organizational support on account of personal vocational contacts with the responsible parties. The funders did not have a specific role in conceptualization, design, or preparation of the manuscript.

Data Availability

Restrictions apply to the availability of the additionally processed secondary data from the emergency call center of Ludwigshafen, which were used under license for the current study, and so are not publicly available. Data are however available from the authors upon reasonable request and with permission of the emergency call center Ludwigshafen.

Authors' Contributions

LMN developed the study design as well as the questionnaire design and content. She organized the on-site process and implementation of the study at the rescue stations. She was a major contributor in writing the manuscript. RL was a supervisor and co-developed the study, particularly the research question of the study. He was also a major contributor in writing the manuscript. GL provided substantial assistance during the development of the study, especially in all points concerning data management, data privacy, and data analysis. AA and JS advised on the study and critically revised the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Type 2 diabetes mellitus (T2DM) is one of the leading noncommunicable diseases that require diabetes self-management (DSM) practices. This study proposes to develop a customized mobile health (mHealth) app integrated with a hospital information system (HIS) to enable real-time, two-way transfer of information between the patient and physician. The captured information in the electronic health record will facilitate physicians to have a chronological account of the patient's diabetes history and enable tweaking of the treatment.

Objective: The objectives of the study are (1) to develop the HIS-integrated Electronic Diabetes Diary (EDDy) per the end-user expectations at a tertiary care hospital in a south Indian state with a high prevalence of T2DM and (2) to evaluate and test adherence to EDDy in the management of T2DM.

Methods: The study will be carried out in 3 phases. Phase 1 involved in-depth interviews with primary end users to gather information regarding their expectations from the hospital-based EDDy. Phase 2 will use this information to develop a customized mHealth app using an iterative model of software development. Phase 3 will involve a pre- and posttest design; the developed app will be tested among consenting patients, where physicians will receive the patients' data through the HIS-integrated mHealth app. The pre- and posttest values will be analyzed for adherence leading to improvement in patients' self-management of blood glucose, user experience, glycemic control, and clinical utility.

Results: Phase 1 was completed on November 28, 2023. Phase 2 commenced in December 2023 and will end in May 2025. Phase 3 will follow afterward.

Conclusions: The proposed app will include a convenient and simple alert system that enables the patient to test glucose values at self-selected intervals, provide grading options to enter diabetic-related complications, enhance patients' knowledge of tracking and managing the complications of diabetes, and help in maintaining the visual representation of glucose values and complications. The simplicity and usability of the modules are its novelty, which may motivate the patients to keep track of their glucose values and help them attain better health outcomes.

KEYWORDS

self-management of blood glucose; SMBG; diabetes self-management; DSM; personal health records; electronic diabetes diary; glycemic control; patient adherence; digital health

Introduction

In India, 11.8% of the population have diabetes per the National Diabetes and Diabetic Retinopathy Survey released by the Ministry of Health and Family Welfare in 2019, and this is projected to have a steady rise of 3.8% annually [1]. This prevalence is higher in the southern states and union territories of India [2]. *The Indian Glucose Monitoring Device Market Reports of 2020* [3] suggested that the use of glucometer was always on the rise, and it was specifically noticed that there was an exponential increase in its sale during the COVID-19 pandemic period. Technology-enabled self-management has been increasingly recommended, along with proper medication and lifestyle modification, to tackle diabetes. There are numerous diabetes managements apps available in the Google Play store; however, subscription to such apps is not proportional to the population with diabetes [4]. Literature from other parts of the world suggest that the adoption of digital diabetes-monitoring solutions is expected to reach 21% by 2027 [5].

Diabetes is an irreversible chronic condition that need to be well managed by altering lifestyles, food habits, and physical activities [6]. However, a standard diabetes management regimen may not be feasible to everyone around the globe, as each of these factors varies according to geographical locations and general living conditions [5]. Using customized information that is specific to the local lifestyle may be more effective and easier to ensure adherence. Existing literature suggests that nonadherence to treatment regimen and irregularity in following a diabetes-friendly lifestyle leads to poorly managed diabetes and poor disease outcomes [7]. To enhance the existing measures to manage T2DM, efficient methods needs to be formulated to ensure adherence to treatment regimen [8]. The success of such activities requires active involvement of the patients and caregivers. They should be motivated to follow T2DM management instructions from health care professionals.

This study setting already has an existing system of manual diabetes information documentation that expects its patients to record their self-management of blood glucose (SMBG) practices systematically and submit them to the treating physician during consultation. These glucose monitoring records are used by the physician to evaluate the patient's glycemic status and make appropriate clinical decisions. This study proposes to automate this process and make it more efficient for the patients and physicians. The proposed electronic diary is expected to reduce the loss of documented values, minimize errors, as well as motivate the patients to effectively make use of technology and manage their condition.

A pilot study was conducted to analyze the knowledge and attitude to digital diabetes management practices among 50 existing patients with diabetes, which indicated that ignorance and technological illiteracy are the main reasons behind nonuse of digital apps among them. Those who used digital apps, such as mobile health (mHealth) apps, suggested that the information available is more general in nature and that they find it difficult to navigate and comprehend the information, eventually leading to the discontinuation of its use.

Methods

Overview

The study will be carried out in the outpatient department (OPD) of the endocrinology department at a tertiary care hospital in a south Indian state, and it is divided into 3 phases. In phase 1, a qualitative study was conducted; in phase 2, the mobile app with be developed and integrated with a health information system (HIS); and finally, in phase 3, the developed app will be tested for its feasibility using a pre- and posttest design.

The study is based on the principles of the "theory of change," where stakeholders will be consulted through in-depth interviews (IDIs) to identify the deterrents to acceptance and adherence of electronic diabetes-monitoring practices, potential challenges, as well as ethical issues related to electronic information sharing. This feedback will provide the cues for the development of a customized electronic diabetes-monitoring system. The study would also attempt to identify the reasons that would lead to the discontinuation of electronic monitoring practices among patient with T2DM and address them by developing a more user-friendly mHealth app. This study will also analyze the patient acceptance of the mHealth app and their adherence to SMBG practices.

The model will then be developed and integrated with an HIS. Finally, it will be tested among patients with T2DM regarding their acceptance and adherence to using the Electronic Diabetes Diary (EDDy), its usability, contextual relevance according to user expectation, and clinical utility in terms of glycemic control.

Ethical Considerations

This study has been approved by the Institutional Ethics Committee (IEC; IEC No:223/2022). The participants personal information will be anonymized, and all privacy, confidentiality, and compensation policies will be adhered to as per the IEC guidelines.

Pilot Study

As a precursor to this study, a pilot study was conducted in a tertiary care hospital among 50 patients with T2DM to understand the existing personal record-keeping practices, the challenges they face, and their awareness of personal record keeping. The perception, expectations, and concerns of the target population were studied using a validated questionnaire survey. Patients with T2DM who are within the age group of 40-65 years were included in the study. The study setting encouraged patients with T2DM to document their SMBG values by providing a data sheet to enter the values and asking patients to bring it with them when they come for a doctor's appointment. It is a valuable tool for the doctor to assess the

values and make better clinical decisions in the management of the disease.

A cross-sectional study was conducted, and a purposive sampling technique was followed to select the participants. A mixed-type questionnaire (both open- and close-ended questions) was used to collect data.

Phase 1

Study Design

IDIs with key stakeholders was carried out to identify the reasons for nonadherence, expectations from EDDy, and mandatory requirements to develop the intervention mechanism. The key stakeholders included the following participants:

- Patients with T2DM
- Their caregivers
- Treating doctors
- Diabetes counselors (includes nursing counselors, diet counsellors, and physiotherapists)

Sample Selection

The IDI participants were enrolled according to the following criteria: patients who own an Android smartphone and those who regularly attend doctor's appointments (ie, those who visit the OPD at least once in the last 6 months). Patients who are literate, can understand the local language (Kannada or Tulu) or English, aged 40-65 years, and have hemoglobin A_{1c} values between 7% and 10% were selected to ensure homogeneity. Patients with gestational diabetes and other terminal illnesses were excluded. The IDIs were conducted among the immediate caregivers of the patients (ie, those who are actively involved in the care of the patient). To understand the practical aspects of the treatment and management of patients, physicians, nurses, and counsellors were also interviewed.

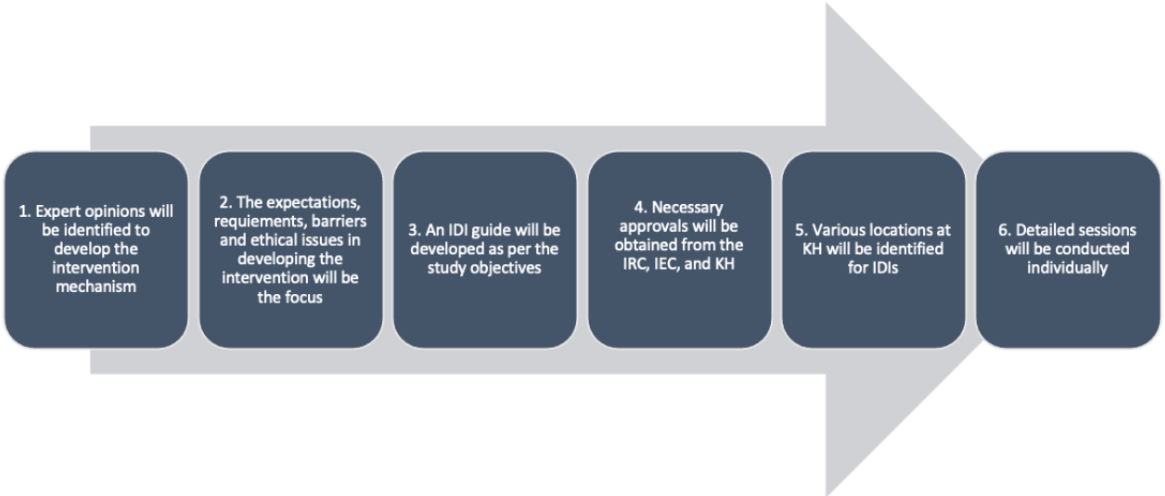
Even with the availability of various diabetes management apps, studies suggest they are not very popular among the general population. The reason for this underuse and nonadherence, along with their expectations from mHealth apps, are the key areas that were addressed among patients with T2DM and their caregivers. The doctors and diabetes counselors were interviewed to understand the challenges they face while managing patients with T2DM and their SMBG practices.

IDI Process

The IDIs focused on the perspectives of patients with T2DM and their caregivers along with physicians and diabetes counselors who are actively involved in the care of patient with T2DM. Additionally, IT and health information management professionals were also consulted on ethical challenges and technical expertise. The IDI guide was designed based on the objectives of the study and the content was validated by experts. The IDI process is shown in Figure 1.

Qualitative data generated during the IDIs will be analyzed by using ATLAS.ti software (version 8; ATLAS.ti), and a report will be prepared. Based on the report, the researchers and the subject experts will identify the most feasible options that will be considered for incorporation into EDDy.

Figure 1. Process of the in-depth interviews (IDIs). IEC: Institutional Ethical Committee; IRC: Institutional Research Committee; KH: Kasturba Hospital.



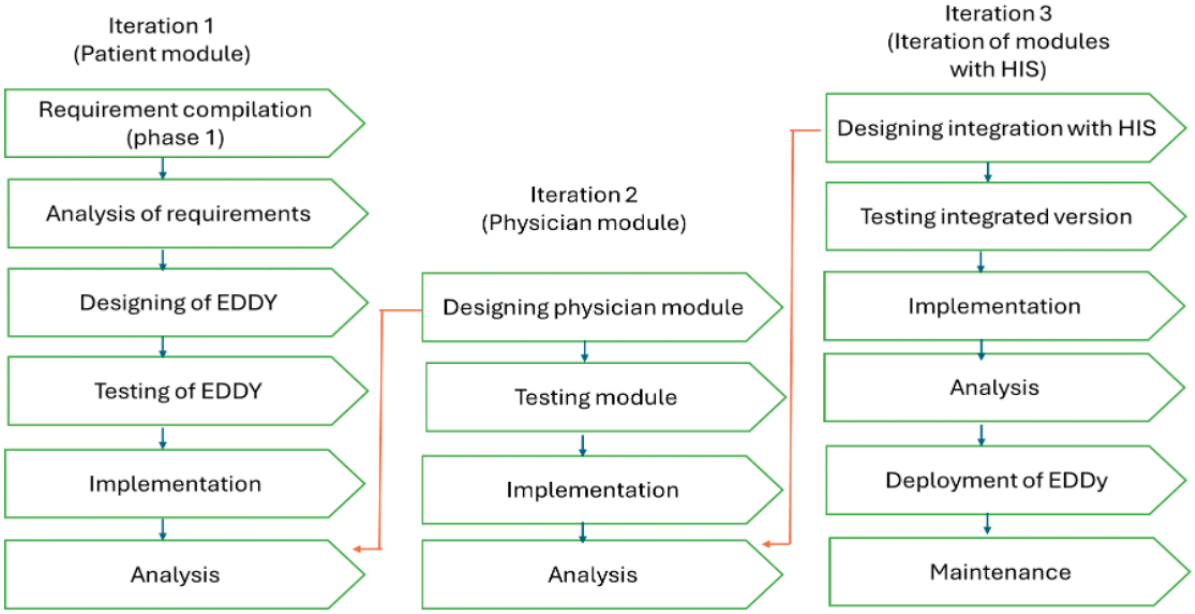
Phase 2

Development of EDDy

Phase 2 is the main part of this research, where the software will be developed based on inputs from the IDIs and the literature. The mobile app will be developed on Android Studio (Google) using an iterative model design.

The iterative model (Figure 2) is one of the Software Development Life Cycle models, where the development of a system goes through repeated cycles (iterative) and is conducted in smaller portions at a time (incremental) [9]. As and when the different modules of the app are developed, they will be tested and reviewed against the end user's expectation, and accordingly, modifications and further development will be done. This process will enable easier debugging and fixing of errors as and when tested.

Figure 2. Iterative model of Software Development Life Cycle. EDDy: Electronic Diabetes Diary; HIS: hospital information system.



The development and testing of the app will involve development, pilot-testing, and debugging at each phase. Each iteration will be subjected to the development, testing implementation, and analysis of each component of EDDy. The components for incorporation into the software will be validated by the following experts:

- An endocrinologist
- Qualitative experts
- The IT team at the hospital

The expected pattern and time period for phase 2 are as follows.

System Development

Step 1: Requirements

This is the phase where the stakeholders' requirements are enquired and compiled, which was primarily covered in phase 1. The captured data will be systematically entered into Microsoft Excel for further evaluation.

Step 2: Analysis

The compiled information will be divided into feasible and nonfeasible items as per the system development and HIS-interfacing requirements. This step will be conducted with the researchers and technical experts.

Step 3: Designing and Development

This step will be done by a software developer with the support of a researcher. Once the feasible requirements are sorted and finalized by the researcher, the design of the app will take place. First, a prototype of the system will be developed, and the requirements for each module of the app will be determined. This step includes the coding of the app based on the design. Android Studio, an open-source program for Android software development, will be used to develop the proposed mobile app. The iteration process has 3 phases, where a patient module and a physician module will be designed, and integration with an HIS will be performed as depicted in Figure 2.

Step 4: Implementation

After development, each module of EDDy will be pilot-tested for its intended use. The modules will be connected to a web-based backend database application to help the validation of content, visualization, and analysis of the data collected.

Step 5: Testing and Quality Assurance

The developed app will undergo a standard testing and quality assurance process to identify and rectify any issues and bugs. Each module will be validated during testing to ensure its intended performance.

Step 6: Analysis of Feedback

A pilot test among 2 potential users will be carried out at each level of iteration, and user experience will be measured using a Likert scale on various aspects of the app's functionality. The parameters that will be measured during the piloting process will be the app's functionality, usability, accessibility, compatibility, and performance under real-life scenarios.

Once the app is fully developed and interfaced with an HIS, it will be installed in the respective systems of the stakeholders and tested for its performance. Gaps and technical glitches will be rectified at each phase.

Step 7: Deployment

The final app will be deployed among end users (patients and physicians).

Step 8: Maintenance

The final app will be integrated into an HIS. Once the module is fully functional, the study will proceed to phase 3.

Expected Outcomes From EDDy

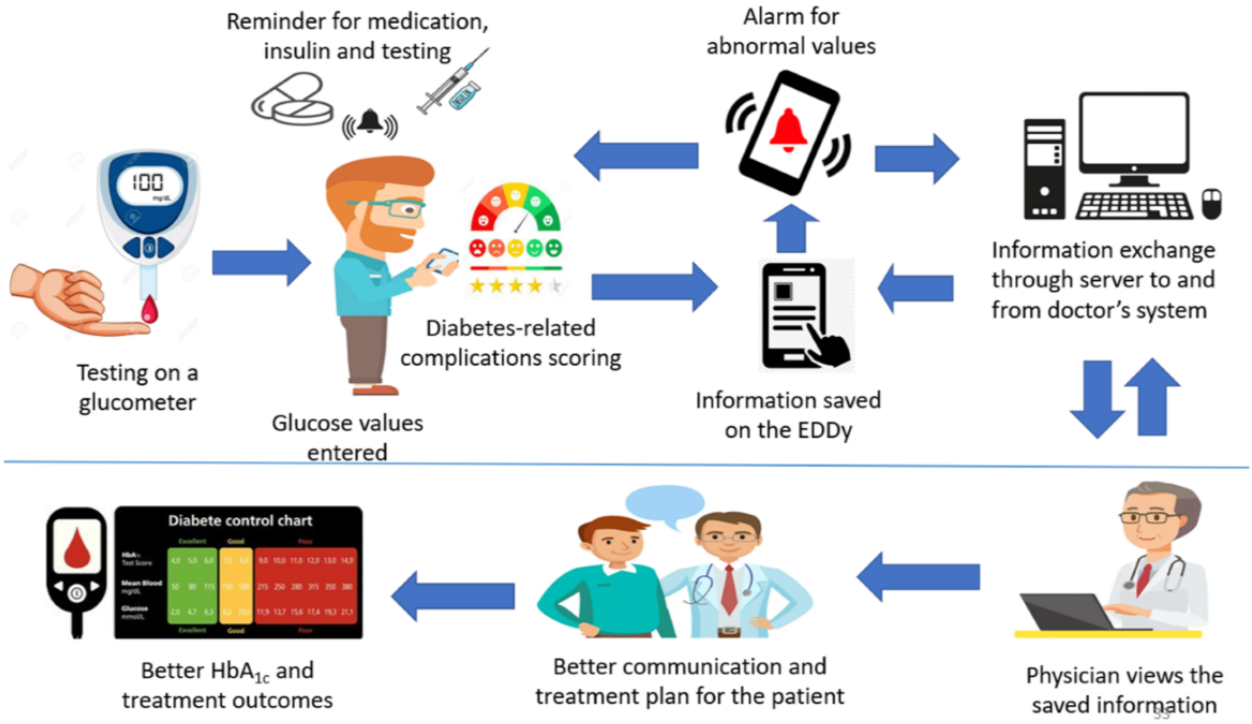
The app is expected to improve the SMBG practices in patients with T2DM. EDDy is expected to motivate the use of the app (*acceptability*) and improve the user experience on the *contextual relevance*. The *ease* of using the customized system and a clinician's feedback mechanism through the physician

module is expected to improve the *clinical utility* of the app. It is expected that adherence to using the app would improve compliance to treatment protocol, thus improving treatment outcomes.

The entry of information into EDDy can be done either by the patient or their caregiver. The entry of SMBG values by the patient is a standard clinical practice in patient management. The current practice is that these self-monitored blood glucose values (SMBG data) is maintained by the patient on a printed form provided by the hospital. It is standard practice that such SMBG data function as a mechanism that helps physicians to optimize medication in routine clinical practice [10].

A researcher will provide instruction to the patient or patient party on how data entry needs to be done on the app. Additionally, a built-in user manual will be provided with the system. This will be developed as a part of the app development. A multilingual *user manual* or *instructional videos* will be developed to assist the patient in using EDDy. The pictogram in Figure 3 represents the workflow of EDDy.

Figure 3. Prototype of EDDy.



Phase 3

Study Design

Phase 3 will involve testing the adherence and usability of the developed app. This phase will use a pre- and posttest design among 48 patients with diabetes selected through purposive sampling.

At a 5% level of significance with 80% power and an effect size of 0.25, the minimum sample size required for a single-group, repeated measures study design involving 1 primary quantitative outcome (adherence) measured across 3 time points (preintervention, after 3 months, and after 6 months; correlation among repeated measures is 0.3) to understand the adherence to EDDy integrated with an HIS is 38 individuals. Incorporating a dropout rate of 20%, the minimum sample size requirement is 48 individuals.

The sample size was computed using G*Power (version 3.1.9; Universität Düsseldorf). The sample size may be amended (if required) based on pilot study findings.

The study setting will be the endocrinology OPD of a tertiary care hospital in coastal Karnataka, India.

Regarding study participants, patients with T2DM who have regular follow-up records will be considered for the study.

This study will analyze the adherence of patients with T2DM to EDDy in comparison to the existing manual method of documentation. Adherence will be evaluated in terms of the following:

- Adherence of entering SMBG values as predetermined by the patient: The study participants will be instructed to fix the frequency that they will monitor their blood glucose; based on this frequency, they will be prompted to conduct the glucometer testing and enter the values into EDDy. The values will be stored in the app and will be transferred to the server on a regular basis as the EDDy is integrated with an HIS.
- Adherence to diabetes self-management (DSM) practices: Pre- and posttest adherence to DSM practices will be analyzed using the same content-validated questionnaire.
- Adherence to routine blood investigations and screening regimen: Pre- and posttest adherence to periodic blood investigation and comorbidity screening will be analyzed.

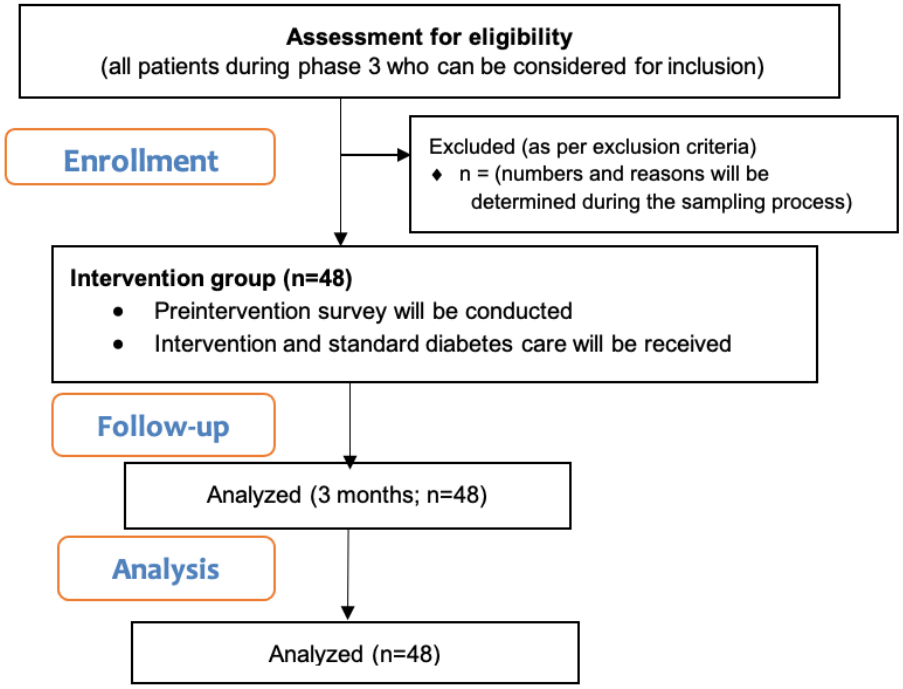
The inclusion and exclusion criteria for sample collection will remain same as that of phase 1.

Phase 3 will be evaluated in 3 intervals:

- First evaluation (preintervention): During enrollment into the study, the patients will undergo an entry survey using a content-validated questionnaire to analyze the current DSM and SMBG practices they follow.
- Second evaluation (follow-up): An interim follow-up will be conducted in the third month.
- Third evaluation (postintervention): The same questionnaire used in the first evaluation will be used to evaluate DSM and SMBG practices after the intervention.

The study participants will be provided with EDDy on their mobile phones and will be trained to use it along with standard diabetes care. Training materials will be a part of the app for patient's ready reference. The pre- and posttest process is shown in Figure 4.

Figure 4. Pre and Posttest Process of development of EDDy.



Analysis

Study participants will be followed up for 6 months and will be analyzed primarily for their adherence to using EDDy. It will be assessed based on patients' willingness to use it, the ease of use, their acceptance of EDDy in terms of the contextual relevance, and the clinical utility. The participants will undergo an exit survey at the end of the study period using a validated questionnaire. It will be specific for assessing the qualitative parameters such as *user experience*, *glycemic control*, *adherence leading to improvement in their SMBG*, and *clinical utility.*

The qualitative outcomes are as follows:

- Ease of use and adherence: User's perception on accessing the various modules in the app, ease of entering information, ease for retrieving information, and ease of comprehending information
- Glycemic control: Adherence in terms of regular monitoring and tracking of blood glucose values to keeps it under check, leading to well-managed T2DM
- Contextual relevance: Relevance of the contents of EDDy in terms of the user expectations and requirements as expressed in phase 1 of the study
- Adherence to SMBG and DSM practices: Reminders and alerts that ensure adherence to medications, insulin injections, regular glucose testing, and comorbidity screening
- Clinical utility: Improvement in treatment outcomes due to adherence to reminders or alerts and monitoring of blood glucose, adherence to medication, and follow-ups

The frequency will be tested based on the Diabetes Co-Conditions Screening Checklist provided by the Association of Diabetes Care & Education Specialists [11].

The following standard tools will be used for assessment, which are modified according to the study requirements and will be content validated by experts:

- Perceived Health Web Site Usability Questionnaire: A 12-item questionnaire that is validated for assessing the usability of health websites for older adults will be used [12].
- Diabetes Self-Management Questionnaire: It describes self-care activities related to diabetes. SMBG practices will be analyzed using this tool. A validated 12-item questionnaire to assess self-care activities associated with glycemic control will be used [13].
- A self-developed, content-validated questionnaire: Adherence will be evaluated, including the regularity of use; ease of use with respect to entering diabetes-related information such as regular testing and entry of glucose levels; adherence to medications or insulin doses; reporting of diabetes-related emergencies or complications, if any; and adherence to periodic screening such as laboratory

investigations, peripheral neuropathies, retinopathy, diabetic foot, and BMI.

The physicians will be interviewed to assess the clinical utility of the app and their experience in using the app using a content-validated questionnaire.

Expected Outcomes

A customized mHealth app that provides adequate information specific to the T2DM management will be developed. This can lead to an effective intervention that will reduce the risk of a person diagnosed with T2DM from developing further disease complications, such as chronic kidney disease, diabetic foot, retinopathies, and peripheral neuropathies, thereby reduce the cost of health care expenditure.

Results

Pilot Study

Out of 50 patients with T2DM (aged 40-50 years), 22 (44%) documented their self-monitored glucose values, whereas the remaining 28 (56%) did not. The percentage score of sources used by patients with diabetes to document the values of self-care activities showed that most of the patients (n=21, 42%) were using a personal diary to document, whereas only 1 (2%) patient each used a diabetes app and mobile notes. Responses from patients with diabetes regarding the necessity of personal health information in diabetes management showed that 31 (62%) patients were not completely aware of personal health information management.

The study results reflected the perception of patients with T2DM about their personal health information documentation practices. Additionally, the study gave a brief outlook about the challenges and barriers that patients face during their DSM activities.

Study Status

Phase 1 was completed on November 28, 2023. Phase 2 of the study, which is the app development, commenced in December 2023 and will end by March 2025. The wireframe model of EDDy is shown in Multimedia Appendix 1. Phase 3 of this study will follow afterward, analyzing the effectiveness of adherence to the app and its usability.

Discussion

Pilot Study Findings

It was evident from the pilot study that there is a strong requirement to promote documentation of SMBG and DSM practices. Overall, the study concluded that there is a scope for strengthening DSM, knowledge development, and improved self-documentation practices by promoting personal health information practices among patients with diabetes. It has the potential to improve the quality of life of patients with diabetes by better promoting self-care.

Expected Findings

When considering a country such as India, which has a very diverse population belonging to different socioeconomic backgrounds, it is difficult to implement a standard practice to tackle a problem. Statistics show that out of 45% of Indians over 45 years of age, about 11.5% are diagnosed with diabetes or high blood sugar levels [3]. Patients belonging to this age group are comparatively less familiar with technology and digital apps. Understanding their requirements and developing a hospital-based electronic diary may promote its use and adherence among them and, eventually, all patients with T2DM.

Considering India's socioeconomic background, the requirements for this population need to be assessed from various angles. It can be demonstrated by analyzing the findings of the study conducted by Walle et al [14] among 422 patients with diabetes in Ethiopia. The study aimed at understanding the willingness of patients with diabetes mellitus to use mHealth app and its associated factors for self-care management in a low-income country as a precursor to digital health implementation in Ethiopia. The study concluded that the mHealth app developers should consider factors such as the patients' age, place of residence, internet connectivity, attitude, perceived ease of use, and perceived usefulness while developing similar apps [14].

The pilot study conducted to analyze the awareness of patients with T2DM also clearly stated that they were aware of the importance of SMBG and DSM practices and the availability of mHealth apps to help them manage their T2DM. However, they were not very keen on using it due to various personal factors.

It was evident from the findings that there is a clear requirement to generate awareness about T2DM management and the use of mHealth apps. It is equally important to understand the challenges that keep them from using available mHealth apps. Based on these observations, if an mHealth app can be developed and the information can be transferred to the patients' records in real time, it will be beneficial for both the patients and the doctors to better manage the condition.

Conclusion

The literature review and pilot study conducted suggests that an easily manageable, personalized diabetes-monitoring system for patients to do regular self-checks and that provides the end users with accurate data on the patient's diabetic history will be beneficial for better management of T2DM. It would enable better sharing of information between patients and doctors, thus improving the communication between patients and doctors, which is significant in the management of diabetes and leads to better treatment outcome. The available apps are not very popular among the end users as they find it difficult to use and understand the contents. To ensure better usability and adherence, a convenient and simple alert system that enables the patient to conduct glucose testing at intervals set by the patients themselves can be designed. The proposed app EDDy will provide grading options to enter the diabetic-related complications (such as neuropathy, retinopathy, diabetic ulcers, etc), thus alerting patients and doctors for prompt action. It is also expected to enhance patients' knowledge of tracking and managing the complications of diabetes and help in maintaining the visual representation of glucose values and complications. The simplicity and usability of the module are its novelty, which

may motivate the patients to keep track of their glucose values and help them to attain better health outcomes.

Acknowledgments

The author would like to acknowledge the participants of the pilot study and Mr Prajwal L Salins and Ms Ashika Shetty.

Data Availability

As this is a study protocol, the results of the pilot study have been reported, and the data will be submitted as required.

Conflicts of Interest

None declared.

Abstract

Background: Electronic medical records (EMRs) streamline medical processes, improve quality control, and facilitate data sharing among hospital departments. They also reduce maintenance costs and storage space needed for paper records, while saving time and providing structured data for future research.

Objective: This study aimed to investigate whether the integration of the radiation oncology information system and the hospital information system enhances the efficiency of the department of radiation oncology.

Methods: We held multidisciplinary discussions among physicians, physicists, medical radiation technologists, nurses, and engineers. We integrated paper records from the radiation oncology department into the existing hospital information system within the hospital. A new electronic interface was designed. A comparison was made between the time taken to retrieve information from either the paper records or the EMRs for radiation preparation. A total of 30 cases were randomly allocated in both the old paper-based system and the new EMR system. The time spent was calculated manually at every step during the process, and we performed an independent 1-tailed *t* test to evaluate the difference between the 2 systems.

Results: Since the system was launched in August 2020, more than 1000 medical records have been entered into the system, and this figure continues to increase. The total time needed for the radiation preparation process was reduced from 286.8 minutes to 154.3 minutes ($P<.001$)—a reduction of 46.2%. There was no longer any need to arrange for a nurse to organize the radiotherapy paper records, saving a workload of 16 hours per month.

Conclusions: The implementation of the integrated EMR system has resulted in a significant reduction in the number of steps involved in radiotherapy preparation, as well as a decrease in the amount of time required for the process. The new EMR system has provided numerous benefits for the department, including a decrease in workload, a simplified workflow, and conserving more patient data within a confined space.

Introduction

The advantages of electronic medical records (EMRs) include facilitating medical process management, quality control, and the sharing of medical record data among different departments in a hospital, as well as reducing both costs and storage space for paper medical records [1,2]. The Ministry of Health and Welfare in Taiwan implemented a pilot program for the digitalization of medical records in 2002, and our hospital participated in this program to digitalize our medical records.

However, due to the highly complex nature of the information contained in radiotherapy (RT) treatment plans [3,4], the paper records of RT are not easily integrated into the hospital information system (HIS) [5-7], causing operational difficulties for medical staff across different departments. These difficulties included obtaining information such as a patient's cumulative dose, fractionations, and frequency of treatment through our HIS. Additionally, searching for treatment history in paper records is a time-consuming and inefficient process that can lead to errors, especially as the records are handwritten. Moreover, the software used in a linear accelerator is independent of the HIS in most radiation oncology departments. Doctors and other medical personnel must use 2 different systems, which means they often have repeated tasks. For example, when a physician wants to write an RT certificate for a patient, information such as date of treatment, total dose, and frequency of treatment must be entered into a certificate manually, which is prone to errors and is time-consuming. Integrating the 2 systems would allow doctors to work more efficiently and serve more patients. Structured data can also be used for future quality control and clinical medical research. Furthermore, various monthly and annual reports in an integrated system can allow the department manager to effectively monitor the clinical load in the department, and the data can be used as a reference for manpower deployment and overtime budget application [8].

In line with national policy and the needs of our hospital, an EMR system for the radiation oncology department was established. This study examines how the integration of the RT EMR system with our HIS improved the efficiency of our department and the accuracy of the data. In this study, we demonstrated that by consolidating the 2 separate systems into 1, we were able to significantly increase efficiency, save time, and conserve valuable resources.

Methods

Overview

In January 2020, the first meeting was convened to discuss the implementation of EMRs. Representatives from various staff groups, including physicians, physicists, medical radiation technologists, nurses, and engineers, were appointed to discuss workflow arrangements and functional requirements. The preliminary system was completed in July 2020, followed by internet-based testing and debugging. The updated system was fully deployed in August 2020, replacing the old system entirely. We kept a monthly review of the system in order to debug or improve the user experience.

The first step involved reviewing the paper documents, including graphs, tables, and written records. Staff from different departments held monthly discussions in the Radiation Oncology Department conference room, and the records of our meetings were saved in our database for the future. Our staff and engineers discussed the feasibility of transforming each item into electronic records. In the paper documents, check marks were made under the date in the table upon completion of daily treatment. If daily treatment was not performed, the field would be left blank. The total number of treatment days was calculated manually. Following discussions with the engineers, key information, such as the radiation beam energy, radiation technique, planned target volume and dose, treatment date, and daily treatment status, were selected as items to be included in the electronic records.

The subsequent step involved educating physicians about how to input treatment plan information into the HIS. A new electronic interface was designed for physicians to input crucial data, such as the treatment intent, planned target volume, planned dose, and planned number of treatment days. These data would then be integrated into the EMR.

In addition, daily treatment progress was recorded automatically in the HIS. The total number of treatment days was controlled by the electronic treatment plan entered by the physician, thus preventing unnecessary dose delivery. The EMR retrieved the actual treatment dates from the HIS, thereby providing precise treatment progress information. After several adjustments, the final version of the EMR system was launched in the HIS (Figure 1).

Figure 2 shows the comparison of the preparation processes between paper record usage and the integrated electronic record system. In order to evaluate the results of our integration, a comparison was made between the time taken to retrieve information from either the paper records or the EMRs for radiation preparation. A total of 30 cases were randomly allocated in both the old paper-based (legacy) system and the new EMR system. The time spent was calculated manually at every step during the process, and we performed an independent *t* test to evaluate the difference. All statistical analyses were performed with SPSS (version 23; IBM Corp). A *P* value of <.05 was considered statistically significant. This study explores the benefits of converting paper medical records in the radiation oncology department into EMRs and integrating them with the hospital's existing electronic medical systems. It does not involve personal information or related ethical issues.

Ethical Considerations

Our research mainly focuses on the integration of the EMR system into the HIS and the efficiency of our new protocol in preparing RT records for new patients. The study does not involve personal or sensitive information related to human participants, so privacy and confidentiality protection considerations for human participants are not applicable [9]. There is no image or identifiable information related to an individual patient.

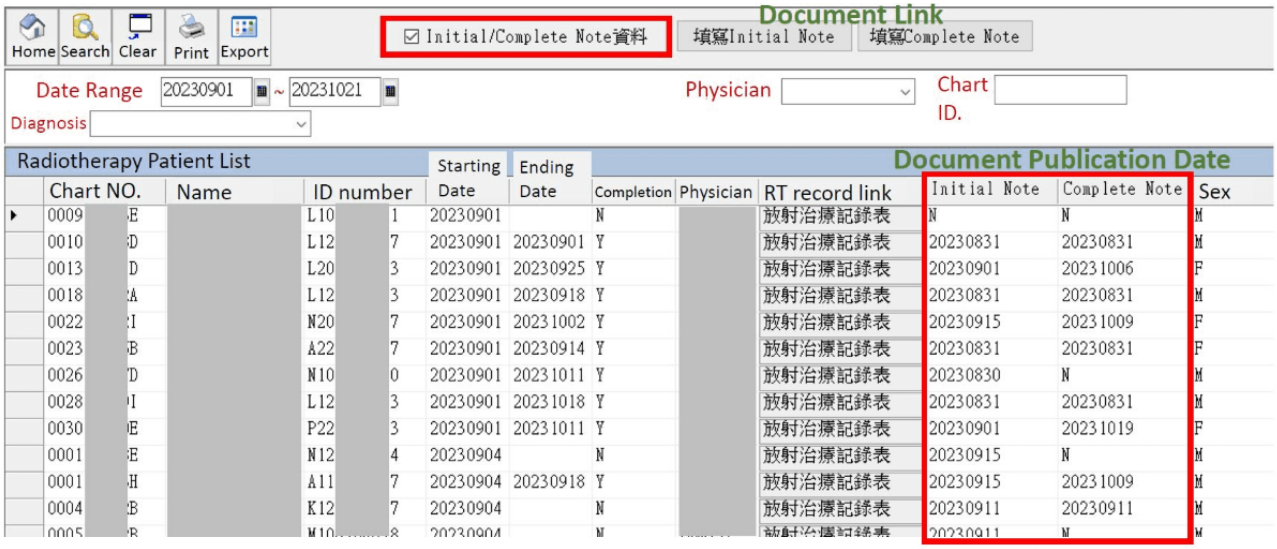
Results

Since launching in August 2020, the system has been highly used, with the number of medical records entered exceeding 1000 and continuing to increase. Integration of the system has

meant that patient lists and their related information are now displayed (Figure 3), allowing physicians to easily check the treatment status of each patient. Physicians can also query the records of past treatments of patients, review their past treatment status, and link their latest EMRs to track their current condition. The new system can also export the files of all patients who have been treated in the past for the purpose of statistical analysis. Additionally, the number of treatment days for each patient can now be automatically calculated. The medical record writing format is now consistent among physicians.

As shown in Figure 2 the integration of the electronic record system has led to a significant reduction in the time required for the radiation treatment preparation process. The new protocol post integration of the EMR streamlines procedures by obviating the need for retrieving previous paper records or generating new ones. Physicians input treatment information directly into the HIS instead of transcribing it onto paper records, eliminating the necessity for printing treatment plans. In addition, physicians can scrutinize the treatment plan and monitor treatment progression seamlessly through the HIS. Radiologists, in turn, can access the treatment plan on the HIS and commence patient treatment, thereby economizing time previously spent awaiting the transportation of paper records. Specifically, the processing time has decreased from 286.8 minutes to 154.3 minutes (P<.001), representing a total reduction of 46.2%.

Figure 3. The list of patients and their related information created by our electronic medical record. Integration of the system allowed the patient lists and their related information to be displayed, allowing physicians to easily check the treatment status of each patient. RT: radiotherapy.



Discussion

Overview

Before the implementation of the EMR system, retrieving RT history was conducted manually, which was time-consuming and burdened nurses with a significant workload. The integration of the electronic system has simplified the process by eliminating several procedures and allowing physicians to instantly access RT records. Many new functions have also been added to this system.

First, the establishment of the new scheduling system allows physicians to modify the treatment schedules of new patients at any time. All staff in the department have the authority to modify the scheduling system. Second, the scheduling system has a hyperlink on the interface, which allows a doctor to view the patient's schedule while browsing the medical records, as well as edit the patient's RT notes. Third, a doctor can easily check the patient's status on the system. The patient list generated by the system can show information about a patient, including contact information, RT starting date or ending date, the number of treatments, and the completion status of RT notes.

The new electronic system has brought several benefits. First, it facilitates communication between physicians and other staff within the department. Clinical RT requires both intensive and extensive communication and cooperation among various groups of staff, including physicians, physicists, medical radiation technologists, nurses, and administrative personnel, in order to proceed smoothly. It is crucial that communication be both correct and instantaneous. With our system, a physician can enter the handover of a patient into the system, and a radiologist can read the handover before the treatment. Staff from different departments can also find the treatment details of a patient on the HIS.

Second, there is no longer a need to arrange for a nurse to organize the RT paper records, which saves a workload of 16 hours each month. Aguirre et al [2] concluded that electronic health records can minimize delays, increase health care workers' satisfaction, and decrease the chances of usability being compromised. Our study also showed that the integration of the radiation oncology EMRs and the HIS simplifies the workflow at our clinic (Figure 2), saving time spent performing radiation preparation procedures and enhancing efficiency. The protocol covered seamless transitions from one stage of the process to the next, ensuring that the entire workflow remained in compliance with standards for RT preparation. Furthermore, Chen et al [10] and Huang et al [11] showed that shortening the preparation time needed before the start of RT improved the treatment effect. Previous research has also shown that, with the assistance of an information system, the work process

becomes smoother. Physicians can be given an automatic reminder or warning, which, in turn can shorten the necessary work preparation time from 12.2 days to 8.9 days [12].

Third, the statistical functions of this information system allowed the manager of the department to obtain accurate information on the number of people treated by each machine, as well as the number of fields per day, the number of simulations, the number of brachytherapy procedures, the number of people waiting for treatment, and the waiting time for each patient. The workload for each physician can also be monitored, and various monthly and annual reports allow the department manager to effectively trace the clinical workload in each treatment room. Monthly and annual reports can also be used as a reference baseline for manpower deployment and overtime budget applications [8]. Having mastery over these data can contribute to a better understanding of the operation of the department, and the information provided by the system can serve as important reference data for decision-making on issues such as whether to purchase new machines or modify manpower.

Additionally, the new system can assist with medical summary writing and education for a resident doctor. Each RT summary requires an average processing time of 10-15 minutes. Currently, with the new system, it only takes about 5 minutes to complete an RT summary because the detailed information on RT is automatically retrieved from the EMR. Doctors simply need to fill in the information about side effects and the treatment response. The system can also remind physicians to finish the initial note and to complete the RT summary when treatment is completed. For educational purposes, an electronic RT summary allows a resident doctor to quickly review the modifications from an attending physician and become familiar with the key points of the appropriate medical record [6,13].

Finally, at least 39,600 sheets of paper were used to prepare RT paper records per year, which is equal to 713 kg of carbon emissions. Furthermore, the demand for storage space tends to increase annually for paper records, but electronic records only require a relatively small physical space to store a large amount of patient data. The implementation of the improved EMR system has freed up space in our department that can now be put to better use. On the other hand, the number of our new patients increased annually. In 2020, we accommodated 1920 new patients, attended to 2118 newcomers in 2021, and extended our services to a total of 2230 fresh patients in 2022. Because the EMR system has decreased the number of radiation therapy transactions per day, physicians and nurses can manage clinical matters more efficiently, allocating more time for meaningful communication with patients. Furthermore, our department is relieved of the necessity to expand storage space for paper records as the EMR system adeptly conserves extensive patient data within a more confined space.

The system offers great flexibility for future expansion and can adapt to changes in clinical practice. We plan to improve the system by introducing an automatic patient registration system, a face recognition system, and an artificial intelligence scheduling system.

Limitations

The challenge of transitioning from paper records to electronic records remains high. The process is time-consuming and requires multidisciplinary team discussions. One limitation of our study is that the multidisciplinary team discussions only included engineers and staff in our department. Ideally, feedback and opinions should also have been collected from other departments in our hospital to improve our EMR system and make it more user-friendly. A survey to assess satisfaction with the new system will be conducted in the future. Any future studies should also have a larger sample size to validate our results. Furthermore, a comparison with other radiation oncology departments would be insightful.

Conclusion

The implementation of the integrated EMR system has resulted in a significant reduction in the number of steps involved in RT preparation, as well as a decrease in the amount of time required for the process. The new EMR system has provided numerous benefits for the department, including a decrease in workload, a simplified workflow, and conserving more patient data within a confined space.

Abstract

Background: Care for patients with heart failure (HF) causes a substantial load on health care systems where a prominent challenge is the elevated rate of readmissions within 30 days following initial discharge. Clinical professionals face high levels of uncertainty and subjectivity in the decision-making process on the optimal timing of discharge. Unwanted hospital stays generate costs and cause stress to patients and potentially have an impact on care outcomes. Recent studies have aimed to mitigate the uncertainty by developing and testing risk assessment tools and predictive models to identify patients at risk of readmission, often using novel methods such as machine learning (ML).

Objective: This study aims to investigate how a developed clinical decision support (CDS) tool alters the decision-making processes of health care professionals in the specific context of discharging patients with HF, and if so, in which ways. Additionally, the aim is to capture the experiences of health care practitioners as they engage with the system's outputs to analyze usability aspects and obtain insights related to future implementation.

Methods: A quasi-experimental design with randomized crossover assessment will be conducted with health care professionals on HF patients' scenarios in a region located in the South of Sweden. In total, 12 physicians and nurses will be randomized into control and test groups. The groups shall be provided with 20 scenarios of purposefully sampled patients. The clinicians will be asked to take decisions on the next action regarding a patient. The test group will be provided with the 10 scenarios containing patient data from electronic health records and an outcome from an ML-based CDS model on the risk level for readmission of the same patients. The control group will have 10 other scenarios without the CDS model output and containing only the patients' data from electronic medical records. The groups will switch roles for the next 10 scenarios. This study will collect data through interviews and observations. The key outcome measures are decision consistency, decision quality, work efficiency, perceived benefits of using the CDS model, reliability, validity, and confidence in the CDS model outcome, integrability in the routine workflow, ease of use, and intention to use. This study will be carried out in collaboration with Cambio Healthcare Systems.

Results: The project is part of the Center for Applied Intelligent Systems Research Health research profile, funded by the Knowledge Foundation (2021-2028). Ethical approval for this study was granted by the Swedish ethical review authority (2022-07287-02). The recruitment process of the clinicians and the patient scenario selection will start in September 2023 and last till March 2024.

Conclusions: This study protocol will contribute to the development of future formative evaluation studies to test ML models with clinical professionals.

Introduction

Care for patients with heart failure (HF) causes a substantial load on the health care system. One of the prominent challenges associated with HF care is the elevated risk of readmissions within 30 days following initial discharge [1]. While this readmission risk underscores that patients receive life-saving care, it also encompasses implications of health care costs, patient's stress, and the impact of socioeconomic determinants on care outcomes [2]. The risk of readmission due to the worsening of HF symptoms is heightened by inappropriate treatment strategies, infectious complications, or prematurely executed discharges. Therefore, readmissions can be reduced by taking steps both during admission and hospitalization and post discharge to ensure compliance with care plans and improved treatment outcomes.

In current practice, clinicians make expert decisions, weighing in the probability of readmission of a patient by evaluating clinical data such as a patient's medical history, medication list, laboratory tests as well as social factors [3]. However, the process of assessing a patient's readiness for discharge introduces an element of subjectivity and uncertainty. Questions surrounding the probability of readmission emerge, prompting deliberation on optimal timing for discharge—whether immediately or with a slight delay. Additionally, the patient's social context plays a critical role; decisions must be made regarding the suitability of home care versus outpatient clinic assignment.

In pursuit of curbing health care costs and mitigating uncertainty novel risk assessment tools, often in the form of predictive models have been developed. Drawing upon statistical, conventional machine learning (ML), and deep learning methodologies, these tools are designed to identify patients at risk of hospital readmission [4-6]. Leveraging risk indicators such as age, illness severity, prior hospitalizations, and other factors, these models predict the likelihood of readmission within a specific time frame. Preventive approaches can then be developed and applied to target the identified high-risk patients. The profound potential for cost savings within the health care domain has fueled substantial interest in rigorous testing and validation of similar models, underscoring the imperative of optimizing patient care while securing resource efficiency.

In this project, our objective is to evaluate the applicability and potential benefits of a previously established ML model for predicting unscheduled readmission of patients with HF within 30 days after discharge from medical care [5]. This model has been further fine-tuned and tailored for practical integration and usage within clinical settings [3,7], encompassing the identification of potential barriers and enablers for implementing a clinical decision support (CDS) tool presenting the model output for clinical use. Refinement also encompassed the augmentation of the model with interpretability features and a comprehensive exploration of the optimal timing and manner in which the model's findings should be presented to users within the clinical domain [7]. The primary aim of the study outlined in this protocol is to investigate how the developed CDS tool alters the decision-making processes of health care professionals in the specific context of discharging patients with HF, and if so, in which ways. Additionally, the aim is to capture the experiences of health care practitioners as they engage with the system's outputs to analyze usability aspects and obtain insights related to future implementation.

Methods

Study Design

The design of this study used the principles of Template for Intervention Description and Replication [8] to support clarity of the description of the intervention and the replicability of its implementation. This study has a quasi-experimental design with a randomized controlled crossover assessment of 2 groups of physicians and nurses working in pairs. This study will be conducted within the health care settings of 1 region in Southern Sweden. The 2 groups will be presented with patient scenarios using purposeful sampling [9] on which they are to make decisions on subsequent care plans and treatment strategies.

HF Care Setting

An HF patient's referral to the hospital can occur through the emergency department, primary care, or home care services. Upon arrival, the patient is allocated to one of the medical departments within either of 2 hospitals in the included region possessing specialized cardiology units. Once admitted, a comprehensive care plan is made, considering the patient's symptoms, prior diagnoses, and relevant test results. This care plan also includes decisions regarding the appropriate timing for discharge. Within the framework of this study, this in-patient scenario, as detailed in a prior work [3], serves as the setting for HF care in which our investigation into the application of the CDS model takes place.

Preparation for This Study

CDS Model

The model is based on comprehensive retrospective electronic health data in a Swedish region [10]. The cohort used for the development consisted of patients diagnosed with HF according to the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision;* I10.0, I42, I43, and I50), were residents, and receiving care in the region. The patients included were aged ≥40 years and had at least one admission after being diagnosed with HF between January 1, 2017, and December 31, 2019. All-cause hospitalization was considered. For each admission in the cohort, all patient's previous admissions within 5 years were considered from the time of admission as the medical history of the patient (look back period); these admissions are not considered as events in this study but were used only as historical data.

Besides demographic information, variables were collected out of electronic health data related to different categories. These categories can be detailed as follows: comorbidities in which patient conditions related to HF are traced back, for example, hypertension, diabetes, chronic kidney disease, and atrial fibrillation. Diagnoses (including procedures) and medications in the electronic health data system were represented according to standard schemas: *ICD-10-SE* (*Swedish version of the 10th revision of the International Classification of Diseases*) and Anatomical Therapeutic Chemical codes, respectively. Laboratory results were also used, including specific features for some laboratory tests, such as N-terminal prohormone of brain natriuretic peptide, sodium, potassium, ferritin, and estimated glomerular filtration rate. Variables were defined to indicate the level of abnormality in the obtained results of these laboratory tests. Following clinical feedback on model development, features associated with a patient's vital signs collected during the admission such as weight, heart rate, and blood pressure were also considered.

A conventional ML model was developed with *CatBoost*, which resembles gradient-boosting decision trees. The *CatBoost* model makes predictions using a series of decision trees, representing an explainable model [11]. In this study, the *CatBoost* python package (version 1.0.4) was used. The model was trained using a stratified 10-fold cross-validation, such that the training data were further divided into 10 parts where 90% (14,069) of data were used for training and 10% (1842) used for validation. Evaluation of the performance is based on commonly used performance measures such as sensitivity, specificity, F_1-score, receiver operating characteristic curves, the area under the receiver operating characteristic curve, and the area under the precision-recall curve. The performance of the model is presented in a retrospective ML study [7].

The Shapley Additive Explanations (SHAP) technique was adopted to provide more details behind the model decision regarding important features for readmission prediction [12]. SHAP works as a model-agnostic explanation tool and provides local (ie, patient-specific) as well as global explanations (ie, across patient cohorts). SHAP was used to compute explainability outputs for the selected patient scenarios, which were later used as input to the CDS tool. For each prediction, the most important features were listed that were positively or negatively driving toward the readmission risk. The explanations provided were assessed by physicians for clinical relevance.

Stakeholder Study

To prepare for the experiment, an interview study was performed to determine the potential barriers and facilitating factors for the implementation of the CDS tool. In total, 12 interviews with stakeholders were performed in a Swedish health care organization consisting of 2 hospitals, primary care, and partial home care. The views on the CDS tool were collected from different roles such as medical process leaders, medical specialists in cardiology, specialist nurses, physiotherapists, home care physicians, home care nurses, and administrative roles [3]. Interviews were transcribed and thematically analyzed to condense and categorize content.

Explainable Artificial Intelligence Design Process

A design process was carried out to create the user interface of the CDS tool. The initial phases included expert interviews, care process observations, and literature searches about the design of explainable artificial intelligence (AI) systems. There are several design problems to address in creating an interface for such a decision support system, for example, to understand who the intended users are and their needs, what information flows the system shall interact with, and in what part of the care process such information is relevant [13]. Therefore, an iterative design process was adopted, to move forward step by step, while generating and testing different design ideas.

Initial usability tests were conducted after generating a set of low-fidelity prototypes. In total, 5 clinicians (3 physicians and 2 nurses) were individually testing the different prototypes over recorded video calls. The tests evaluated if the prediction score and the explanation presented in the prototypes were understandable, and how clinicians perceived this information given the situation of an AI-model as the source. The tests gave important information on which language to use and what to display in the interface, which was the focus of the next iteration. The initial usability tests further raised questions about where this tool might be needed and who the users could be. Consequently, additional care process observations were made, which led to some changes to the definition of the target users and the place of potential implementation.

All usability test data were analyzed, categorized, and used as input for the further development of the prototype. Thereafter, additional usability testing was performed, following the same procedure as previous tests, however, focusing on exploring how to present more detailed information. Another 5 clinicians (three of them participated in the first usability tests) tested these prototypes over video calls. The outcome of this second round of usability tests was used as input to another design update before a high-fidelity prototype was created. This prototype was tested with 4 clinicians (2 physicians and 2 nurses who also participated in the previous tests).

As the last step of the prototype development, a series of design workshops were conducted with user experience resources, to finalize the prototype and set the details, before a smaller

usability test was performed with 2 clinicians (1 physician and 1 nurse). Their input led to some minor interface changes, and now the development of the CDS tool could begin.

Scenario Creation

From the same data set used to develop the CDS model, 20 patients were selected to constitute the target population in this study by using stratified random sampling. The stratification was made to ensure that there are equal amounts of readmitted patients and control patients. For each of these 20 patients, scenarios comprising narrative reports and clinical data describing demographics, and clinical events and outcomes, including potential readmittance, were recreated retrospectively based on real patient historical data from the regional database of electronic health data.

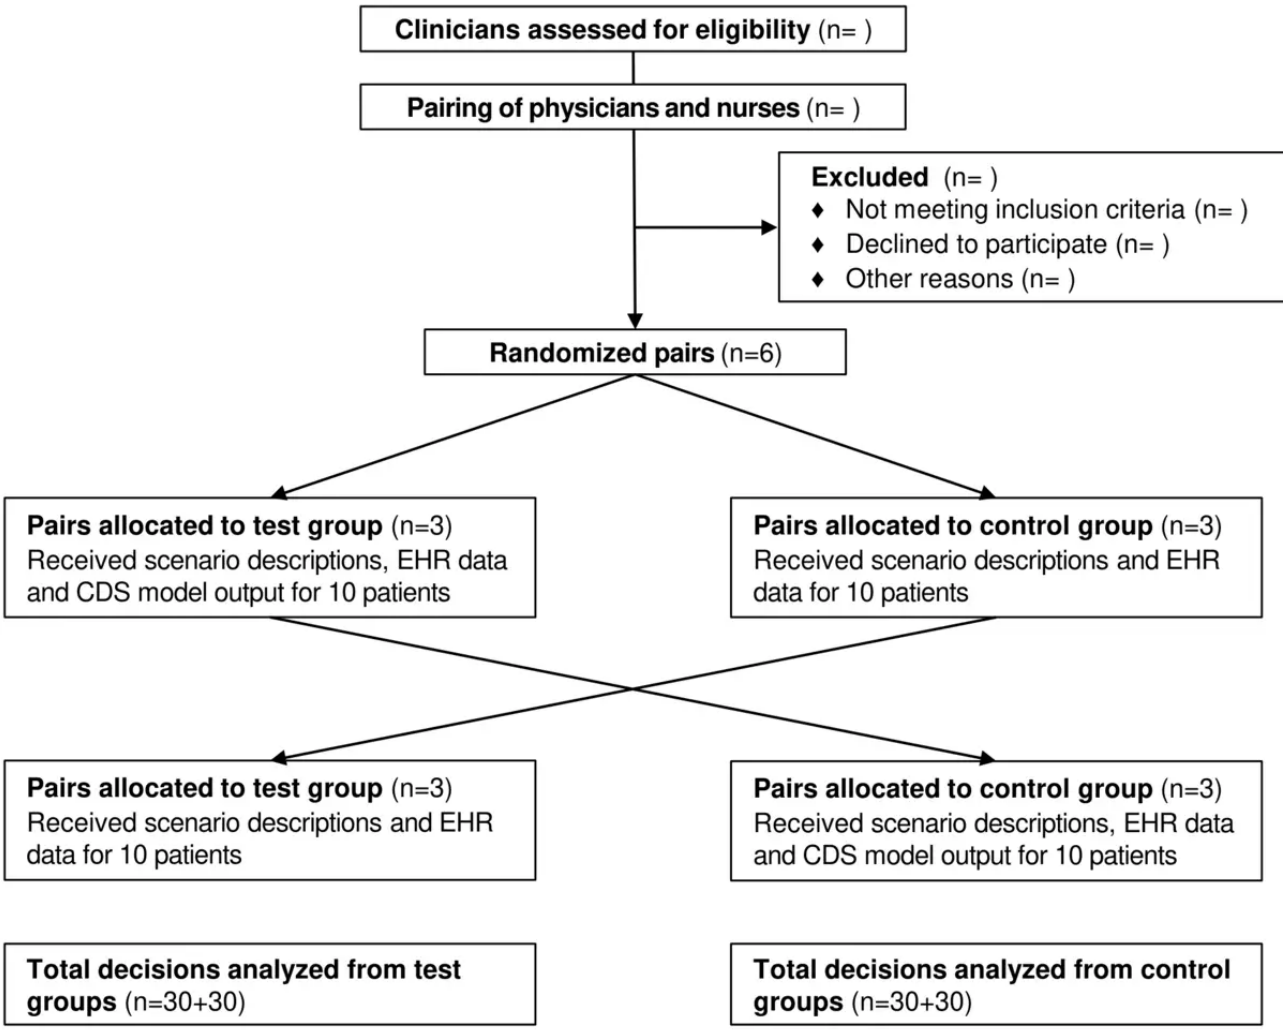
Recruitment

The participants involved in the experimentation will include both physicians (n=6) and nurses (n=6) and will be recruited from the clinical staff at the 2 hospitals based on the following inclusion criteria: a minimum of 3 years of experience in the treatment of patients with HF, and currently active engagement in clinical practice within either of the 2 specialized cardiology departments in the region. This study will use purposeful sampling [9] for recruiting physicians and nurses according to the inclusion criteria, a process led by the hospital. Although there might be a limited availability of staff, physicians and nurses who were involved in the design of this study and the CDS model will be excluded from participation in this study, to prevent bias.

Experimentation and Data Collection

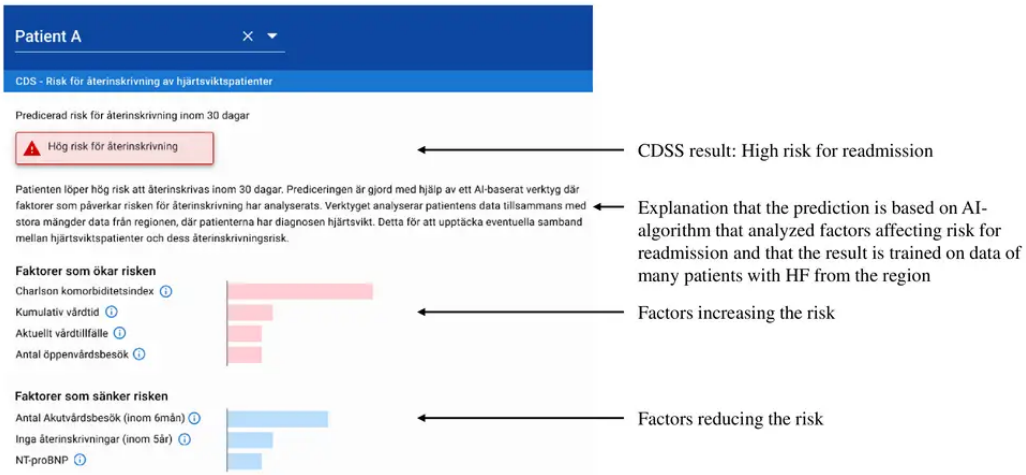
The experiment simulates the decision-making process of a patient's discharge, further treatments, and care plan, based on real historical data. Patient data for model output are preloaded into the CDS model. The participants will be randomly paired with 1 physician and 1 nurse in each pair, reflecting the real-world setup in the decision-making regarding the patient's potential readmission (Figure 1). Pairs will then be randomly assigned into test (n=3) and control (n=3) groups using simple randomization with stratification. The pairs in the test group will be given 10 scenario descriptions, patient electronic health record (EHR) data, and the CDS model output based on each of the 10 patients. The pairs in the control group will be given the same 10 scenario descriptions and EHR data but not the CDS model output. After making decisions based on the 10 scenario descriptions the test group and the control group will switch roles and 10 new scenario descriptions will be given to the groups, again with and without the CDS model output.

Figure 1. Flowchart for the randomized controlled cross-over design. CDS: clinical decision support; EHR: electronic health record.



Before the experiment, each group will be briefly trained in how the CDS model works and how to interpret its output [14,15]. The clinicians will be asked to think aloud so that both the conversation and reasoning during the decision process are recorded. The scenarios will be presented to the clinicians via a text document in a separate computer room at the hospital, and the CDS output in a web-based interface as depicted in Figure 2. The clinicians will be able to either make a decision or request for more information about the patient, which will be provided by an additional clinician who is part of the research group that will be in another room using a chat function on the local information system. This clinician is connected to the EHR system and has access to all patient data. The additional information can include admission notes, laboratory test results, and medication lists, and this procedure will be carefully explained to the clinicians before the experiment. This information will not be available from the beginning, to mimic the real-world information search between different systems or system modules and to research what level of information would be sufficient to decide in both groups; a clinician shall provide extra information about the patient only if requested. Every such request will be documented by the researchers present in the rooms together with the clinicians, observing the decision-making and the experiment. All clinical notes available in the experiment will undergo a deidentification process before this study. The decisions made by the participants will be noted by the observing researcher.

Figure 2. CDS model output showing readmission risk and explanations of model decision for a hypothetical patient. AI: artificial intelligence; CDS: clinical decision support; CDSS: clinical decision support system; HF: heart failure.



At the end of the experiment, each clinician will be interviewed individually by the researcher using the interview questions defined in Multimedia Appendix 1. The dialogue will be audio-recorded and transcribed verbatim.

Outcome Measures

A research-based evaluation framework specifically designed for AI-based decision-support systems [16] has guided and inspired the selection of the outcome measures for this study. The added value of the AI system will be assessed through a mixed methods evaluation design: process efficiency and patient-related outcomes shall be assessed using a quantitative approach, while quality, reliability, trust, and similar parameters shall be addressed through qualitative semistructured interviews. Table 1 provides details on the outcome measures selected for this study.

Table 1. Outcome measures.

Outcome indicator	Goal	Analytic approach
Impact on decision-making		
Decision consistency	To explore decision consistency between the users and the CDS[a] model to research whether having the CDS model increases uniformity among the decisions taken compared to decisions without the model.	• Comparing the taken decisions: • Between the CDS model output and the test group to assess the extent of how much the users agreed with the model output. • Between test and control groups to assess similarity in decisions taken with and without the model output. • Potential decisions: • To discharge, with x, y, and z treatment. • Move to another department (which?). • Take additional tests for an extended investigation. • To send a referral or follow-up at outpatient clinical, primary care, or home care. • To stay for some more days.
Decision quality	To explore whether the CDS model could improve decisions.	• Comparing decisions taken by the test group with: • Historical data—what decision was actually taken for the patient and what event followed afterwards. • Control group's decisions on the same patients to control the influence of the experiment and set up over the decisions taken: do decisions differ from the test group and the historical data?
Work efficiency	To explore performance changes due to using the CDS model output.	• Measuring speed of decision-making for both test and control groups. Comparing the average speed between groups with and without CDS.
Impact on experience with decision-making		
Perceived benefits	Clinicians' attitude toward perceived benefit for patients and clinicians of AI[b].	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q1).
Knowledge	Knowledge sufficiency and possible gaps.	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q5).
Confidence	Confidence in making decisions using the algorithm (trust in the algorithm and data, and self-confidence).	• Asking the participants in the test and control groups to take decisions for some patients with and without the CDS model output. Clinicians will be asked to rate their decision confidence and indicate to what extent the CDS output helped them using a 5-point Likert scale (1=not at all, 5=a great deal) [16]. • Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q3 and Q7).
Reliability and validity	How reliable and valid are the suggestions by the algorithm—perception?	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q3).
Perceived service quality	How is the perception of the overall clinician-provided service perceived?	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q2 and Q6).
Unintended consequences	Unintended consequences are foreseen.	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q4).
Intention of use	Obtaining an indication of worthiness to continue developing the AI-based system.	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q1, Q2, and Q6).
Implementation aspects		
Workflow integration	How integrable is the solution into the current workflows?	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q4 and Q8).

Outcome indicator	Goal	Analytic approach
Usability		
Perceived ease of use	Perception of the features, human-computer interface.	• Interview with nurses and physicians who were exposed to the CDS model output (Multimedia Appendix 1, Q5).

[a]CDS: clinical decision support.

[b]AI: artificial intelligence.

Data Analysis

The quantitative analysis will primarily employ descriptive statistics. The interview data to address the rest of the outcome measures shall be transcribed and thematically analyzed using the thematic coding scheme corresponding but not limited to the outcome measures of this study (Table 1) [16-18].

Ethical Considerations

This study conforms to the principles outlined in the Declaration of Helsinki and will fulfill the following requirements for research: information, consent, confidentiality, and safety of the participants, guided by the ethical principles of autonomy, beneficence, nonmaleficence, and justice. The anonymized patient data used in this study are available (2022-07287-02).

Patients whose data will be used for creating the scenarios will be informed through an advertisement on the university web pages and provided with the possibility to express a will to opt out of this study. The absence of an objection to the use of personal medical data in the research process will be considered as consent to participate.

All participants will receive written and oral information about the studies in which they are directly or indirectly involved. Participants will also be given information about the voluntary nature of the studies, confidentiality, and the ability to withdraw their consent at any time without having to justify why. All personal data will be registered according to the General Data Protection Regulation (GDPR2016/679) and the data will be stored per the Archive Act in Sweden (SFS1990:782).

Results

The project is funded by the Knowledge Foundation and is part of the Center for Applied Intelligent Systems Research Health research profile (280042), which started in July 2021 and ends in 2028. The profile conducts research projects in coproduction with industry about the development, design, and implementation of AI systems in health care. The project HF readmission prediction started in July 2021 and will end in June 2024.

The recruitment process will start in September 2023 and last until March 2024. First, the testing and fine-tuning of this study process using the prototype shall be conducted (planned for September 2023). Then, data will be collected and analyzed during the experiment from October 2023. This study's results are expected to be published. This research will involve several partners: Halmstad University (Sweden), Cambio AB (Sweden), and 1 Swedish region. This research aims to reduce avoidable readmissions of patients with HF.

Discussion

Principal Findings

This study focuses on the ML model for predicting unscheduled readmission of patients with HF within 30 days of discharge [5]. The purpose of the study described in this protocol is to assess the impact of this ML model on decision-making by health care professionals and to capture their experiences in using the model.

A quasi-experimental study shall be conducted with clinicians using the model and results shall be compared against a control group. Throughout the experiment, the researchers shall observe the decision-making process, take measurements, and collect feedback. Such knowledge shall increase an understanding of the potential impact on the decision-making, usability, perceived value if such a model is deployed, and willingness to use such tools in the future. Furthermore, this study will give practical insights into the factors that will potentially influence implementation that could be further used in the implementation process. In addition, concrete outcomes' measures are suggested which can assist in future developments of similar models.

This study has several limitations. First, although the CDS model output shall be provided as a digital interface, the system is not in this version integrated with EHR and it will not be possible to check the actual impact of the CDS model on the workflow. Second, the samples of admissions will be selected using stratified sampling where subgroups will be created for readmission labels assigned to patient encounters. The readmission rate in our data set is 21% (3334 out of 15,911 admissions), thus the chance to obtain enough examples where the readmission label is true will be very low. Accordingly, stratification will be used to divide the population data into 2 subgroups before sampling, then select 10 cases having true as a value for readmission label. Third, this study shall not assess the impact of the use of the model on the cost-efficiency or resource planning. Fourth, the presence of a researcher (an observer) in the computer room while clinicians assess the patient scenarios might influence the results.

To sum up, the findings from this study protocol shall contribute to the development and implementation of a CDS system based on ML models for readmission reduction. The results of this study will be presented at scientific conferences, seminars with professional organizations, articles for media outlets, and submitted to a scientific peer-reviewed journal specialized in health technology.

Abstract

Background: The Processing of Positive Memories Technique (PPMT) is a promising new treatment approach for posttraumatic stress disorder (PTSD), which involves detailed narration and processing of specific positive autobiographical memories. Indeed, preliminary case-series studies have found reductions in PTSD symptoms, negative affect, and negative cognitions among survivors of trauma who have received PPMT. However, PPMT's effects have not been investigated at the daily level. In this study, we describe the protocol for a study that will examine the daily-level impacts of PPMT in a trauma-exposed, nonclinical community sample.

Objective: This study uses an innovative research protocol that combines case-series design and daily diary approaches to examine changes in daily affect, daily cognitions, and daily PTSD symptoms pre- and post-PPMT. We hypothesize that at the daily level, in comparison to their own pre-PPMT levels, following the PPMT intervention, participants will report (1) a lower count of endorsed daily PTSD symptoms, (2) increases in daily positive affect and decreases in daily negative affect, (3) increases in positive affect reactivity to daily positive events, and (4) decreases in daily posttrauma cognitions.

Methods: We are currently recruiting participants (target n=70) from a metroplex in the southwest United States. Following a screening survey, eligible participants complete a preintervention baseline survey, followed by 21 daily surveys in their natural environments. Then, they receive 4 PPMT sessions on a weekly basis. After the conclusion of the PPMT intervention, participants complete a postintervention outcome survey and 21 daily surveys. To compare daily affect, daily cognitions, and daily PTSD symptoms before and after PPMT, we will use the daily diary report data and conduct multilevel random intercepts and slopes linear regression models.

Results: Data collection was initiated in March 2022 and is expected to end by June 2024. As of November 28, 2023, a total of 515 participants had consented to the study in the screening phase. No analyses will be conducted until data collection has been completed.

Conclusions: Study findings could clarify whether deficits in positive autobiographical memory processes may also characterize PTSD alongside deficits in traumatic memory processes. Furthermore, PPMT could be an additional therapeutic tool for clinicians to help clients reduce posttraumatic distress in their everyday lives.

KEYWORDS

affect; case series design; cognitions; experience sampling; intensive longitudinal assessment; positive autobiographical memories; posttrauma health; posttraumatic stress disorder; trauma survivors

Introduction

Posttraumatic stress disorder (PTSD) is a psychological condition that can develop following exposure to traumatic events, characterized by intrusive thoughts and re-experiencing symptoms, avoidance of trauma reminders, negative cognitions and mood, and heightened arousal [1]. A proposed mechanism underlying the development and maintenance of PTSD is disruptions in the encoding, consolidation, and retrieval of negatively- and positively-valenced autobiographical memories [2-4]. Evidence suggests that survivors of trauma with PTSD report difficulties accessing and detailing positive autobiographical memories [5-7], akin to reported difficulties with traumatic autobiographical memories [8]. Unsurprisingly, PTSD interventions typically target the content, processes, and phenomenological characteristics of autobiographical memories [9,10]. While such trauma-focused interventions (eg, prolonged exposure and cognitive processing therapy) are effective for many survivors of trauma, a significant proportion of survivors of trauma do not respond to these treatments, and there is a high degree of dropout from these interventions [11]. This highlights the need to develop alternative therapeutic approaches.

While most PTSD interventions address engagement with only traumatic autobiographical memories, only a few other interventions address both traumatic and positive autobiographical memories or only positive autobiographical memories and have been shown to be effective. For instance, Memory Specificity Training (targeting one's ability to retrieve specific autobiographical memories irrespective of valence) is effective for PTSD and posttrauma distress [12,13]. Also, Broad-Minded Affective Coping, a positive emotion induction technique through the retrieval of positive autobiographical memories, improves mood among individuals with PTSD [14]. Such evidence suggests that a focus on positive autobiographical memories may be a helpful target in PTSD interventions.

The PTSD-Positive Memory Model [15,16] outlines that when survivors of trauma repeatedly retrieve, relive, and detail specific positive autobiographical memories, they may experience an improvement in PTSD symptoms, affect, and beliefs over time [15]. This model was foundational to the development of the Processing of Positive Memories Technique (PPMT), which is a 4- to 5-session intervention tailored to PTSD symptoms. During PPMT sessions, survivors of trauma are guided to narrate details of salient positive autobiographical memories; to access and strengthen positive values, affect, strengths, and thoughts associated with these memories; and to engage in positive affective, cognitive, and behavioral changes [17]. PPMT is influenced by positive psychology, a field that emphasizes factors and mechanisms that enhance psychological well-being rather than focusing solely on pathology [18,19]. PPMT draws from positive psychology interventions (eg, sharing positive narratives with others and using mental imagery to re-expereince positive events) [19-21] and from interventions that increase memory retrieval to improve mental health [22]. The detailed session-by-session content of PPMT is outlined by Contractor and colleagues [17].

Practicing PPMT may help survivors of trauma retrieve more positive autobiographical memories over time, which may also translate to retrieving fewer negative autobiographical memories. Consequently, survivors of trauma may be able to better contextualize and integrate traumatic autobiographical memories with existing beliefs [23] and with other memories [2,24], which in turn could aid recovery after a trauma [2,25]. Positive autobiographical memories may also become primary reference points to interpret experiences and influence self-concept [26-28]. Furthermore, by repeatedly retrieving positive autobiographical memories and associated content, survivors of trauma may lessen their focus on negative material, experience more positive affect, and downregulate negative affect [29-32]. This may be especially helpful for survivors of trauma who experience emotional distress from retrieving negative autobiographical memories. In turn, this improved affect may help survivors of trauma positively interpret events [29,33] and note more positive content in their thoughts [34]. Overall, retrieving positive autobiographical memories may improve well-being [35], resilience [36], and adaptive coping [37], serving as a reminder that there are positive values and thoughts to hold on to despite the hardships faced by survivors of trauma.

Pilot studies have shown that PPMT is feasible and may improve therapeutic outcomes for survivors of trauma. Using an experimental design, a 2-session modified-PPMT [38] and a 5-session PPMT protocol [39] were compared to a neutral memory condition among survivors of trauma. In the first study, authors found that participants who repeatedly narrated the content of positive autobiographical memories reported decreases in PTSD symptom severity and negative affect, as well as increases in positive affect across time compared to the control condition [38]. In the second study, authors found that survivors of trauma who repeatedly retrieved positive (and neutral) memories reported less PTSD and depression severity, fewer posttrauma cognitions, and improved affect [39]. Using an open-label pilot trial, the feasibility and effects of the 5-session PPMT were examined among 12 survivors of trauma [40,41]. The authors found that PPMT reduced PTSD symptoms, reduced negative affect, and improved regulation of positive affect, and there were good feasibility indicators for PPMT (eg, PPMT was acceptable).

Critically, no study has examined PPMT's effects using a larger community sample, nor has there been any exploration of whether PPMT is associated with postintervention changes in how survivors of trauma react to events in daily life. We can hypothesize that PPMT may impact individuals' daily-life affect and cognitions; these impacts represent hypothesized

mechanisms through which PPMT may reduce PTSD symptom severity over time. Most studies examining PTSD intervention impacts use case-series designs, in which data are collected from a group of individuals pre- and postintervention and an aggregate assessment of symptomatology pre- and postintervention is conducted and compared. However, this approach has some noteworthy limitations. Affect, cognitions, and PTSD symptoms are dynamic and vary daily in response to trauma reminders and experiences [42-44]; thus, evaluating intervention effectiveness using 2 snapshot assessments of symptomatology is not sufficiently reliable or nuanced. Furthermore, case-series designs do not examine the daily-level mechanisms of change for an intervention. Given that PPMT may impact daily life affect, cognitions, and symptoms, it is crucial that the data enable an examination of these constructs at the daily level.

These limitations can be overcome by integrating case-series designs with a daily diary framework for the pre- and post-PPMT assessments. Daily diary studies are an intensive longitudinal data collection method in which participants provide daily reports of their experiences each day over a period of time. Compared to retrospective assessments, daily diary data are considered more ecologically valid as they are collected in an individual's everyday life rather than in a laboratory, more accurate and robust, and less vulnerable to recall bias [45]. Thus, the proposed study outlines information on the protocol of an ongoing study that combines case-series design and daily diary approaches to provide novel insights into PPMT's effects on daily-level cognitive and affective experiences. This approach can be conceptualized as a special subtype of case-series design that enables an examination of within-person changes at the daily level.

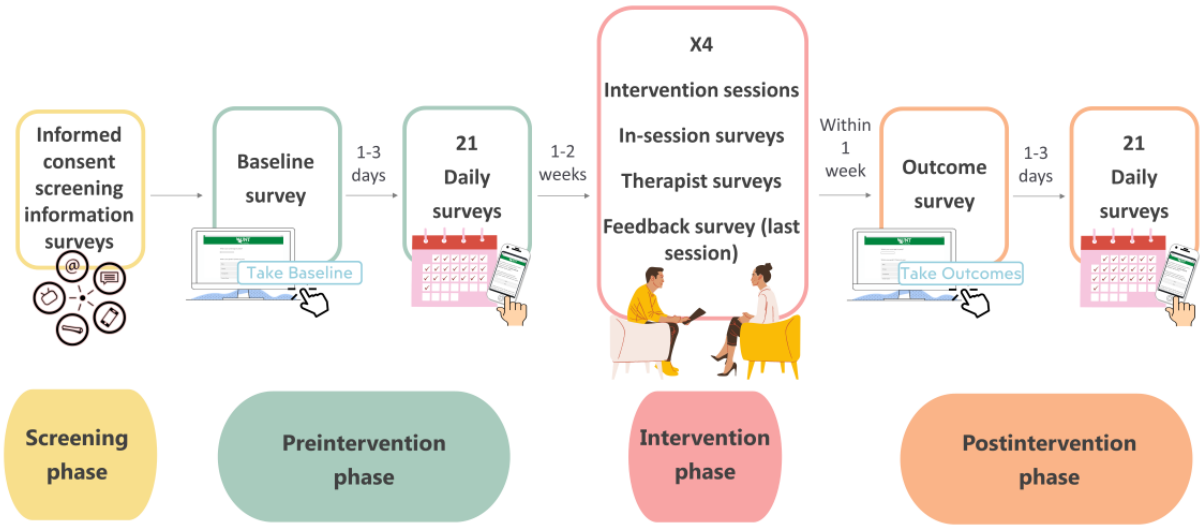
Specifically, the proposed study aims to use daily diary data pre- and post-PPMT to examine changes in daily PTSD, daily affect, and daily cognitions. We hypothesize that at the daily level, participants will report (1) a lower count of endorsed daily PTSD symptoms pre- to post-PPMT, (2) increases in daily positive affect and decreases in daily negative affect pre- to post-PPMT, (3) increases in positive affect reactivity to daily positive events (a within-person index of linear relations between daily positive events and daily positive affect) pre- to post-PPMT, and (4) decreases in daily posttrauma cognitions pre- to post-PPMT. The aim of this study is to detail the proposed research protocol and our hypotheses regarding daily PTSD, daily negative affect, and daily cognitions pre- and post-PPMT. As a supplementary analysis, we will examine if participants report a greater count of retrieved specific positive memories pre- to post-PPMT.

Methods

Study Design

The study involves four phases: (1) screening phase (eligibility survey), (2) preintervention phase (baseline survey and daily surveys), (3) intervention phase (PPMT and weekly surveys), and (4) postintervention phase (outcome survey and daily surveys). Figure 1 provides an illustration of the study procedure. All assessments are completed by participants using a computer or smartphone. Greene and colleagues [46] provide a detailed protocol for the questionnaires. Briefly summed up, following a web-based screening survey, eligible participants are asked to complete a preintervention phase baseline survey followed by 21 daily surveys in their natural environments. Then, they receive 4 PPMT sessions, completing 1 web-based survey per session and a feedback survey in the last session. After the conclusion of the PPMT intervention, participants are asked to complete a postintervention phase outcome survey and 21 daily surveys.

Figure 1. Study procedure: explaining the step-by-step process of the study.



Participants

Participants (target n=70) are currently being recruited from a metroplex in the southwest United States through social media postings, flyers at businesses and public places, and university announcements since March 2022. The inclusion criteria are: (1) being aged between 18 and 65 years; (2) endorsing a trauma with posttrauma symptoms assessed by the Primary Care PTSD Screen for DSM-5 [47]; (3) access to an electronic device (eg, a computer or a smartphone) with internet capabilities; (4)

working knowledge of English; (5) no active suicidal plan, suicidal attempt, homicidal plan, or homicidal attempt (past 3 months including current); (6) being a current resident of the Dallas Fort Worth metroplex; (7) not currently in therapy with a mental health provider; (8) willingness and availability to participate in approximately 10 weeks of this study (including 4 therapy sessions); and (9) willingness to be video-recorded during sessions for quality control purposes.

Procedure

Screening Phase

During this phase, interested participants complete an eligibility survey. First, they read the informed consent document (information about the study, eligibility criteria, compensation, benefits and risks to study participation, and steps to ensure data confidentiality) and provide electronic informed consent if they wish to participate. Next, they answer questions to determine eligibility. Eligible and consenting participants are automatically redirected to a separate survey, wherein they provide contact information for study purposes. Research personnel then contact eligible participants to provide more information on the study (eg, survey timelines and PPMT sessions). No compensation is provided for this study phase.

Preintervention Phase

Participants complete 1 baseline survey and 21 daily surveys as part of this phase. The baseline survey contains questions on demographics, trauma history, PTSD symptoms, and other psychological symptoms, as well as affect and cognitive processes (approximately 30-minute completion time). Eligible participants receive the baseline survey link by email at a date determined to be feasible based on contact with participants. Participants are given up to 48 hours to complete the baseline survey and are sent reminders if they do not complete the survey in a timely manner. Research personnel monitor survey responses for completion, response times to identify unfeasibly short times, accurate participant ID entry, therapy history to confirm they are not currently in therapy, and trauma history.

Participants who complete the baseline survey are asked to complete 21 daily surveys. The daily surveys include questions assessing daily PTSD symptoms, affect, cognitions, and events that occurred in the last 24 hours (approximately 3-5 minutes to complete each survey). The link to the first daily survey is emailed to participants within 1-3 days after completing the baseline survey. Participants receive daily surveys once a day at fixed intervals (at 7:00 PM each day) over a 21-day period, and they have until 11.59 PM to complete each daily survey. Participants are sent text reminders for survey completion to enhance compliance and are contacted if they miss any surveys.

Intervention Phase

PPMT is administered weekly as a 4-session protocol during the intervention phase. The sessions are scheduled within 1-2 weeks after completing the preintervention phase. In session 1, participants receive psychoeducation on PTSD symptoms, an overview of PPMT, and are assessed for psychological symptoms. Sessions 1-4 involve the detailed processing of a salient positive autobiographical memory to elicit "values, affect, strengths, and thoughts" related to that positive memory. Homework assignments include listening to an audio recording of that memory, completing a "values, affect, strengths, and thoughts" log, and engaging in a behavioral activity. In session 4, the therapist also reviews psychological symptoms and addresses termination. Following the completion of session 4, the participants complete a feedback survey on PPMT.

Postintervention Phase

Participants complete 1 outcome survey and 21 daily surveys as part of this phase. Within approximately 1 week after completing the intervention phase, participants complete an outcome survey. The procedural aspects of this phase mimic the preintervention phase. The outcome survey has questions similar to those of the preintervention phase baseline survey (without demographics and trauma history items and with different cue words for the measure examining the count of retrieved memories).

Dropout

Participants who do not complete the outcome survey after 2 days, consecutively miss 4 daily surveys, or miss more than 8 daily surveys (<60% of the daily surveys) in either the preintervention or postintervention phases are considered dropouts for this study, and they do not continue to receive survey links in order to avoid burdening participants with repeated requests to complete the surveys if they no longer wish to participate.

Study's Primary Measures

Overview of Primary Measures

In this section, we outline the measures that relate to the primary outcomes of this study. The primary outcomes of interest are daily positive affect levels, daily positive affect reactivity (within-person index of linear relations between daily positive events and daily positive affect [48]), daily negative affect levels, daily posttrauma cognitions, daily PTSD symptoms, and the number of retrieved specific positive memories as measured pre- and postintervention. Secondary measures (eg, difficulties in positive emotional regulation using the "Difficulties in Emotion Regulation Scale-Positive" and the severity of PTSD symptoms using the "PTSD Checklist for DSM-5") are also administered to allow for the assessment of possible mediators and moderators of treatment effects. Table S1 in Multimedia Appendix 1 [40,47,49-58] provides detailed information on all study measures (including measures for supplemental analyses).

Preintervention Phase Baseline Survey

The number of retrieved specific-positive memories is measured by the Autobiographical Memory Test (AMT) [49,59]. The AMT uses a cued memory recall technique involving the presentation of individual cue words, followed by a prompt to recall a personally meaningful and specific memory of an event that took place within any 24-hour period. For this study, participants are shown cue words and asked to retrieve a personal and specific memory of the cue-word-related event within 60 seconds [59]. The instructions were adapted from previous autobiographical memory studies [49,60,61]. In the preintervention baseline survey, we included 5 cues drawn from

previous studies: friendly, happy, honest, kind, and humorous [62-64]. We will follow coding guidelines to categorize AMT responses [65,66]. AMT responses will be coded as specific (event that occurred at a certain place within 24 hours), extended (event that lasted >1 day), or categorical (summary of repeated events). AMT responses will also be coded as positive or nonpositive following the Coding and Assessment System for Narratives of Trauma [67]. Lastly, AMT responses will be coded as semantic associate (no personal memory) and omission (did not retrieve the memory within 60 seconds or was unable to recall a memory). The AMT demonstrates good psychometrics [68].

Preintervention Phase Daily Surveys

Daily negative and positive events are measured by asking participants to rate their most positive and negative events in the last 24 hours from 0 (not at all unpleasant) to 3 (very unpleasant) [50].

Daily affect levels (ie, positive and negative) are assessed by rating the extent of 4 positive (excited, cheerful, satisfied, and relaxed) and 6 negative (stressed, irritated, anxious, sad, hopeless, and insecure) emotions in the last 24 hours. These emotions were used in a previous daily diary study based on a theoretical circumflex of emotions. The study showed excellent between-person reliability and good within-person reliability [69]. In this study, responses are rated on a 5-point Likert scale ranging from 1 (very slightly or not at all) to 5 (extremely).

Daily posttrauma cognitions are measured by the Brief Version of the Posttraumatic Cognitions Inventory [51], which is a 9-item self-report measure assessing posttrauma cognitions. Responses are provided on a 7-point Likert scale ranging from 1 (totally disagree) to 7 (totally agree), with the time frame modified to “in the last 24 hours.”

Daily PTSD symptom severity is assessed using the Primary Care PTSD Screen for DSM-5 [47], which is a 5-item self-report measure with dichotomous “yes” or “no” items; the time frame is modified to “in the last 24 hours.” We will use the count of endorsed PTSD symptoms as a measure of daily PTSD symptom severity.

Postintervention Phase Outcome Survey

Similar to the preintervention phase baseline survey, the AMT is administered to examine the number of retrieved specific positive memories. Different cue words are used: peaceful, loyal, helpful, safe, and love [62-64].

Postintervention Phase Daily Surveys

The procedural aspects and measures mimic the preintervention phase daily surveys.

Participant Safety and Psychological Distress

There are minimal foreseeable risks associated with this study. Few participants may experience an increase in PTSD severity [70] or suicidal ideation [71], attributed to the sensitive nature of questions targeting trauma reactions and to PPMT itself. To address any such concerns, the study co-principal investigator (co-PI; a licensed clinical psychologist) is training all research personnel on considerations in administering assessments to survivors of trauma, providing clinical training and weekly supervision to study therapists, and training study therapists in anxiety-reduction techniques (eg, guided imagery). Furthermore, study participants receive information on mental health services.

To address any risk factors for self-harm, we are closely monitoring participants during PPMT to assess for any reported suicidal ideation, plan, or attempt (eg, administration of a depression measure every session). Furthermore, the study co-PI is training study therapists to conduct in-depth suicide risk assessments. In the event of suicidal ideation, plan, or attempt reported by participants in session, study therapists conduct a suicide risk assessment and consult with the supervising co-PI to determine if emergency services need to be contacted to ensure participant safety. Also, the participant or therapist may discontinue the study at any time should symptoms worsen or if the participant simply desires to withdraw. Lastly, we are providing information on community mental health centers offering 24-hour access to services and emphasizing contacting 911 or 988 in times of imminent risk.

Treatment Nonresponse or Relapse

Any treatment for posttrauma mental health is associated with some chance of failure to respond or relapse [72]. We are implementing the following procedures to address any such potential concerns. If a participant shows substantial increases in PTSD or depression severity or reports risk factors for self-harm during intervention sessions, we are providing mental health referrals immediately for alternate treatment options, including a 24-hour access local mental health center. Furthermore, research personnel are contacting participants when they miss appointments to check on their health status.

Intervention Training

Therapist Training

The study co-PI trained doctoral students (ie, study therapists) in PPMT. This training included a review of PPMT’s theoretical underpinnings, manuals, and fidelity checklists, as well as practice in PPMT administration. Furthermore, study therapists are required to follow detailed session protocols during each PPMT session. Research assistants were trained in PPMT fidelity ratings; ≥0.81 kappa coefficient and ≥0.8% percent agreement will be considered acceptable interrater reliability (IRR) [73].

Treatment Delivery

All sessions are being video recorded. The co-PI has reviewed all recorded PPMT sessions for 1 participant for each study therapist; she will continue to review 20%-50% of the video-recorded sessions as needed [74]. The co-PI is providing weekly group supervision to study therapists that involves case discussions and feedback.

Fidelity Ratings Across Raters

The authors have created fidelity checklists that include a list of proscribed PPMT components to be recorded as occurring or not occurring. Using these fidelity checklists, 2 trained evaluators will independently code video-recorded sessions for 18-20 participants. These data will be used to compute IRR estimates. If acceptable IRR estimates are not achieved, trained

evaluators will code an additional 20% of sessions. Once acceptable IRR estimates are achieved, the evaluators will solely code the remainder of the treatment sessions for fidelity.

Adherence to PPMT Components

We will compute percentage adherence across sessions for each of the trained study therapists, with the recommended 80%-100% benchmark indicating high fidelity [74].

Data Analysis

Power Analysis

We conducted an a priori power analysis using the *EMAtools R* (Kleiman) package [75] for power curves for multilevel studies. The power analysis was based on two 3-week assessment bursts with 1 questionnaire per day and an estimated intraclass correlation coefficient of 0.36 based on a previous study on daily-level emotions, cognitions, and PTSD [76]. Analysis showed that 70 participants and up to 25% missing data would be sufficient to detect a medium effect size (d=0.5) with 80% power.

Analytical Plan

A paired sample *t* test will be used to examine changes in the count of retrieved specific-positive autobiographical memories pre- versus post-PPMT (comparing the preintervention baseline and postintervention outcome surveys). To examine changes in daily affect, daily cognitions, and daily PTSD symptoms, we will use the daily diary reports pre- and postintervention and conduct multilevel random intercepts and slopes linear regression models for each outcome variable using *MPlus 8*.3 (Muthén and Muthén), *nlme* (Pinheiro et al), and *lme R* (Bates et al) packages, comparing the models pre- and post-PPMT with and without demographic covariates (eg, gender, age, and education). We will also conduct exploratory analyses examining additional variables included in the study as predictors or moderators of post-PPMT outcomes (eg, count of trauma types previously experienced, PTSD severity at baseline, and difficulties in positive emotional regulation).

Missing Data

At the survey level, the web-based questionnaire has been set up with a prompt if questions have been skipped, with the option to continue the survey without completing a particular item or to go back and complete the skipped question. We anticipate a little missing data within the submitted surveys. We will treat surveys that have been submitted with missing data as complete for the purposes of determining dropout and participation compensation. An analysis will be conducted to investigate the pattern of missingness. If data are missing at random or missing completely at random, they will be handled by listwise deletion and models fit by maximum likelihood. If data are not missing at random, then missing data will be imputed using the MICE (van Buuren et al) package in R [77] and fit by maximum likelihood.

Ethical Considerations

The institutional review boards at the University of North Texas (#21-420) and the University of Haifa (#480/21) have approved this study. During the screening phase, interested participants read the informed consent document (information about the study, eligibility criteria, compensation, benefits and risks to study participation, and steps to ensure data confidentiality) and provide electronic informed consent if they wish to participate. Participants are then contacted by research personnel to re-explain any study procedures and obtain or confirm identifying information.

In terms of compensation, participants receive US $1.50 for each completed daily survey and US $10 each for completing each of the baseline and outcome surveys. Participants receive US $10 for completing each of the 4 PPMT session surveys and US $12 toward transportation costs cumulatively for all 4 (attended) intervention sessions. In order to incentivize participants to provide as much data as possible, participants who complete 36 surveys without any missing data receive an additional US $15. The total potential compensation for participation is US $150.

Participants provide personally identifiable information (eg, name and contact information), which is only used for scheduling purposes, study-related communications, and to connect data longitudinally. Each participant receives a unique and randomly generated ID number, which is used on all web-based surveys for this study. At no point is any personally identifiable information linked to participant data. Furthermore, deidentified data will be analyzed for the scientific dissemination of study findings.

Results

Year 1 of the study (October 2021-September 2022) was primarily devoted to recruiting and training research personnel, obtaining ethics approvals, and preparing to launch the study. Year 2 of the study (October 2022-September 2023) has been focused on participant recruitment and data collection. During Year 3 of the study (October 2023-September 2024), we will complete data collection from our targeted sample and start the data cleaning and analysis process. During Year 4 of the study (October 2024-October 2025), we will complete the data analyses and prepare planned scientific outputs (eg, publications and presentations).

Data collection was initiated in March 2022. As of November 28, 2023, a total of 515 participants had consented to the study in the screening phase. Of those, 258 (50.1%) participants were eligible, 92 (35.7%) of which gave their consent by phone and attempted the first daily survey of the study. Of the 92 participants who completed the first daily survey, a total of 58 (63%) participants completed all intervention sessions and ≥13 daily surveys (≥60% of the daily surveys), and 28 (30.4%) participants dropped out in various stages of the study, mostly before the PPMT intervention. As of November 29, 2023, a total of 6 (6.5%) participants are currently participating in various phases of the study. Data collection is expected to end by June 2024. No analyses will be conducted until data collection has been completed.

Discussion

This study aims to examine the daily-level impacts of PPMT, a promising adjunct or alternative to traditional PTSD treatments, in a trauma-exposed, nonclinical community sample. This study combines a case-series design and a daily diary design to examine potential mechanisms of change in PTSD symptoms by assessing daily affect, daily cognitions, and daily PTSD symptoms before and after the PPMT intervention. This approach enables a more nuanced and ecologically valid exploration of changes as compared with retrospective aggregate assessments. We outline the research protocol for this study, including the hypotheses and the proposed analyses. When data collection has been completed (estimated date: June 2024), we will test our hypotheses that, at the daily level, in comparison to their own pre-PPMT levels, following the PPMT intervention, participants will report (1) a lower count of endorsed daily PTSD symptoms, (2) increases in daily positive affect and decreases in daily negative affect, (3) increases in positive affect reactivity to daily positive events, and (4) decreases in daily posttrauma cognitions.

The findings of this proposed study could have significant implications. Results could clarify whether deficits in positive autobiographical memory processes (eg, retrieval and encoding) may also characterize PTSD alongside deficits in traumatic memory processes [7]. If the study's hypotheses are confirmed, PPMT could be an additional therapeutic tool for clinicians to help clients with posttraumatic distress. Unlike other trauma interventions, PPMT exclusively targets positive autobiographical memories in treatment while redirecting attention away from negative content embedded in the positive memories. By uniquely combining positive and symptom-focused techniques and theories, PPMT aims to increase positive elements (eg, values, affect, and thoughts) while simultaneously decreasing PTSD severity [17].

There are some limitations to this study that should be considered. The study uses a self-report approach, which, although it reduces recall bias, is still subject to potential difficulties in the recall of experiences over the course of each day. Relatedly, while it reduces participant burden, the PC-PTSD measure is a PTSD symptom screener and usually is coupled with a comprehensive structured diagnostic interview for PTSD or a self-report measure assessing all 20 PTSD symptoms (which we do not do in this study due to the daily-level methodology and associated participant and time burdens). Furthermore, we are not gathering information on trauma characteristics such as the ages at which the trauma was experienced, the frequency or chronicity of each experienced trauma, or the time since the trauma has elapsed. Such information can impact posttrauma distress [78-80] and may moderate the impacts of PPMT in this study; hence, it should be empirically investigated in future research. In addition, while the research design of one assessment per day enables examination of changes in daily symptoms, affect, and cognition before and after the intervention, it does not have a sampling frequency nor sufficient power to examine fine-grained dynamic interactions between symptoms, affect, and cognition using even more complex modeling techniques. Lastly, our eligibility criterion permits individuals endorsing even 1 PTSD symptom at a clinical level to be included in the study. While such an approach accounts for impairment among individuals endorsing sub-threshold PTSD [81], it may also make it statistically difficult to detect any changes in PTSD symptoms (ie, the floor effect).

In conclusion, this study will contribute to the development of more personalized and alternative PTSD interventions for survivors of trauma who drop out or do not benefit from existing PTSD treatments. Further studies could examine PPMT as an ecological momentary intervention, wherein individuals receive daily reminders and instructions for engaging in therapy-relevant behaviors (eg, processing of positive memories). Such interventions can particularly benefit communities that do not have easy access to mental health services and are underserved in that regard [82]. Finally, this study will give insight into the mechanisms of change in the PPMT intervention through elucidating daily-level changes in affect, cognition, symptoms, and event reactivity.

Acknowledgments

This research was supported by a grant (2020017) from the United States-Israel Binational Science Foundation (BSF). The authors would like to acknowledge the work of Gurleen Kaur for participant recruitment and data collection and the work of Sidonia Compton as a study therapist.

Data Availability

The data sets that will be generated through this study will not be publicly available due to the sensitive nature of the posttrauma daily-level data, however the corresponding author will make deidentified data available on reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: Biphasic calcium phosphates (BCP) may serve as off-the-shelf alternatives for iliac crest-derived autologous bone in alveolar cleft reconstructions. To add osteoinductivity to the osteoconductive BCPs to achieve similar regenerative capacity as autologous bone, a locally harvested buccal fat pad will be mechanically fractionated to generate microfragmented fat (MFAT), which has been shown to have high regenerative capacity due to high pericyte and mesenchymal stem cell content and a preserved perivascular niche.

Objective: Our primary objectives will be to assess the feasibility and safety of the BCP-MFAT combination. The secondary objective will be efficacy, which will be evaluated using radiographic imaging and histological and histomorphometric evaluation of biopsies taken 6 months postoperatively, concomitant with dental implant placement.

Methods: Eight patients with alveolar cleft (≥15 years) will be included in this prospective, nonblinded, first-in-human clinical study. MFAT will be prepared intraoperatively from the patient's own buccal fat pad. Regular blood tests and physical examinations will be conducted, and any adverse events (AEs) or serious EAs (SAEs) will be meticulously recorded. Radiographic imaging will be performed prior to surgery and at regular intervals after reconstruction of the alveolar cleft with the BCP-MFAT combination. Biopsies obtained after 6 months with a trephine drill used to prepare the implantation site will be assessed with histological and histomorphometric analyses after methylmethacrylate embedding and sectioning.

Results: The primary outcome parameter will be safety after 6 months' follow-up, as monitored closely using possible occurrences of SAEs based on radiographic imaging, blood tests, and physical examinations. For efficacy, radiographic imaging will be used for clinical grading of the bone construct using the Bergland scale. In addition, bone parameters such as bone volume, osteoid volume, graft volume, and number of osteoclasts will be histomorphometrically quantified. Recruitment started in November 2019, and the trial is currently in the follow-up stage. This protocol's current version is 1.0, dated September 15, 2019.

Conclusions: In this first-in-human study, not only safety but also the histologically and radiographically assessed regenerative potential of the BCP-MFAT combination will be evaluated in an alveolar cleft model. When an SAE occurs, it will be concluded that the BCP-MFAT combination is not yet safe in the current setting. Regarding AEs, if they do not occur at a higher frequency than that in patients treated with standard care (autologous bone) or can be resolved by noninvasive conventional methods (eg, with analgesics or antibiotics), the BCP-MFAT combination will be considered safe. In all other cases, the BCP-MFAT combination will not yet be considered safe.

Introduction

Alveolar cleft is defined as a bone gap in the primary palate from the nasal sill to the incisive foramen [1]. The defect occurs as a result of disruption of primary palate development between 4 and 12 weeks of gestational age, specifically in the frontonasal prominence [2]. The treatment protocol varies on the basis of the following factors: timing, surgical procedure, and grafting material. Secondary alveolar bone grafting (SABG) is the most preferred and successful method that is usually performed during the mixed dentition period (6-11 years), which allows the provision of support to teeth eruption and facial growth [1]. The iliac crest as a bone graft donor for alveolar cleft reconstruction has gained popularity since it was first introduced by Schmid [3] in 1954, and, in particular, for SABG procedures because it allows harvesting of large amounts of bone for alveolar cleft surgery [4]. Other bone graft sources include the cranium, tibia, and the mandibular symphysis [5]. However, several studies have reported risks of general postoperative complications using autografts, such as pain, prolonged hospital stay, and donor site–specific complications such as scarring, cutaneous nerve injury near the iliac crest, and hematoma after harvesting the cranial bone [6-9]. Therefore, alternative materials are being evaluated for alveolar cleft surgery.

Biphasic calcium phosphate (BCP) is a bioceramic that consists of 2 materials, hydroxyapatite (HA) and β-tricalcium phosphate, mixed in different ratios [10]. It is a biocompatible, easy-to-handle, safe material with a mineral composition comparable to that of human bone tissue [10]. BCP has been mixed in vivo and in vitro with autografts, inducing factors or cells to improve its osteoinductivity [11,12], also in the fields of dentistry and maxillofacial surgery [13-15]. Although calcium phosphate ceramic is not yet considered standard-of-care, it has been used for alveolar cleft reconstruction with satisfactory results [16], reportedly providing support for teeth eruption [17].

Adipose tissue is a source of mesenchymal stem cells, and adipose stem cells (ASCs) can be collected with minimum risk and discomfort from the buccal fat pad (BFP) [18]. The BFP surrounds the buccinators muscle and other superficial muscles such as the masseter, the zygomaticus major, and the zygomaticus minor [19]. Moreover, multiple studies have shown that the cell yield of ASCs per volume is at least 100-500 times that of mesenchymal stem cells in bone marrow aspirates [18,20]. Commonly, ASCs are prepared using enzymatic (collagenase) digestion which, however, is considered “more than minimal manipulation” of the cells by the US Food and Drug Administration and the European Medicines Agency [21]. An alternative method, which also takes considerably less time, involves processing the adipose tissue mechanically into microfragmented fat (MFAT) [22]. MFAT is reported to have similar or even higher secretory activity of regenerative growth factors and cytokines and pericyte content than an enzymatically derived stromal vascular fraction (SVF) [23]. In addition, the MFAT procedure can be applied even in regular hospitals because its harvesting and processing does not require a major invasive surgery, specialized equipment or expensive disposables, or good manufacturing practices–qualified cell culture expansion. Autologous application of MFAT has, among others, been used with success for clinical reconstructions in the maxillofacial area [24].

We hereby describe the protocol of a first-in-human clinical safety trial using BCP mixed with MFAT for alveolar cleft reconstruction. Our hypothesis is that the combination will be a safe, efficient, and effective alternative to conventional autograft since the osteoconductive BCP is supplemented by the regenerative capacity from the MFAT.

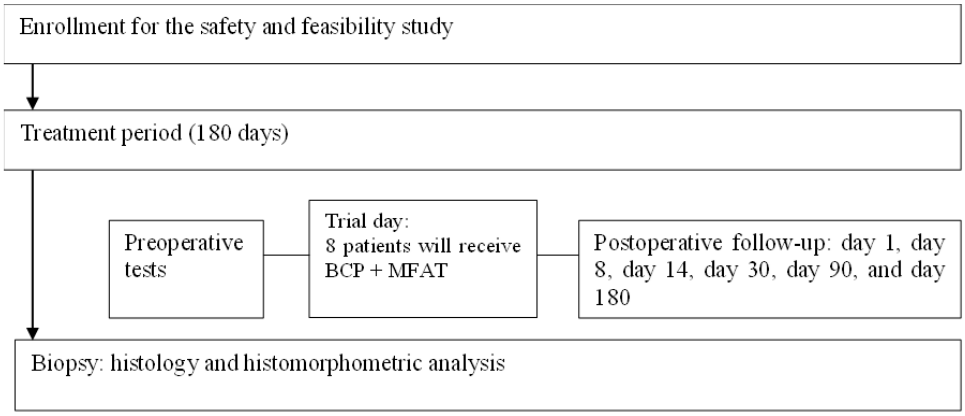
Methods

Study Design

This first-in-human surgical study can be classified as a “stage 1” study in accordance with the IDEAL (innovation, development, exploration, assessment, and long-term study) framework [25]. It is a single-center prospective clinical trial comprising 8 patients, assessing the safety of a combination of MFAT and BCP (BoneCeramic, Straumann) as bone graft material for alveolar cleft reconstruction. The BCP is a synthetic bone graft containing 60% HA and 40% β-tricalcium phosphate, a porosity of 90%, and an interconnected pore size of 100-500 µm. The BCP will be combined in a 1 g:1 cm^3 ratio with MFAT prepared from the patients’ own BFP, which is processed with a 1.2-mm single-use sizing transfer Tulip Gen II Nanofat Kit

(Tulip Medical). The primary end point will be set at 6 months. At each follow-up visit, adverse events (AEs) or serious AEs (SAEs) will be documented, and clinical assessments will be performed at time points specified in the *Interventions* section. After these 6 months, a bone biopsy sample will be taken using a hollow drill during dental implant preparation and subsequently processed for histological or histomorphometric analysis (Figure 1). Finally, a report on safety and proof of concept with regard to bone formation will be made and published.

Figure 1. Simplified diagram of the study protocol (adapted from the SPIRIT [Standard Protocol Items: Recommendations for Interventional Trials] checklist; Multimedia Appendix 1). BCP: biphasic calcium phosphate; MFAT: microfragmented fat.



Ethical Considerations

The clinical trial protocol was approved by the ethical committee of Hasanuddin University, Makassar, Indonesia (1063/UN4.6.4.5.31/PP36/2019) and registered in the Indonesian trial registry (INA-EW74C1N). Informed consent will be obtained from candidates or their parents or legal guardians who are willing to join the trial after being fully educated about the trial procedure. This study complies with the principles of the Declaration of Helsinki. In the informed consent form signed by the patients or their legal representatives, consent to publish their data in a deidentified manner is included.

Inclusion and Exclusion Criteria

Patients will be included on the basis of the following criteria [26]: being healthy male or female participants aged ≥15 years, having unilateral alveolar cleft without any previous history of grafting procedures, being categorized as normal healthy patients for anesthetic risk per the American Society for Anesthesiologists' criteria, and having a normal blood count.

Patients will be excluded on the basis of the following criteria [26]: having poor oral hygiene with mouth plaques; having systemic disease; having systemic or local infection; having received chemotherapy, radiotherapy, immunosuppressives, or anticoagulants that may interfere with the healing process; having received bone growth–inducing factors, malnutrition, or active influenza; and being pregnant.

Interventions

Under general anesthesia and infiltration with lidocaine (1%) with epinephrine (1:100,000 dilution), the surgeon will identify the Stensen's duct with a lacrimal probe and make an incision 2-3 cm below the duct [27]. A dissection penetrating the muscles and the superficial fascia will allow spontaneous herniation of the BFP [27]. This procedure will be carried out bilaterally on both cheeks in order to obtain approximately 3 cm^3 of fat. After vasoconstrictor infiltration with epinephrine (1:100,000), a full mucoperiosteal flap spanning the first molar to the central incisor is lifted. After exposure of the full alveolar cleft and to separate the nasal layer from the oral mucosa, the tissue was meticulously dissected. Following the reflection of a palatal mucoperiosteal flap from either side of the cleft, the palatal tissues are elevated. The oronasal fistula is repaired cranially by elevating and suturing the nasal mucosa [4], thereby creating a pocket for BCP-MFAT deposition.

In parallel with the defect surgery, the harvested fat will be chopped into small pieces with a scissor and soaked in normal saline for 10-15 minutes. The normal saline then will be drained and the chopped fat will be processed into MFAT using 2 syringes (size 10 cm^3) connected with the 1.2-mm single-use sizing transfer Tulip Gen II Nanofat Kit in accordance with the manufacturer's protocol. MFAT will be mixed with BCP (Straumann Bone Ceramic) in a ratio of 1 g:1 cm^3 until it reaches homogenous consistency. The BCP-MFAT mixture will be placed as a graft material into the alveolar cleft defect. If the defect is large and requires more bone graft, another mixture will be prepared with the same mixing ratio. If necessary, a membrane will be used to cover the grafted defect. Finally, the defect will be closed by suturing the palatal mucoperiosteal flaps using absorbable sutures with 3-0 vicryl sutures for mucosa and 4-0 vicryl sutures for nasal reconstruction. All patients will be prescribed antibiotics and analgesics postoperatively.

AE Assessment

Any change in the health of subjects will be documented in their medical history, and required medical care will be provided. Any unexpected physical or laboratory change, symptom, or disease that occurs in a treated patient who has been administered the graft will be documented as an AE. An AE will be graded in accordance with the World Health Organization's classification [28] as either serious or nonserious based on its intensity. The Clavien-Dindo Classification of Surgical Complications will also be used in case of any incidence [29]. In the case of an SAE, a report will be made to the sponsor within 24 hours and to the ethical committee within

3 days from the date of onset. If the SAE concerns severe toxicity or infection associated with graft products, the trial will be terminated immediately.

Sample Size

This is a first-in-human phase I clinical trial aimed to obtain insight on the safety and feasibility of the treatment with the BCP-MFAT combination. We assume that no SAEs or AEs will occur, based on our clinical experience with other applications of MFAT and the well-proven safety of BCP. Upon consultation with a statistician, a sample size of 8 individuals is expected to be sufficient for this trial.

Recruitment

Patients will be recruited from an existing database of the Hasanuddin University Dental Hospital, from general practices of Hasanuddin Dental Hospital and in the area around Makassar. Thereafter, we will determine whether the candidates fulfill the study's inclusion and exclusion criteria. Thorough assessment and training regarding the safety measurements at the research site at Hasanuddin University Dental Hospital will be performed prior to the trial by the ethical and surgical teams.

Since we did not want to enroll children in a safety study with this novel concept in clinical practice, we chose to only include older adolescent and adult patients, being themselves capable of decision-making. Within Indonesia, this age group is more common due to cultural and religious backgrounds causing abstinence from cleft surgeries.

The trial will be conducted at Hasanuddin Dental Hospital. All participants will be asked to sign an informed consent form after risks and possible complications of the procedure (eg, bleeding, infection, cheek asymmetry, parotid duct injury, possibility of facial nerve branches injury, and—although not likely—nonclosure) were appropriately communicated with the patient. Data will be handled and stored in a coded—that is, deidentified—format, so that data cannot be traced back to the patient without a decoding key, which is stored in a locked place and only accessible to the study's principal investigator. Implants will be offered free of charge.

Randomization and Blinding

Since this trial comprises only 1 type of treatment, no randomization or blinding to the treatment is possible.

Data Collection and Access

The research team will be informed about the rules and their responsibilities. All members of the research team, which will collect the data in accordance with the evaluation table (Table 1), will receive training on how data collection should be performed. The data manager will document the data in a patient-coded manner (ie, each patient will be assigned a study-specific code under which the data will be stored in order to conceal their identity), which will subsequently be handed over to the clinical evaluators and investigators. The primary end point is set at 6 months.

Table 1. Patients' assessments.

	Consent form	Orthopantomography	Cone-beam computed tomography or computed tomography	Physical examination	Complete blood count	Thermometry	Biopsy
Preoperative	✓	✓	✓	✓	✓	✓	
Operative day				✓		✓	
Postoperative day 1		✓		✓	✓	✓	
Postoperative day 8		✓	✓	✓	✓	✓	
Postoperative day 14				✓		✓	
Postoperative day 30				✓	✓	✓	
Postoperative day 90		✓		✓		✓	
Postoperative day 180		✓	✓	✓	✓	✓	✓

Posttrial Care

After the primary end point assessment, the participants will be followed up for an additional period of 3 years to ensure their safety and to record whether any delayed side effect occurs as a result of treatment with the BCP-MFAT combination, as previously done in a similar study [26].

Monitoring

Internal monitors of the Ethics and Research Committee, Faculty of Medicine, Hasanuddin University, will evaluate whether the data are accurately collected. Since negligible risk to the patient is expected as both materials (MFAT and BCP) have been tested in other clinical trials [16,17,24], no data safety monitoring board will be installed. A safety report will be submitted every year to the Medical Research Ethics Committee, Faculty of

Medicine, Hasanuddin University. No interim analysis is deemed necessary.

Amendments

If deemed necessary, amendments to this protocol will be submitted to the ethical committee and competent authority and should be approved prior to implementation to ensure the safety and integrity of participants as well as the scientific value of the trial.

Evaluation Methods

Safety Assessment Based on Physical Examination and Laboratory Measurements

When an SAE occurs, it will be concluded that a combination of MFAT and BCP is not yet safe in the current setting. For AEs, if they do not occur at a higher frequency than that in patients treated with standard care (autologous bone) or can be resolved through noninvasive conventional methods (eg, analgesics or antibiotics), the combination of MFAT and BCP will be considered safe. In all other cases, combination of MFAT and BCP will not be considered safe yet.

Radiographic Analysis

To evaluate the success rate of the bone graft, the Bergland scale will be used [30]. This scale will evaluate the integrity and height of the alveolar bone graft and will classify bone height into 4 grades: grade I, bone height is almost normal; grade II, a bone height that is at least 75% of the interalveolar septum; grade III, a bone height of less than 75%; and grade IV, no evidence of bone integration [31].

Histological and Histomorphometric Analysis

Histological and histomorphometric analysis will be performed for at least 3 patients who received dental implants after alveolar cleft reconstruction, in accordance with previously published procedures [32]. Briefly, the implant preparation site will be developed using a trephine burr (2.0 mm × 10.0 mm in length) that allows biopsy specimen collection from the implant site without interfering with the regular procedure. The biopsy specimens will be fixed in 4% phosphate-buffered formaldehyde, dehydrated in an ascending series of ethanol, and embedded in 80% methylmethacrylate (BDH Chemicals) supplemented with 20% dibuthylphtalate (Merck), 8 g/L lucidol CH-50 L (Akzo Nobel), and 22 µL/10 mL N,N-dimethyl-p-toluidine (Merck). The biopsy specimens will be cut into 5-µm-thick sections and subjected to 2 different staining procedures (Goldner's trichrome and Tartrate-resistant acid phosphatase staining). Several histomorphometric parameters (bone volume, osteoid volume, graft volume, and number of osteoclasts) will also be measured for quantitative analysis [32]. Two trained examiners will perform the histologic and histomorphometric analyses. In case of dispute, the biopsies will be reanalyzed to reach consensus.

Statistical Analysis

Since this is a single-arm safety study, statistical analyses will not be performed.

Results

The primary outcome parameter will be safety after 6 months' follow-up, assessed by closely monitoring possible occurrences of AEs or SAEs, radiographic imaging, blood tests, and physical examinations. For efficacy, radiographic imaging will be used for clinical grading of the bone construct using the Bergland scale. In addition, bone parameters such as bone volume, osteoid volume, graft volume, and number of osteoclasts will be histomorphometrically quantified. We expect that the feasibility and safety of the procedure will be apparent, as well as its initial efficacy. Recruitment started in November 2019, and the trial is currently in the follow-up stage. This protocol's current version is 1.0, dated September 15, 2019.

Discussion

In recent years, there has been increasing interest in the use of adipose tissue for cleft lip and palate reconstruction [33]. Its applicability mostly relies on the quantity of the tissue, the ease of surgical harvesting, and the type of surgical reconstruction in which the tissue is used, for example, correction of cleft lip volume asymmetry [34,35], improvement of velopharyngeal insufficiency after cleft lip and palate repair [36,37], or as an extra flap in cleft palate repair [38-41]. In this study, we will make use of the BFP for bone reconstruction. The BFP is a specialized adipose tissue rich in vascular supply, which is easy to harvest via the oral cavity during an intraoral surgery with minimal morbidity and discomfort [42].

Until now, there are only few reports on the use of adipose tissue as a regenerative compound for bony cleft reconstruction—a phase I clinical trial conducted by Khojasteh et al [24] and an animal study using ASCs for alveolar cleft repair [43]. Both studies used collagenase digestion of the tissue and culture expansion to obtain ASCs for personalized cleft reconstructions. An alternative is the SVF derived from adipose tissue via collagenase digestion, which requires a shorter time frame and may yield similar stem cell–like quantities, allowing intraoperative applications [44,45]. A previous clinical study by Prins et al [44] showed that addition of SVF in an intraoperative setting to calcium phosphate ceramics had an additive value on bone formation, implying that SVF can provide osteoinductivity when combined with calcium phosphate. However, so far, regulatory issues and relative expensive SVF production procedures prohibit its wide applicability [22,23]. Mechanically processed fat or MFAT has emerged as a rapid processing alternative to SVF and is being considered minimally manipulated and thereby less regulation restricted [22,23].

This is the first in human study evaluating a combination of MFAT and biphasic BCP as a regenerative graft for alveolar cleft reconstruction [46,47]. BCP is a ceramic scaffold with a balanced ratio between the less-soluble HA and the more-soluble TCP that results in mechanical and biological properties to support bone and cartilage tissue production [48]. It is sufficient for bone reconstruction in non–load-bearing applications and already accepted as standard of care for certain maxillofacial reconstructions [49].

Recently, calcium phosphate has been applied for alveolar cleft surgeries as well [16,17]. Patients within that study were treated at ages of 9-10 years, which is within the optimum age range for SABG [1]. However, we did not want to enroll children in a safety study with this novel concept in clinical practice. Therefore, although we realize that surgeries at a later age will (1) not make optimal use of the growth spurt and (2) may result in cases having larger or even critical size defects (which will not heal unless supplemented with grafts), we chose to only include older adolescent and adult patients, who are themselves capable of being involved in decision-making. We will perform this study in Indonesia because unoperated patients in this age group are difficult to find in Europe.

This is primarily a safety study, so the main conclusions of the study will be based on safety parameters, particularly on the occurrence of AEs or SAEs.

Acknowledgments

We would like to thank Nisrina Ekayani N, DDS, and Citra Dewi Sahrir, DDS, for helping in the administrative process of receiving ethical approval. DSNK received a scholarship from the Indonesia Endowment Fund for Education (LPDP), Ministry of Finance, Republic of Indonesia.

Data Availability

The data generated in the course of this study will be presented in the main manuscript reporting on the trial outcomes in a deidentified manner or provided in a multimedia appendix coupled with that manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The aftermath of the COVID-19 pandemic continues to affect millions worldwide, resulting in persisting postvirus complaints and impacting peoples' quality of life. Long COVID, characterized by lingering symptoms like fatigue and mental illness, can extend beyond a few months, necessitating further research to understand its implications.

Objective: This study aims to quantify the degree of physical and psychological fatigue in patients following COVID-19 infection and examine its correlation with mental health disorders.

Methods: Using a consecutive nonrandom sampling technique, we will conduct a prospective cohort multicenter observational study in 5 Portuguese hospitals. Symptomatic adult patients with previous COVID-19 attending follow-up consultations will be enrolled. We will include patients who had mild, moderate, and severe acute disease. We will assess clinical outcomes related to COVID-19, including the type of respiratory support such as high-flow nasal cannula, noninvasive ventilation, and invasive mechanical ventilation. The exclusion criteria will include previous severe psychiatric disorders confirmed by a psychiatrist; refusal or inability to respond to the questionnaire; concomitant neurological disorder; persistent fatigue symptoms during the 6 months before infection; and the need for invasive mechanical ventilation during COVID-19 infection due to a high prevalence of postintensive care syndrome. Our primary outcome is the prevalence of fatigue in patients with post–COVID-19 depression and/or anxiety, as measured by the Chalder Fatigue Scale (CFQ-11) and the Hospital Anxiety and Depression Scale (HADS). The secondary outcomes will include an assessment of health-related quality of life via the EQ-5D questionnaire and an exploration of the prevalence of symptoms of posttraumatic stress disorder (PTSD) using the 14-item Posttraumatic Stress Scale (PTSS-14). We will also examine the association between mental health symptoms and the severity of acute COVID-19. The post–COVID-19 data will be collected at least 6 months after the positive test and no longer than 9 months during the clinical appointment.

Results: We expect our multicenter study on patients post COVID-19 to reveal a significant link between mental illness symptoms and both physical and psychological fatigue. Patients with heightened depression and anxiety may report increased levels of

fatigue. Additionally, we expect to find persistent PTSD symptoms in a subset of participants, indicating the enduring psychological impact of the virus.

Conclusions: This study may underscore the need for integrated care addressing physical and mental health in patients post COVID-19. The observed connections emphasize the importance of considering mental well-being for long-term health outcomes. Despite study limitations, our findings contribute valuable insights for future treatment strategies and highlight the necessity for comprehensive mental health support in post–COVID-19 care. This research provides valuable insights into the mental health implications of COVID-19 and its impact on post–COVID-19 fatigue and the overall well-being of affected individuals.

Introduction

Despite the World Health Organization (WHO) declaration marking the end of the COVID-19 pandemic on May 5, 2023 [1], millions of people continue to have postvirus complaints. Moreover, the virus remains endemic in many parts of the world. Confirmed COVID-19 cases have exceeded 430 million globally, with 200 million in Europe alone [2]. The causative agent of COVID-19 is the novel SARS-CoV-2 [3]. Although, as the name implies, respiratory symptoms are acute, the term long COVID (or post-COVID syndrome or long-haul COVID-19) began gaining recognition in the scientific and medical communities after the first descriptions of long-lasting symptoms related to mental health, such as anxiety or stress after the first infection [4]. While the definition of long COVID is unclear, the most frequent symptoms are fatigue and dyspnea [5,6]. Other less typical symptoms include cognitive and mental disorders, headache, myalgia, chest and joint pain, smell and taste dysfunction, cough, hair loss, insomnia, wheezing, rhinorrhea, sputum, and cardiac and gastrointestinal issues [4]. These symptoms may persist for up to 6 months after hospital discharge, severely impacting patients' quality of life [7]. Since July 2021, long COVID is considered a disability under the *Americans With Disabilities* Act [8].

Per its definition, long COVID appears within 3 months after the onset of COVID-19, with symptoms lasting for at least 2 months that an alternative diagnosis [9] cannot explain, including, myalgic encephalomyelitis and chronic fatigue syndrome. However, studies have reported different persistent symptoms in contrasting durations and frequencies among survivors of long COVID [10,11]. Long COVID appears like other postviral syndromes observed in other coronavirus diseases. For example, symptoms of fatigue, myalgia, and psychiatric impairments have affected survivors of Middle East respiratory syndrome (MERS) and those with severe acute respiratory syndrome (SARS) for up to 4 years [10,12,13]. Even at 7-year and 15-year follow-ups, pulmonary and bone radiological complications were evident among a proportion of survivors of SARS who were predominantly younger than 40 years [10,14,15]. This is unsettling, as it implies that long COVID may extend beyond just a few months.

Fatigue, a primary persistent symptom of long COVID, has been reported in 10% to 70% of patients [16-19]. It is defined as "a decrease in physical or mental performance that results from changes in central, psychological, or peripheral factors due to the COVID-19 disease" [20]. Thus, post–COVID-19 fatigue depends on conditional and psychophysiological factors comprising the individual's task, environment, physical, and mental capacity, as well as the disease's central, psychological, and peripheral aspects [20].

While fatigue is not traditionally considered a neuropsychiatric disorder, it can be a symptom of many mental health conditions, such as depression, anxiety, and posttraumatic stress disorder (PTSD) [21,22]. Therefore, it is often included in discussions of mental health symptoms in post–COVID-19 syndrome [23]. The term "neuropsychiatric" often refers to a wide range of disorders affecting the brain and mental health. In contrast, "neuropsychological" refers to studying the relationship between brain function and behavior [24]. The primary focus of this study is on psychiatric symptoms, particularly depression and anxiety. However, we will also investigate PTSD, which is a neuropsychiatric disorder involving both neurological and psychiatric aspects. In addition, the health-related quality of life (HRQoL) assessment includes a section that evaluates aspects related to anxiety and depression. While not designed for diagnosing psychiatric disorders, this assessment can help gauge how these symptoms affect a person's overall quality of life, making it more of a general health assessment.

The current literature on long COVID and its mental sequelae has relied on self-reported symptoms through questionnaires administered either in-person or through telephone interviews to comply with public health guidelines. However, the correlation between these self-reported symptoms needs to be clarified. There is an obvious need to accurately characterize the mental sequelae of COVID-19 and the risk factors associated with these outcomes.

This study aims to quantify the degree of physical and psychological fatigue in patients post COVID-19 and assess the correlation of fatigue with other mental sequelae—particularly depression, anxiety, and PTSD. Furthermore, we aim to explore its impact on HRQoL.

Our research questions for this study are outlined in Textbox 1.

Textbox 1. Research questions of the study.

Research Question 1 (primary outcome):

- Do patients with long COVID who experience depression and/or anxiety symptoms have a higher prevalence of fatigue?

Research questions 2 to 4 (secondary outcomes):

- Is there a correlation between the type of fatigue and depression and/or anxiety symptoms among patients post COVID-19?
- Is there a correlation between fatigue and the presence of PTSD symptoms in patients post COVID-19?
- Do patients with fatigue associated with mental health disorders have a lower health-related quality of life (HRQoL) after COVID-19?

Methods

Overview

This protocol adheres to the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) statement [25]. This research is designed as an observational prospective cohort study.

Recruitment

Our study will be conducted in 1 private and 4 public Portuguese hospitals that have established follow-up post–COVID-19 medical consultations. Patients who meet the eligibility criteria will be invited to participate in the study at the end of their appointments in the follow-up clinics. This study will be conducted using a consecutive, nonrandom sampling technique.

Inclusion Criteria

Patients who cumulatively meet the following criteria will be eligible for inclusion: (1) ≥18 years; (2) previous case of COVID-19 at least 6 months after the diagnosis that is duly documented in the clinical record; (3) persistent symptoms after COVID-19 recovery, as defined by the WHO [9]; and (4) SARS-CoV-2 RNA confirmed by a positive real-time reverse-transcription polymerase chain reaction (RT-PCR) on a nasopharyngeal swab or SARS-CoV-2 antigen confirmed with a nasopharyngeal swab by a health care professional within 7 days of initial symptoms.

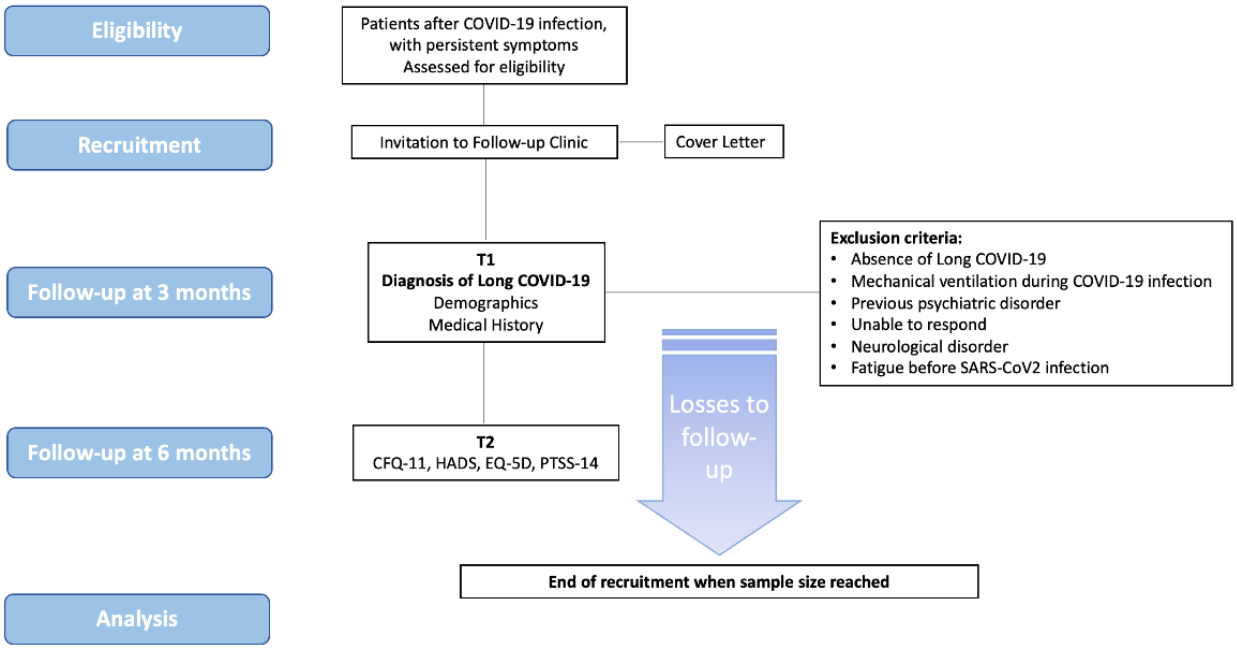
We will implement multiple measures to exclude the possibility of second infections and ensure that the individuals included have persistent symptoms following their initial COVID-19 recovery. Our inclusion criteria stipulate that individuals must have a positive test result for SARS-CoV-2 RNA or antigen within 7 days after their initial infection. Additionally, we will conduct thorough reviews of medical records and clinical assessments to assess symptom presentation and timing, differentiating between persistent cases and new infections. In cases of uncertainty or potential overlap with new infections, we are prepared to conduct repeat testing, which may include RT-PCR and genomic sequencing for accurate classification.

Exclusion Criteria

Patients who meet the following criteria will be excluded from participation: (1) preexisting psychiatric disorders diagnosed by a psychiatrist before contracting COVID-19; (2) inability to respond to the questionnaire; (3) concurrent neurological disorders, such as stroke with sequelae, Alzheimer disease, and Parkinson disease; (4) individuals subjected to invasive mechanical ventilation during their COVID-19 infection; or (5) those experiencing persistent fatigue symptoms within the 6 months before SARS-CoV 2 infection.

The study design and inclusion criteria will be reviewed regularly to ensure they align with current best practices and the latest understanding of COVID-19. A patient enrollment flowchart is presented in Figure 1.

Figure 1. Study flowchart. CFQ-11: Chalder Fatigue Scale; HADS: Hospital Anxiety and Depression Scale; PTSS-14: 14-item Posttraumatic Stress Scale.



Data Collection

Data collection will take place during appointments at the long COVID follow-up clinics in all participating hospitals. Qualified clinical study staff will gather the data using a clinical research form (CRF) (Multimedia Appendix 1). These individuals comprise health care professionals, such as nurses, clinical research coordinators, and health care experts who have received appropriate training and have the necessary expertise to conduct data collection and assessments in a clinical research setting. Their training ensures adherence to research protocols and ethical guidelines, guaranteeing accurate and consistent data gathering during clinical appointments. Two months after hospital discharge, we will mail all patients a letter offering a follow-up consultation in the outpatient clinic. Patients who agree to attend will be offered 2 appointments, consisting of an anamnesis and a physical examination, and given several self-administered tests in the waiting room. We will allocate 15 minutes for the questionnaire completion in the waiting room. In the first visit (T1, 3 months), the following data will be additionally collected: demographic characteristics like age, sex, and BMI (kg/m^2); each participant's medical history, such as the date of the first positive COVID-19 test (PCR or antigen) and smoking, alcohol, and drug consumption status; comorbidities and usual medication intake; and screening of symptoms and severity of the acute disease. Data collection in the second visit (T2, 6 months) will include post–COVID-19 symptoms, the Chalder Fatigue Scale [26] (CFQ-11), the Hospital Anxiety and Depression Scale (HADS) [27], the 14-item Posttraumatic Stress Scale (PTSS-14) adapted to COVID-19, and the EQ-5D [28] questionnaire.

Ethical Considerations

This study involves human participants and has adhered to all applicable ethical standards and procedures. The Algarve University Hospital Centre Ethical Committee approved this study (141/21; Multimedia Appendix 2). The patients' race will not be included in the study because the ethics committee did not approve this differentiation. A paper-based consent form was previously approved by the ethics committee. This consent form has 2 components: information for the participant (regarding the project) and declaration of informed consent (to date and sign, in case of acceptance). The informed consent procedure, mailed to potential participants, will provide them with detailed information about the study's objectives, risks and benefits of participation, and data management practices (Multimedia Appendix 3). The study will follow ethical guidelines and regulations related to informed consent, and participants will have the opportunity to ask questions and provide voluntary consent before enrolling. Participants will be given a month for reflection before written informed consent. As for data management, the study will implement a secure and confidential system that uses data encryption and secure storage procedures to protect participant confidentiality and comply with data protection laws and regulations. Only authorized individuals who have a legitimate need to access the data will be permitted to do so, and any data sharing will be done in compliance with the relevant ethical and legal requirements. As applicable, all procedures from this investigation followed the Declaration of Helsinki. All researchers will comply with the Data Protection Acts of their respective academic institutions.

Primary Outcome

Fatigue

A validated fatigue assessment tool will be used at the follow-up visit to capture a broader range of participants. This will provide a more comprehensive understanding of the relationship between fatigue and mental symptoms in individuals with long COVID. Fatigue will be measured using the CFQ-11 [26]. This is an

11-item self-report measure of physical and mental fatigue. Participants rate their fatigue experienced over the past month compared to their usual energy levels using a 4-point Likert scale ranging from 0 (“less than usual”) to 3 (“much more than usual”) [29]. Scores range from 0 to 33. A bimodal version can also be calculated, where scores range from 0 to 11, with a cutoff score of 4 or more indicating a case of fatigue [29]. Reliability coefficients for the CFQ-11 have been shown to range between 0.8 and 0.9 [29-31] in both patients with chronic fatigue and the general population. This study will use only the Likert scale to reduce the risk of ceiling effect bias.

Secondary Outcomes

Depression and Anxiety

Symptoms of depression and anxiety will be assessed using the HADS [27], a practical, validated tool for assessing symptom severity in anxiety and somatic disorders in psychiatric and primary care settings and the general population [32]. This measure comprises 14 items, 7 measuring symptoms of anxiety and 7 measuring symptoms of depression. The scores are categorized into different ranges: 0 to 7 as “normal,” 8 to 10 as “mild,” 11 to 14 as “moderate,” and 15 to 21 as “severe.” The HADS questionnaire has been validated in many different languages and settings [32-34].

HRQoL Assessment

HRQoL will be assessed using the original EQ-5D questionnaire, which comprises 2 parts. The first part is the EQ-5D-3L questionnaire [28], a health state classification scheme of 5 items (mobility, self-care, usual activities, pain/discomfort, and anxiety/depression), each having 3 alternatives (1=no problems, 2=moderate problems, and 3=severe problems). The combination of answers for the 5 items represents the health state (given as an index), ranging from 0 (worst possible health state) to 1 (best possible health state). The second part comprises the EuroQol Visual Analog Scale (EQ-VAS), which represents health states in a range from 0 (the worst possible health state) to 100 (the best possible health state). The EQ-5D can distinguish between the health conditions of patients with diverse injuries [35,36] and has been validated in several populations [37].

PTSD Assessment

This study includes an assessment of PTSD as a secondary measure. It aims to evaluate the potential impact of PTSD on the primary outcome of fatigue and provide a better characterization of the study population. Although previous PTSD to COVID-19 infection is an exclusion criterion, some participants may still have experienced PTSD symptoms after their COVID-19 infection, so evaluating the prevalence and severity of these symptoms in the study population could be relevant.

Given that the “gold standard” clinician-administered, semistructured psychiatric interviews to diagnose PTSD symptoms were not feasible during the workload of the COVID-19 follow-up clinic, we chose the patient-reported outcome instrument PTSS-14. This scale was developed based on the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) criteria for PTSD and subsequently validated for patients following intensive care [38]. Patients were asked to assess the frequency of 10 common PTSD symptoms on a 7-point Likert scale from 1 (never) to 7 (always). Item scores were summed up to a total score (ranging from 10 to 70). A total score above 35 was suggested to indicate clinically relevant PTSD symptoms. A similar 14-item version of PTSS was later developed to reflect the changes in the fourth edition of the DSM (DSM-IV), where a cutoff value of 45 indicated presumable PTSD [39]. We modified the latter to include COVID-19 patients—whenever the term “intensive care unit (ICU)” appeared, we substituted it with “COVID-19.” We applied the same diagnostic cutoff to this adapted scale.

Association of Mental Illness Symptoms With the Severity of Acute COVID-19

COVID-19 severity will be categorized according to the WHO classification [40]. The classification includes the following: mild illness (mild symptoms without the radiographic appearance of pneumonia); pneumonia (having symptoms and the radiographic evidence of pneumonia, with no requirement for supplemental oxygen); severe pneumonia (having pneumonia, including one of the following: respiratory rate >30 breaths/minute, severe respiratory distress, or blood oxygen saturation level ≤93% while at rest and breathing room air); and critical cases (eg, respiratory failure requiring invasive mechanical ventilation or nasal high flow oxygen, septic shock, other organ failure occurrence, or admission to the ICU).

Statistical Analyses

The statistical analysis methodology is designed to align with the study’s defined objectives. All analyses will be conducted using SPSS (version 27; IBM Corp) and R (R Foundation for Statistical Computing) software. The analyses will be carried out in 5 phases, as outlined in Textbox 2.

Textbox 2. The 5 phases of the statistical analyses carried out in this study.

- Phase 1: Characterization of the patient sample
  - 1.1. Sociodemographic analysis of the variables collected at T1 and the variables from the surveyed instruments at T2. This involves descriptive analysis, both univariate and bivariate, which will be differentiated by:
    - 1.1.1. Quantitative variables: mean and SD, coefficient of variation, and median and IQR
    - 1.1.2. Qualitative variables (nominal and ordinal categorical): analysis of distributions through absolute and relative frequencies, including absolute and relative accumulated frequencies
    - 1.1.3. Quantitative variables will be reported alongside appropriate tests for normal distribution to ensure the accuracy and validity of our statistical analyses.
  - 1.2. Bivariate and descriptive analysis using 2D tables will be calculated for all qualitative variables belonging to T1 with all instrument scores collected at T2: Chalder Fatigue Scale (CFQ-11), Hospital Anxiety and Depression Scale (HADS), 14-item Posttraumatic Stress Scale (PTSS-14) adapted to COVID -19, and EQ- 5D plus recorded COVID-19 symptoms. The previous points will be reiterated in this bivariate context, utilizing the computational aid of split->file categorical variables in situations where one variable is metric and the other is categorical.
  - 1.3. Internal consistency and reliability analysis of the T2 instruments: calculation of the Cronbach alpha (general and partial) for all ordinal items and item subgroups differentiated by the subscales defined by the respective authors
- Phase 2: Determination of fatigue incidence caused by long COVID and its relationship with T1 and T2 variables
  - 2.1. Procedures for determining fatigue cutoff points in this cohort of patients:
    - 2.1.1. Bivariate analysis using optimal binning procedures for categorical variables (age class, sex, and BMI) with the total fatigue score, as well as partial scores of physical and psychological fatigue
    - 2.1.2. Multivariate analysis by constructing models in the format of decision trees via the CHAID (chi-square automatic interaction detection) algorithm [41], with total and partial fatigue scores as dependent variables
  - 2.2. Inferential analysis based on variables resulting from 2.1.1 and/or 2.1.2, considering the complexity of variables in T1 and T2:
    - 2.2.1. (1) Chi-Square tests to capture the association of categorical variables; (2) Shapiro-Wilk tests to verify the distribution of quantitative variables; (3) tests for comparing 2 or more population means: parametric analysis of variance (ANOVA) test and nonparametric (Kruskal-Wallis) test; and (4) correlation tests (Spearman or Pearson) to verify the degree of association between T2 instrument scales
- Phase 3: Determination of patient groups based on fatigue differentiation
  - 3.1. Conducting classification analysis using clustering techniques, specifically the 2-step cluster analysis, to explore variables with greater power in differentiating groups of patients
- Phase 4: Exploration of the best combination of T1 and T2 variables capable of discriminating patient fatigue levels through a discriminant multivariate analysis
- Phase 5: Investigation of the association between phase 3 groups and all T2 instrument scales using chi-square association tests

Power and Sample Size

We plan to conduct a prospective multicentric observational study to investigate the prevalence and severity of mental illness symptoms and fatigue in individuals with long COVID. Based on previous studies and expert opinion, we expect the prevalence of fatigue and mental symptoms in this population to be around 50% [42,43]. We aim to detect a minimum effect size of 0.2 with a power of 80% and a significance level of P=.05.

Using these assumptions, we performed a sample size power analysis using a 2-sample t test. We found that a total sample size of 200 participants (100 with adverse mental health symptoms and 100 without) would be required to detect the minimum effect size of 0.2 with 80% power and a significance level of P=.05. The required sample size was calculated using an a priori power analysis with an online calculator [44]. To compensate for a projected 25% loss to follow-up, we aimed for 250 participants.

We plan to recruit participants from multiple hospitals and primary care centers across Portugal, focusing on individuals who have been diagnosed with long COVID and are experiencing mental illness symptoms and/or fatigue. Recruitment will be closely monitored throughout the study to assess the pace at which participants are enrolled. The need for sample size adjustment will be determined based on the observed recruitment rates and the accumulating data. We plan to conduct an interim analysis after the recruitment of the first 100 patients.

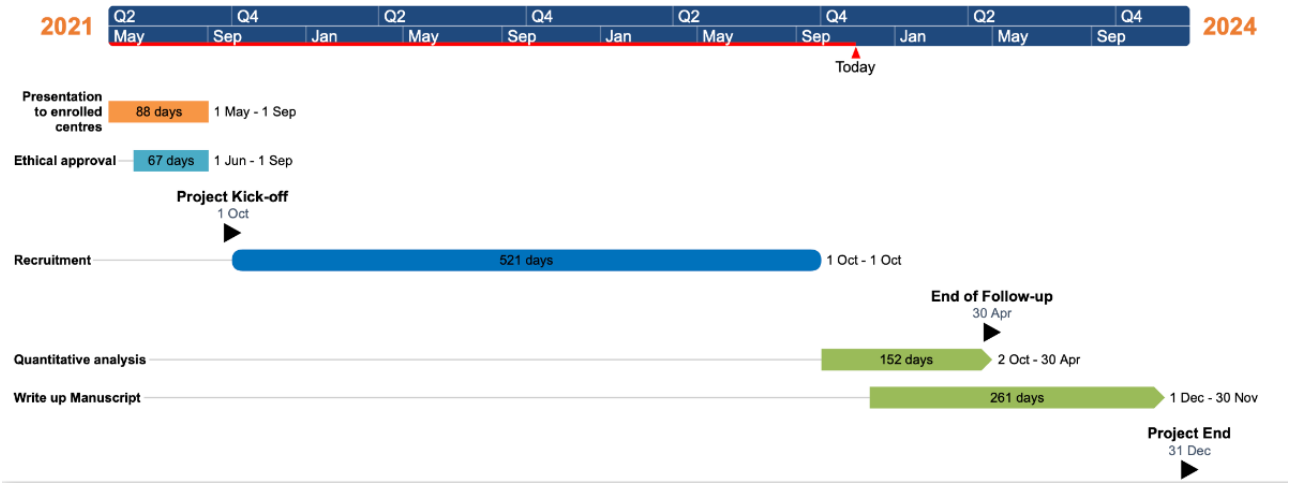
Results

This study received no specific grant from any funding agency in public, commercial, or not-for-profit sectors. Recruitment began in October 2021 at Portimão Hospital and Alvor Hospital,

in June 2022 at Faro Hospital and São Sebastião Hospital, and in October 2022 at Fernando Fonseca Hospital. The deadline for the end of the recruitment period in all centers was December 2023. The preliminary study results will be published in a peer-reviewed international medical journal after October 2023.

The study timeline is shown in Figure 2. This study is included as part of the first author's (LP) PhD thesis. The initial study results were presented at the PhD interview in November 2023. We aim to publish the study in an indexed scientific journal and present the results at national and international congresses.

Figure 2. Study timeline.



We plan to enroll 250 participants, including 100 with adverse mental health symptoms and 100 without, to explore the intricate relationship between adverse mental health symptoms and both physical and psychological fatigue in individuals recovering from long COVID. Preliminary analyses indicate a compelling connection, wherein patients who report heightened levels of depression and anxiety also tend to experience increased fatigue. These findings underscore the importance of considering mental health as a pivotal factor in understanding the enduring impact of COVID-19 beyond the acute phase. In addition to depression and anxiety, our study explores the persistence of PTSD symptoms in a subset of participants. Initial results suggest that, even after recovery from the acute phase of the infection, a proportion of individuals continue to grapple with the psychological repercussions of the virus. This observation aligns with emerging evidence suggesting a prolonged psychological impact of COVID-19, emphasizing the need for comprehensive mental health support for patients after contracting COVID-19. The identified links between mental health symptoms and fatigue have broad implications for the holistic care of this patient population. Understanding these connections can guide targeted interventions, emphasizing the importance of addressing mental well-being alongside physical recovery. As we delve deeper into the data and conduct further analyses, a more nuanced understanding of these relationships will emerge, informing future health care strategies and interventions.

Discussion

Expected Findings

As the COVID-19 pandemic ceases, more patients enter the chronic phase of the disease. Identifying groups at high risk of cognitive and psychiatric dysfunction may allow for targeted intervention to effectively meet their physical, neurological, and psychological health care needs. Our study, conducted in the aftermath of the COVID-19 pandemic, provides a unique opportunity to investigate the persisting health effects of the virus on those who have recovered from the acute phase of the disease. We specifically aim to explore post–COVID-19 fatigue and mental health disorders using specific tools to separate physical and psychological fatigue symptoms. We also use a prospective cohort multicenter study design, which is less prone to bias, and we aim to include both hospitalized and nonhospitalized patients, covering all degrees of acute COVID-19 severity. We anticipate that our research will reveal a significant association between the presence and severity of mental health symptoms, including depression, anxiety, and PTSD, and the degree of physical and psychological fatigue in patients following COVID-19. We expect to observe that patients experiencing more pronounced mental symptoms will report higher levels of physical and psychological fatigue.

The potential links between mental symptoms and fatigue suggest a connection between the mental well-being of patients post COVID-19 and their experience of fatigue, encompassing both physical and psychological dimensions. The existing research has indicated a high prevalence of anxiety and depression symptoms among patients hospitalized with COVID-19 infection, with a quarter of patients experiencing at least mild symptoms of acute stress disorder [42]. Moreover, a study conducted in Iran after the outbreak of COVID-19 found a correlation between the prevalence of chronic fatigue syndrome and PTSD [45]. The study reported that 5.8% of subjects experienced PTSD symptoms 6 months after the onset of SARS-CoV-2 infection. Interestingly, the study also noted that female sex was associated with a higher risk of fatigue. At the same time, variables such as oxygen saturation at admission, primary symptoms, ICU admission, and laboratory test parameters did not show a significant association with fatigue occurrence.

Based on these findings, we anticipate that patients post COVID-19 may exhibit more pronounced symptoms of

depression and anxiety and heightened levels of physical and psychological fatigue. This insight emphasizes the importance of considering mental health as a crucial factor in understanding the long-term effects of COVID-19. It underscores that the impact of the virus extends beyond the acute illness phase and can manifest in persistent mental symptoms that influence patients' overall well-being. Moreover, it can imply that addressing anxiety symptoms in post–COVID-19 care may have a positive impact on reducing fatigue and improving patients' quality of life. We also aim to explore the prevalence and severity of PTSD symptoms in a subset of patients following COVID-19. While this is not the primary focus of our research, assessing the presence of PTSD symptoms in this study population allows for a better characterization of the patient group. Some participants continue to experience PTSD symptoms following COVID-19 infection, suggesting that the psychological impact of the virus can be long-lasting. These findings may shed light on the need for comprehensive mental health support for patients post COVID-19.

The implications of our potential findings are widespread. They underscore the importance of integrated care for patients post COVID-19 that addresses both physical and mental health aspects. Clinicians and health care providers will then be aware of the potential for persistent mental symptoms and their impact on patients' fatigue levels and overall HRQoL.

Limitations

Our study's limitations include the possibility of sampling bias, as individuals with more severe symptoms of fatigue or other mental health symptoms may be less likely to participate. This possibility could result in underrepresentation and bias within the study's findings. To minimize this, we will use diverse recruitment methods across multiple sites and collect data on participants' reasons for declining participation. We will also provide detailed information about the study and its potential benefits to participants while ensuring an ethical and respectful recruitment process sensitive to participants' health concerns and symptoms.

We also acknowledge the limitations related to our exclusion criteria and use of the CFQ-11, which has yet to undergo specific validation for patients with COVID-19. This recognition underscores the importance of future research endeavors to validate the applicability of the CFQ-11 within this patient population, despite its utilization in prior studies [46-48].

While there are valid concerns regarding the exclusion criteria and assessment of psychiatric disorders in our study—including the fact that assessing preexisting fatigue may be difficult—we have devised a plan to mitigate these concerns. We intend to meticulously collect detailed medical histories and review the medical records of all enrolled patients to ensure the precise application of the exclusion criteria. However, a notable limitation of our study arises from the absence of a baseline assessment conducted before the onset of COVID-19 infection. This absence impedes our ability to comprehensively evaluate the influence of COVID-19 on various health parameters, such as fatigue and mental health. The absence of a baseline assessment may also limit our capacity to distinguish between preexisting conditions and post–COVID-19 effects, which is a key consideration in understanding the full spectrum of the virus's impact on individuals. Additionally, while we acknowledge that the measurements used in the study are based on self-report—and therefore subjective—we emphasize that self-reported questionnaires are commonly used in scientific studies. These questionnaires hold significance in assessing the extent of physical and psychological fatigue in patients following COVID-19. Despite these limitations, our study is poised to make a significant contribution to the existing literature by shedding light on the impact of COVID-19 on mental health. This research has the potential to guide future treatment and management strategies, serving as a valuable resource for the health care community.

Conclusion

This study protocol outlines a critical investigation into the lingering physical and psychological effects of long COVID. It emphasizes the importance of understanding the ongoing health challenges individuals face even after recovering from the acute phase of the virus. This study's research questions focus on assessing the potential correlations of mental illness symptoms (ie, physical and psychological fatigue) among patients post COVID-19.

In the aftermath of a global pandemic, this research is timely and crucial. It has the potential to inform health care strategies and interventions that provide targeted and holistic care to individuals grappling with long COVID. Ultimately, this study aims to improve patient outcomes, enhance the quality of life for those affected, and contribute to broader efforts to address the multifaceted health implications of this unprecedented global crisis.

Authors' Contributions

LP conceptualized the study, wrote the first draft of the protocol, and planned the study. CR and RF helped write the first draft of the protocol. AB gave critical input throughout the study.
JB-E wrote the first draft of the protocol and gave critical input throughout the study. AM was responsible for the statistical planning and methodology. MD planned the study. All authors contributed to the manuscript and approved the submitted version. No generative artificial intelligence (AI) was used in any portion of the manuscript writing.

Conflicts of Interest

JB-E is an associate editor for BioMed Central (BMC) Medical Education and has received travel expenses from Medtronic for the "Save the Brain Initiative" training. The remaining authors have no conflicts of interest to disclose.

Abstract

Background: Women are at high risk of experiencing trauma, guilt, and stress when forced to separate from their companion animals when fleeing domestic violence. Where little support is available for women and pets to stay together, women may be forced to delay leaving the abusive relationship or leave the pet with the abuser. Forced separation places both women and pets at substantial risk, where pets may be used as a coercive control measure. However, little evidence exists regarding the extent to which Australian services or policies offer support in these circumstances.

Objective: This research aims to increase the understanding and the impacts of forced separation between women and their pets in domestic violence situations. The research will investigate the effectiveness of service responses for both women and animals, aiming to develop a policy framework that guides service improvement with the goal of enhancing outcomes for women and pets fleeing domestic violence.

Methods: This protocol paper describes the process of developing a conceptual framework of 4 studies that include a scoping review, policy analysis, focus groups, and interviews that guide the design of the qualitative research project.

Results: A scoping review of the literature on forced separation from pets in domestic violence, natural disasters, and homelessness situations has led to the development of a conceptual framework that guided the design of the proposed study. The review also confirmed the necessity of the proposed research project in addressing the lack of Australian national frameworks and guidance available for women and pets seeking formal support in domestic violence situations. As of August 2023, supporting organizations have commenced the distribution of the research flyers. Expected data collection will be completed between August and October 2023. The results are expected to be published in June 2025.

Conclusions: Via a systematic process, the importance of the proposed study in improving the understanding of the impact of forced separation between women and their pets at times of domestic violence and the gaps in best supporting both women and their pets has been confirmed. A study design based on the learnings from previous studies and the focus of the current research has been finalized. The impact of the research project in developing an Australian national framework for best supporting women and their pets in crisis situations is anticipated.

Introduction

In Australia, 69% of households live with a companion animal (pet), and 86% of households with a pet have children [1]. Dogs and cats are the most popular type of pets [1]. The main reason for living with a companion animal is companionship [1]. The relationship is considered beneficial both psychologically and physiologically for humans and animals [2]. Pets are a vital support system providing emotional support or strength at times of domestic violence [3]. Survivors in domestic and family violence situations often live in terror and face threats to themselves and their pets [4]. Sadly, women in domestic violence situations are often faced with the torturous decision to leave their pet with the perpetrator to seek safety or access temporary fostering, resulting in forced separation from their companion animal (Montgomery et al [5], in press), thus losing the emotional support normally received from the relationship [3].

Barrett et al [6] found that decisions to leave or stay in the relationship were impacted by the concerns for the animal's welfare, with 56% of women delaying leaving the relationship to protect their pet. Women with both children and pets were also found to delay leaving an abusive relationship out of concern for the pet's welfare [7]. Most women who delayed were forced to leave their companion animal with the perpetrator when they eventually fled to safety and 47% of women would have fled to safety with their companion animal if support was available [8]. Completing a safety plan when leaving domestic violence situations was often compromised due to a lack of pet-inclusive shelters, often leading to homelessness in order to stay with their pet [7]. When survivors are forced to leave their companion animals with the perpetrator, the risk of coercive control (such as monitoring a person's movements) increases where the companion animal is used as a coercive control tool [9]. The companion animal in this situation may be subject to continued maltreatment [9], often resulting in torture or death [10] and survivors experience additional guilt and trauma [3] as a result. Often, they consider returning to their partner for the sake of their companion animals' safety [8]. Where companion animals have survived domestic violence, signs of distress in the animal have been observed through behavioral changes, such as avoidance and vocalization [4,11]. Devastatingly, in Australia, such behavioral changes often result in euthanasia of the pet [4,11].

The emotional attachment between survivors of domestic violence and their pets may be substantial due to sharing the experience of abuse [4], which makes a deliberate act of cruelty or death of a companion animal particularly torturous [12]. While it is the case that domestic violence is a human issue that affects both men and women, it is recognized as a gender-based issue where men are more likely to perpetrate violence against women and is considered an epidemic problem that requires change in Australia [13]. A recent report on homicide in Australia [14] reveals that, from 1989 to 2020, the incidence of intimate partner homicide is consistently much higher for female survivors than male survivors. The most recent statistic (2019-2020) states that female individuals were the targets in 36 (80%) of the 45 intimate partner homicides. Considering Australia is one of the highest pet ownership countries in the world, where women with children are more likely to have a pet [15], it is vital to address the risks for survivors and their companion animals at times of forced separation because of domestic violence. In such a context, a research project has been developed to investigate the existing policy framework and relevant services that provide support to people and companion animals in domestic violence situations. This protocol paper will explain the process of confirming research gaps and determining research questions and will provide details of the overall project design to be used by the proposed project as informed by the learnings from previously published studies.

Methods

Overview

A scoping review [5] using the keywords "human-animal relationship/bond," "pets," "companion animals," "animal abuse," "violence," "homelessness," "housing," and "disasters," was conducted between March and August 2022. The review focused on identifying empirical studies on the human-animal relationship and crisis or situational change with no date limitation. The review was guided by Arksey and O'Malley's [16] framework for scoping reviews and conformed to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) checklist for scoping reviews [17]. English-language, scholarly peer-reviewed papers that included adults with a strong relationship with a pet and an event or change of situation were a criterion for the scoping review. All methodology types were accepted. Gray literature and certain animal types (rodents, wildlife, zoo animals, and working animals) were excluded. The papers were assessed on their ability to fit within the inclusion criteria. Five databases (MEDLINE Ovid, PsycINFO, Scopus, CINAHL, and Emcare Ovid) were searched, and a total of 42 scholarly papers that met the inclusion criteria were identified and included for data extraction. The scoping review mapped the concept of forced separation between people and their companion animals in areas of crisis or situational change and examined policies that included companion animals. The study design and methods used for the studies were also examined to inform the current project design. Please see the full list of papers included in the scoping review in the Multimedia Appendix 1 [3,4,6-11,18-51].

Scoping Review Findings That Informed the Development of the Protocol

The identified studies in [5] scoping review were predominately quantitative and conducted in the United States, with a focus on the co-occurrence of animal abuse and domestic violence. The lens of research has recently focused on the relationship and animal maltreatment or welfare concerns. Surveys and semistructured interviews were the common forms for collecting quantitative studies and qualitative data respectively. The average sample size consisted of 200 participants for quantitative studies and 20 participants for qualitative studies. The target population was predominantly female adults seeking refuge from domestic violence shelters and support services.

The scoping review [5] confirmed a lack of support for both humans and animals at times of forced separation because of domestic violence. The oversights of the animals' safety and welfare showed that animals were being left with the abuser [18] and women delayed leaving a violent relationship to protect the companion animal [19]. Additional barriers that were identified included geographical locations, lack of available supports [19], lack of awareness of supports, and attachment or fear of separation from the companion animal [4]. As a result of these barriers, the risks to safety, health, and well-being for women, children, and their companion animals have increased.

The scoping review [5] findings revealed survivors were often reluctant to reach out to services due to a lack of trust in accessing support services, veterinary care, and law enforcement. A lack of trust was associated with a fear of being forced to separate from their companion animal [10,18,20,21]. The reluctance to access support, and the responsibility weighing on women to access supports [6,22] is highly concerning. Although many studies in the literature provided implications for service providers, no research was found that investigated the policy frameworks that provide support to people and companion animals in domestic violence situations at any system, organization, societal, or individual level [5].

Ethical Considerations

The following ethical considerations are guided by the Global Women's Institute for the Department of Foreign Affairs and Fair Trade [52], which provides recommendations for projects specific to researching women in domestic violence situations. Ethical approval was granted from the Human Research Ethics Committee (approval H9148). Participation in this study is voluntary and written and verbal consent will be obtained from every participant. The data will be retained for a minimum period of 5 years and will only be accessible to the research team. All data collected will be deidentified and pseudonyms will be provided. All audio recordings for both target populations will be erased after transcription. The primary target population will have the opportunity to review the transcriptions in writing via email. To avoid comprising anonymity and confidentiality for the primary target population, specific locations, age, occupation, culture, and religious discourse in the primary target will not be included in the narrative where there is potential to make the participant identifiable. Consent will be obtained verbally prior to the commencement of the focus group discussion and interviews. Participants are reminded of the voluntary nature of the study and their rights to not answer questions or withdraw their participation from the study. The focus group will be informed that confidentiality is not guaranteed and will be requested to anonymize discussions of their opinions and keep the group discussions private. Confidentiality and anonymity are provided to the interview participants.

Research Focus and Research Questions

The research aims to inform the Australian policy framework by investigating how support services operate across different contexts for adult women and their companion animals affected by forced separation to reduce negative impacts for both people and animals when fleeing domestic violence situations. The research aim will be achieved by the following two objectives:

1. Identifying the impacts of forced separation between adult female survivors of domestic violence and their companion animal's health, safety, and living conditions.
2. Identifying the existing strategies and support services, the perceived effectiveness of these strategies, and areas for improvement to develop recommendations that maximize support to people and their companion animals fleeing domestic violence situations.

The research seeks to answer the following two questions.

1. How does forced separation impact the domestic violence survivor and their companion animal under the existing policy and support framework in Australia?
2. What are the factors and how do these factors influence the extent that the benefits of the existing services currently available to people and their companion animals are realized?

A qualitative design will be used to address the gaps in the literature of a lack of national framework to guide pets and women in domestic violence; the impact of forced separation; and the roles, attitudes, and beliefs of seeking and providing services to better understand the impacts and perceptions of forced separation. The transformative paradigm views privilege and power as a social construction that is embedded through social, political, cultural, economic, gender, age, disability, race, and ethnicity. The transformative worldview is a suitable framework providing the lens of power and oppression with a focus on positive social change [53].

Conceptual Framework

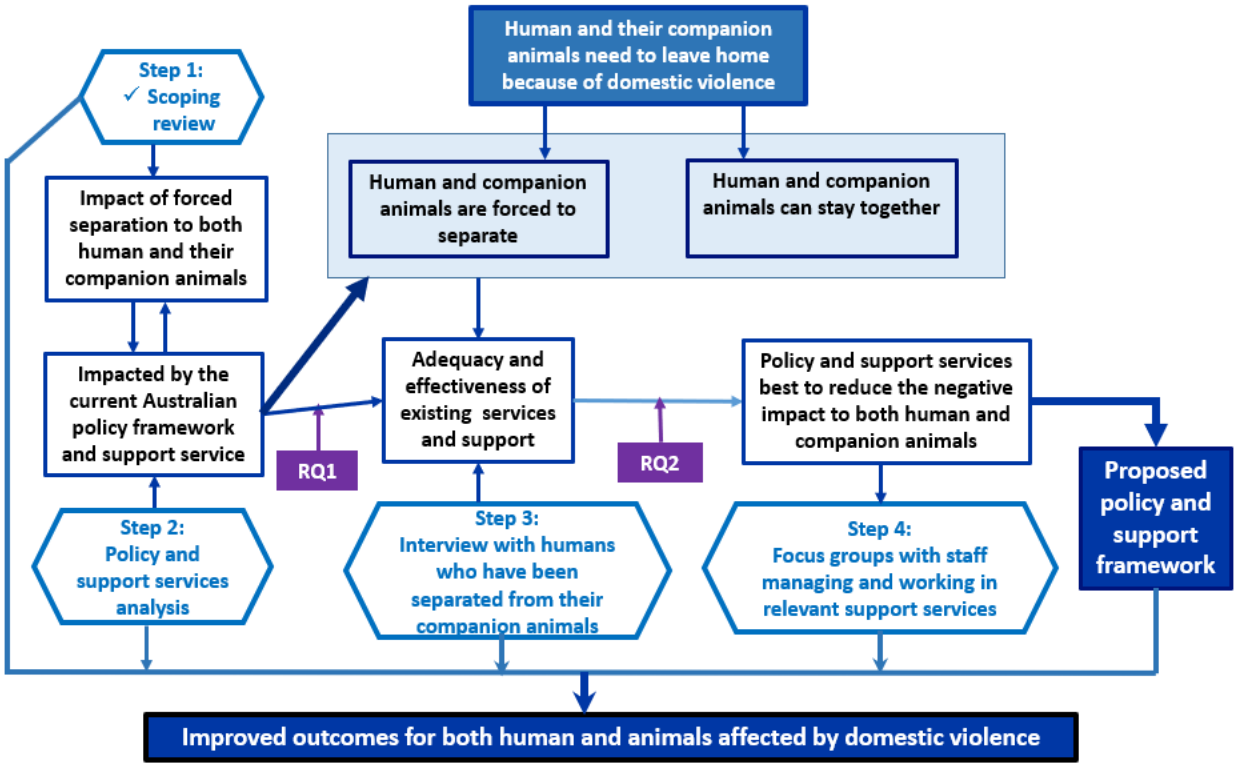
Based on the findings of the scoping review [5] and the role of support services in preventing or minimizing adverse outcomes due to forced separation, a conceptual framework (Figure 1) was developed. The framework indicates that policy and adequate, effective support services are required to improve the outcomes for people and companion animals who must leave their homes because of domestic violence. The scoping review [5] confirms that a policy framework, key supports, and elements required to achieve these outcomes remain unclear. It is important to understand existing policies, support services or providers, and those who use the services in Australia so that improvements can be made to best support people and companion animals fleeing domestic violence. Guided by the conceptual framework created for this study, 4 steps (Figure 1, studies 1-4) need to be implemented to enrich our understanding of the key elements leading to the development of a policy framework on the forced separation of companion animals because of domestic violence that is relevant to the Australian context. The steps include:

1. A scoping review [5] of forced separation at times of crisis or situation (completed).
2. A policy or services analysis and a scanning of the key supports to humans and animals that will analyze the purpose; construction; implementation; and impacts to understand, evaluate, and provide meaning and context [54].

3. Semistructured individual interviews with participants who have accessed a variety of support services (refuges, crisis services, animal welfare services, and mainstream such as women's legal services) will be conducted to increase the understanding and impacts of forced separation on people and companion animals.
4. Focus groups with staff and service providers will be conducted to understand and identify perceptions of the effectiveness and adequacy of service provision.

A critical analysis of steps 2-4 will be completed to compare the findings of the most common types of support, service gaps, and availability of services, leading to the development of an improved policy and support framework.

Figure 1. The conceptual framework. RQ: research question.



RQ 1: How does forced separation impact the domestic violence survivor and their companion animal under the existing policy and support framework in Australia?

RQ 2: What factors and how do these factors influence the extent that the benefits of the existing services currently available to people and their companion animals are realized?

Project Design and Method

Participants: Characteristics and Recruitment

The research project has 2 target populations. The primary target population is female individuals who have or have had considered themselves to have a strong emotional bond in a relationship with their companion animals; have experienced domestic violence; and have been forced to separate from their companion animals or sacrificed their own health, safety, and living arrangements to stay with the animals. The secondary target population is those who have not been directly affected by forced separation and domestic violence but have provided or are currently involved in providing professional support services to the primary target population. Due to the complex and sensitive phenomenon, both target populations are adults, 18 years and older [52].

Both target populations will be recruited through relevant domestic violence or animal welfare organizations. The organizations will be responsible for making direct contact with the potential participants via emails or organization-based advertisements. Potential participants will be encouraged to make direct contact with the principal researcher (first author) should they wish to participate in the study. Both target populations will be geographically recruited nationally across all states and territories in Australia. Due to financial and logistic constraints [55], both target groups are required to be fluent in the English language.

Sampling Strategy

Purposive sampling will be used to gather specific characteristics of survivors who have a strong emotional bond with their companion animals (primary target population) to maximize the richness of the data in addressing the research questions [56]. People who received an invitation from their perspective organization and made contact to participate in the study will need to fit the characteristics of either target population 1 or 2.

Key Stakeholders

To maximize the ethical sensitivity of the research, an advisory group of professionals in the field of domestic violence, advocacy bodies, and animal welfare organizations will be created [52]. Experts participating in the advisory group are

excluded from the secondary target population. The principal researcher candidate and 2 research advisors will hold meetings via Zoom (Zoom Video Communications) prior to ethics submission and after analysis. The advisory group is sought for their expertise regarding sensitivity, recruitment pathways, research questions, and participation sheets. After the analysis, for advice on recommendations based on the findings from the study.

Data Collection Tools

In-depth individual interviews are best suited for "sensitive" populations [52] and web-based options may increase the participant response rate [57]. Hence, the primary target population will be invited to participate in individual semistructured, web-based interviews via Zoom. These interviews are expected to take around 1 hour and will be audio recorded. Focus groups are well suited to discussing beliefs, opinions, and attitudes surrounding programs [52], interventions, and service gaps [58]. Therefore, the secondary target population will be invited to participate in web-based focus groups with audio recordings via Zoom. There will be 4 focus groups nationwide. The focus groups are estimated to last 1 to 2 hours as it is important to allow time during the focus groups for rapport building and voicing opinions [56]. Both types of interviews will be professionally transcribed. Verbal and written consent to participate will be obtained from all participants. All participants will be given the opportunity to review a summary of the transcriptions prior to publication [59].

Sample Size

The average number of participants in related qualitative studies identified in the scoping review was 20 (Montgomery et al [5]). The method of the research project is designed to gather in-depth, rich data or high-quality dialogue [60]. Hence, between 12 and 20 participants will be sampled from the primary target group, with the final number of participants being guided by data saturation of main themes, and no new insights or issues are found [61]. The secondary target population will consist of 4 focus groups throughout Australia. When a group consists of high knowledge, a minimum of 4 participants are required to develop accurate information [62] and the probability of identifying themes with 6 participants is higher than 99% [63]. Due to the expertise and knowledge of the participants, there will be a minimum of 4 and a maximum of 8 participants to allow for space and reflection with each group member [56]. The number of participants for the target populations is supported by a recent systematic review of effective sample sizes for saturation in qualitative research [61].

Data Analysis

Interpretive work is required to identify meanings and themes from participants' opinions, perceptions, and experiences to meet the research aims and overall purpose. Thematic analysis will be used to provide a systematic approach to coding and conceptualizing themes [58]. Areas of analysis will include the impacts and outcomes of forced separation, accessibility of services, types of unmet needs, experiences of accessing services, and benefits of existing services. When the analysis of each step is completed, a critical analysis will be completed to aggregate the data [58] to provide a complete picture of the policy framework [54]. NVivo 12 software (Lumivero) will be used to facilitate the data analysis process.

Results

A scoping review of forced separation of companion animals in crisis situations has been completed, identifying the research gaps and guiding the research questions and design for the research project. As of August 2023, supporting organizations have commenced the distribution of the research flyers. Expected data collection will be completed between August and October 2023. The results are expected to be published in June 2025.

Discussion

Expected Findings

It is expected that the findings will identify the substantial issues experienced by women and pets in domestic violence situations such as psychological distress, grief, loss, and the complexity of decision-making when considering a pet. It is expected that women and pets need to be considered more seriously in Australia and the development of policies and services needs to include the consideration of pets in safety planning, accommodation, and long-term housing as their standard practice.

Comparisons With Prior Work

The research protocol builds on existing knowledge in the literature. We are unaware of any published national Australian frameworks or models that directly relate to responding to women and pets fleeing domestic violence. Previous literature indicates when women are seeking help to flee from domestic violence, the risk of safety increases for both women and their pets. In addition, the pet may be used as a coercive control measure, risking further abuse for both the woman and the animal [18]. The evidence indicates it is vital to address the increased risks to safety when fleeing domestic violence. The prospective data collection of service providers and women using domestic violence and animal welfare services in Australia, as we propose in this study, enables further understanding and development of an Australian framework that is embedded by those with lived experiences to improve outcomes.

Strengths and Limitations

Limitations include the small sample sizes that will not be generalizable to the wider populations, and the exclusion of non–English-speaking populations limits the ability of the research to understand the special needs of the linguistic and cultural populations [55]. The primary target population is recruited from service providers and is considered safe to participate. This is a limitation for women and pets in situations that did not seek formal service provision, had stayed in the relationship, or were not safe from abuse. Bias is more likely to occur in qualitative research than in quantitative methods, resulting in difficulty reaching true objectivity [59]. However, the strength of the qualitative design allows for flexibility and

sensitivity in language, trust, rapport building, exploration of experiences, and collaboration within the community [58] and is appropriate for the study's aims.

Conclusions

A research project guided by a conceptual framework informed by the findings of the scoping review confirms 4 key studies required to better understand the strengths, needs, and gaps of existing policy and support services for women and pets fleeing domestic violence, and the impacts of forced separation from companion animals. Ultimately, the project will develop an Australian national framework that will develop and provide more relevant guidance for supporting women and their pets fleeing domestic violence situations to improve outcomes for both women and their companion animals in Australia.

Acknowledgments

The authors would like to acknowledge Jacqui Watt for her expert advice on domestic violence; the advisory panel members for their contributions regarding animal welfare and domestic violence; and Anna Ludvik, Bridget Brown, Mandy Paterson, Marisa Debattista, and Susan Elvery and the Human Research Ethical Committee and the University Librarians for their contributions. Mentoring support was provided by Diana Mendez and the University Doctoral Cohort Program.

Data Availability

Data sharing is not applicable to this article as no data sets were generated or analyzed during this study.

Authors' Contributions

As the first author, JM developed the first draft of the manuscript guided by the senior author ZL. Both ZL and JL contributed to writing all sections of the manuscript and critically reviewed and approved the final version.

Conflicts of Interest

None declared.

Abstract

Background: Polycystic ovary syndrome (PCOS) is one of the most common endocrine disorders in women and is diagnosed using the Rotterdam criteria, including diagnosis of polycystic ovarian morphology (PCOM) by transvaginal ultrasound (TVUS). Due to high cost, availability, and the impact of the operator and ultrasound equipment on the reliability of the antral follicle count (AFC) by TVUS, an unmet need exists for a diagnostic test to determine PCOM without TVUS. A strong positive correlation between elevated anti-Müllerian hormone (AMH) levels and AFCs has been demonstrated in women with PCOS. In addition, recent updates to the international evidence-based PCOS guidelines state that serum AMH can be used as an alternative to TVUS-determined AFC, in the diagnosis of PCOM. The retrospective APHRODITE study derived and validated an AMH cutoff of 3.2 ng/mL for the Elecsys AMH Plus or Elecsys AMH assays (Roche) to diagnose PCOM in patients with PCOS.

Objective: This study aims to further validate, in an independent prospective cohort, the AMH cutoff (3.2 ng/mL) for PCOM determination, which was previously derived and validated in the APHRODITE study.

Methods: This large, prospective, multicenter, population-based, noninterventional study will evaluate the previously established AMH cutoff for the determination of PCOM during the diagnosis of PCOS using the Elecsys AMH Plus immunoassay in an independent population. Participants were women born between July 1985 and December 1987 in Northern Finland; the study partially links to the Northern Finland Birth Cohort 1986. We assessed the enrolled women, determined with the 2023 PCOS Guidelines, for current PCOS status and divided them by phenotype if positive. Each participant had 1 study visit to collect serum samples, record clinical data, and undergo a gynecological examination including TVUS. All data were collected by highly trained midwives or trained gynecologists. Sensitivity, specificity, and agreement measures were used to validate the previously determined cutoff in the whole population and in subpopulations based on phenotype and relevant demographic or clinical factors. The minimum target sample size was approximately 1800 women, including approximately 10% with PCOS.

Results: At the time of manuscript submission, participant recruitment had concluded, and 1803 women were enrolled into the study. Data collection is complete and biostatistical analysis is planned for 2023.

Conclusions: To limit variability, there were few TVUS operators and only 2 TVUS machines of the same type. Additionally, all women who were taking oral contraceptives were excluded from the primary analysis population. Selection bias was limited as this was a population-based study and participants were not seeking treatment for PCOS symptoms. Validating the AMH cutoff

in a large, population-based study will provide further evidence on the utility of the Elecsys AMH Plus or Elecsys AMH assays in PCOM diagnosis as an alternative to TVUS. Measuring AMH for PCOM diagnosis could reduce delayed or missed diagnoses due to operator-dependent TVUS examinations.

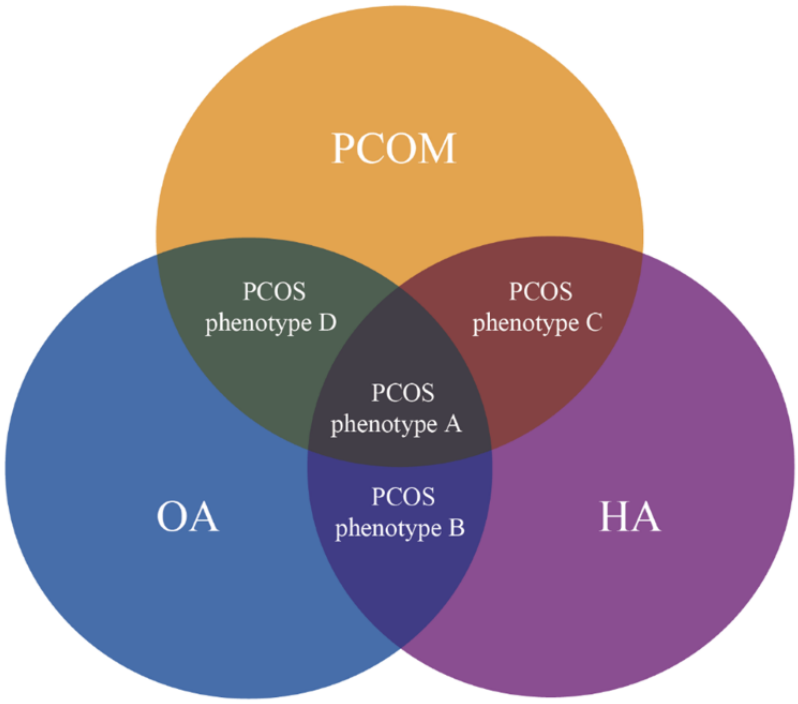
KEYWORDS

anti-Müllerian hormone; immunoassay; polycystic ovarian morphology; polycystic ovary syndrome; transvaginal ultrasound

Introduction

Polycystic ovary syndrome (PCOS) is one of the most common endocrine disorders affecting women and is characterized by symptoms of ovarian dysfunction and an excess of androgen, without other specific diagnoses [1-3]. PCOS is the primary cause of female anovulatory infertility and has metabolic, cardiovascular, and psychological implications [4-7]. The diagnosis of PCOS is based on the Rotterdam criteria [8,9], where 2 or more of the following conditions should be met: oligoanovulation or anovulation (OA), clinical or biochemical signs of hyperandrogenism (HA), a combination of both, and polycystic ovarian morphology (PCOM) based on transvaginal ultrasound [10] (TVUS; Figure 1).

Figure 1. Diagnostic criteria and phenotypes of PCOS based on the Rotterdam criteria. HA: hyperandrogenism; OA: oligoanovulation or anovulation; PCOM: polycystic ovarian morphology; PCOS: polycystic ovary syndrome.



Criteria	Phenotypes			
	A	B	C	D
HA	✓	✓	✓	
OA	✓	✓		✓
PCOM	✓		✓	✓

According to the updated guidelines [9], the diagnosis of PCOM is based on a TVUS with a finding of ≥20 follicles of 2-9 mm in size in at least 1 ovary or increased ovarian volume ≥10 mL, but determination of the antral follicle count (AFC) by TVUS

depends on the operator and ultrasound equipment used [11-17]. Due to the expense of the equipment and the regularity of updates needed, in addition to the very high level of specialized training required by operators, TVUS is not available for many physicians seeing women with symptoms of PCOS (eg, general practitioners, gynecologists, and endocrinologists). Thus, there is significant underdiagnosis of PCOS [18] along with a substantial delay in receiving a diagnosis [19-22]; therefore, an unmet medical need exists for a diagnostic test to determine PCOM without the need for TVUS.

Anti-Müllerian hormone (AMH) is a regulator of follicle recruitment from the primordial follicle pool and inhibitor of follicular growth that is expressed by granulosa cells in the preantral and small antral follicles [23,24]. Serum AMH levels correlate well with the 2-9 mm antral follicles found in TVUS examination in the diagnosis of PCOM [25,26]. Elevated levels of AMH are observed in women with PCOS [27-30], and a strong correlation between elevated levels of AMH and increased AFCs has been demonstrated [12,14,26,29], supporting the use of AMH as a biomarker for PCOM.

In the recent, retrospective, case-control APHRODITE study, a cutoff of 3.2 ng/mL for the Elecsys AMH Plus or Elecsys AMH assays (Roche Diagnostics International Ltd) was derived and validated to identify PCOM as part of PCOS diagnosis in women aged 25-45 years [28]. Moreover, a recent study reported the usability of the Elecsys AMH assay to identify PCOS cases in large epidemiological data sets [31]. All previous findings support the use of AMH measurement using the Elecsys AMH Plus assay as a substitute for AFC in the determination of PCOM, thereby reducing the need for TVUS procedures [28,32].

Since APHRODITE was a retrospective, case-control study that validated the derived cutoff in a population with an increased risk of PCOS, it is of interest to further validate the derived cutoff in a prospective, independent, population-based cohort. By validating AMH levels in a large, population-based study using the Roche Elecsys AMH Plus assay, we aim to provide clinicians with the ability to identify PCOM as part of a PCOS diagnosis using a simple blood test, thereby making diagnosis of the disorder more accessible in a primary care setting. Although it is not anticipated that TVUS as a diagnostic method for PCOM will be discarded from PCOS guidelines, AMH testing could be adopted as an alternative method, particularly in primary care.

Methods

Study Design

The prospective, multicenter, population-based, noninterventional HARMONIA (Human Anti-Müllerian Hormone for Diagnosis of PCOS) study aims to validate the AMH cutoff determined and validated in the APHRODITE study for the determination of PCOM during the diagnosis of PCOS using the Elecsys AMH Plus immunoassay. Study enrollment was conducted between May 2020 and October 2022 at 2 sites in Finland: Oulu University Hospital, Department of Obstetrics and Gynecology, Oulu, and Helsinki University Hospital, Helsinki.

Participants

The target population was women born in Northern Finland between July 1, 1985, and December 31, 1987; the study partially links to the Northern Finland Birth Cohort (NFBC) 1986 study population. The prevalence of PCOS in this population is expected to be approximately 10% when applying the diagnostic criteria for PCOS outlined in the 2018 international PCOS guideline [9,33]. The COVID-19 pandemic resulted in a lower enrollment rate than originally expected, and so the cohort was expanded to include a random cohort of women born in the same geographical area up to 18 months after those in the NFBC 1986, to ensure enrollment met the minimum target sample size of approximately 1800 individuals. As the study is population-based, all nonpregnant women from the target population were invited to participate in the study.

Participants were excluded if they were unwilling to undergo gynecological examination including TVUS, refused to have blood drawn, or did not consent to sharing their personal data with Roche Diagnostics International Ltd, who completed the AMH measurement and analysis. Additionally, women who were taking oral contraceptives at the time of study commencement will be excluded from the primary analysis population.

PCOS cases were defined as women fulfilling 2 or more Rotterdam criteria [8,9]. For each participant, the current PCOS status was assessed. PCOS positive cases were further divided into the following phenotypes: phenotype A (HA+, OA+, PCOM+), phenotype B (HA+, OA+, PCOM-), phenotype C (HA+, OA-, PCOM+), and phenotype D (HA-, OA+, PCOM+; Figure 1). PCOM in PCOS cases included the PCOS A, C, and D phenotypes. PCOS phenotype B cases by definition did not meet the criteria for PCOM based on TVUS (phenotype B accounted for approximately 3% of PCOS cases in the APHRODITE study) and were not included in the case group for the primary objective. Controls were defined as women with negative PCOM with an AFC <20, an ovarian volume <10 mL, and no other diagnostic features of PCOS according to the Rotterdam criteria.

Each participant had 1 study visit during which serum samples were collected through blood draw (taken at any stage of the menstrual cycle), clinical data (including questionnaire responses) were recorded, and a gynecological examination including TVUS (Ultrasound System HS60, Samsung Healthcare) was performed to determine PCOM status; all assessments were evaluated by a clinician (Table 1) [34]. All data were collected by highly trained midwives or gynecologists.

Table 1. Baseline characteristics to be recorded by questionnaire and clinical assessment.

Baseline characteristic	Questionnaire	Clinical assessment
General information and medical history	• Participant identification and date of consent • Age at the study visit • Race • Education • History of radiation or chemotherapy (yes or no) or treatment • Long-term illnesses diagnosed by a doctor (self-reported) • Bothersome hair loss experience • Acne (former or current)	Confirmation of fasting for 12 hours before the clinic visit
Medication use	• Medication use (current) • Use and type of hormonal contraceptives (oral, patch, or intrauterine device; former or current)	N/A[a]
Intoxications	• Smoking (current, former, or never; number of cigarettes) • Alcohol (units per week)	N/A
Obstetric history	• Menarche • Cycle (regular, irregular, or absent) • Shortest and longest menstrual cycle length (days) • Last menstrual cycle • Number of live births, fetus mortus, miscarriages, extrauterine pregnancy, and pregnancy terminations • Fertility treatment • Breastfeeding status (no, exclusively, or partially) • Delivery within 6 months from the study visit	From the transvaginal ultrasound report: • Endometrial thickness • Visualization status of the ovaries • Ovarian length, width, height, and volume • Antral follicle count • Dominant follicle presence • Presence of corpus luteum and/or cysts >25 mm and/or other possible reason for increase of the ovarian volume
Anthropomorphic	• N/A	• Height • Weight • Waist circumference • Hip circumference • Systolic blood pressure or diastolic blood pressure • Gynecological ultrasonography (polycystic ovarian morphology) • Hirsutism (Ferriman-Gallwey-Score) • Acne severity grading (1-5) per the Global Acne Severity Scale [34]. Images of the participant will be assessed by a dermatologist

[a]N/A: not applicable.

Sample Processing

A total volume of approximately 5 mL of serum was collected using VACUETTE Tube 9 mL CAT serum clot activator tubes (Greiner Bio One) and stored at –80 °C. Aliquots were sent to the Nordlab in Oulu for measurement of testosterone by liquid chromatography-mass spectrometry (Sciex Qtrap 5500, Ab Sciex). Additional measurements were performed on-site at Oulu (testosterone, sex hormone-binding globulin, follicle-stimulating hormone, luteinizing hormone, thyroid-stimulating hormone, and prolactin) on the COBAS e 411 analyzer (Roche Diagnostics International Ltd), which was used to assess some of the PCOS criteria. Additional aliquots were shipped to Roche Diagnostics GmbH, Penzberg, Germany, for determination of AMH biomarker levels (Textbox 1). AMH levels were measured using the Elecsys AMH Plus assay on the COBAS pro e 801 analyzer (Roche Diagnostics International Ltd). The measuring range of the Elecsys AMH Plus assay is 0.01-23 ng/mL and the coefficient of variance for repeatability is less than 3% [35]. Participants with AMH levels more than 3.2 ng/mL (the cutoff determined and validated in the APHRODITE study [28]) were classified as AMH PCOM positive, and those with results ≤3.2 ng/mL were classified as AMH PCOM negative.

Textbox 1. Laboratory parameters to be measured from blood samples.

Parameters to be measured

- Hemoglobin A1c
- Complete blood count
- Ferritin
- Fasting plasma glucose
- Fasting total cholesterol
- Fasting plasma high-density lipoprotein
- Fasting plasma low-density lipoprotein
- Fasting plasma triglycerides
- Plasma alkaline phosphatase
- Plasma albumin
- Fasting serum C-peptide
- Plasma alanine aminotransferase
- Plasma amylase
- Plasma aspartate aminotransferase
- Plasma bilirubin
- Plasma gamma glutamyltransferase
- Plasma creatinine
- Plasma uric acid
- Fasting serum insulin
- Serum high-sensitivity C-reactive protein
- Testosterone
- Sex hormone-binding globulin
- Follicle-stimulating hormone
- Luteinizing hormone
- Thyroid-stimulating hormone
- Prolactin
- Anti-Müllerian hormone
- Dehydroepiandrosterone sulfate

Data Analysis

At the time of publication submission, the trial was still underway, although data collection was complete. During the planned biostatistical analysis, baseline characteristics and biomarker data will be analyzed for all participants, and by PCOS phenotype and case or control groups. Additionally, the baseline characteristics will be compared between cases and controls using statistical tests, such as Mann-Whitney *U* tests or chi-square tests.

The primary objective of this study, conducted in the PCOM positive population, will be validating the AMH cutoff for PCOM determined in the APHRODITE study. Agreement measures will be calculated, and tables produced to estimate the performance (ie, sensitivity, specificity, and receiver operating characteristic curve) of the prespecified Elecsys AMH cutoff for the prediction of PCOM status. In addition, performance estimates (sensitivity, specificity, and agreement tables) of the Elecsys AMH Plus cutoff will be performed within subpopulations (phenotype and potentially relevant demographic or clinical factors).

Sample Size and Power

The total sample size for the primary analysis was a minimum of approximately 1800 women, of whom approximately 10% will be PCOS positive cases; however, some individuals may need to be excluded from the primary objective analysis due to hormonal contraceptive use. As PCOS phenotype B cases do not meet the criteria for PCOM based on TVUS, some PCOS cases will also be excluded. In addition, some women may need to be excluded if their PCOS or PCOM status cannot be determined (eg, due to the inability to adequately visualize the ovaries). Assuming a significance level of 0.05 (1-sided lower CIs) and a joint power of 80%, approximately 55-88 PCOS

positive cases and approximately 164-262 PCOS negative cases are needed to achieve agreements of 65% and 70%, if the true percentages of agreement are 79%-82.5% and 78%-80%, respectively.

Ethical Considerations

The study complies with all relevant national regulations and institutional policies and was performed in accordance with the principles of the Declaration of Helsinki. Ethical approval was provided by the Ethical Committee of the Northern Ostrobothnia Hospital District (EETTMK 47/2019), and all participants were required to give informed consent for the use of their collected data for scientific purposes. The trial was registered (NCT05527353) on September 2, 2022.

Results

The first patient provided consent on May 7, 2021, and the last patient provided consent on October 28, 2022; therefore, participant recruitment has been completed. At the time of manuscript submission, 1803 women had been enrolled into the study. Biostatistical analysis will commence later in 2023 and it is expected that the results will be published shortly thereafter.

Discussion

This is the first large, prospective, population-based study to validate an AMH level cutoff for determining PCOM status in the diagnosis of PCOS.

Strengths and Limitations

One strength of this study is that all data were collected by highly trained midwives and specialized gynecologists. The TVUS data is robust due to the limited number of TVUS experienced operators performing the ultrasound assessments, and the use of only 2 TVUS machines of the same type. In addition, while most studies on AMH testing are retrospective, using small, non–population-based cohorts from PCOS clinics, HARMONIA is a large, prospective, population-based study. Furthermore, there will be limited bias, as the study is population-based, and participants were not seeking treatment for PCOS symptoms. However, the study also has some limitations. The age of the participants is limited by the study's linkage to the NFBC 1986 (all participants are within a 3-year age range). In the APHRODITE study, it was also found that AMH levels decreased with age among PCOS cases and controls [28]; findings from this study should therefore be evaluated in the context of these results. Furthermore, due to the geographical location of the study and the fertile age of the participants, most women will be White (with a small minority, estimated below 3%, of indigenous Sámi people), and some will be taking hormonal contraceptives. It has also previously been shown that there is some biological variability in AMH during the menstrual cycle [36]. However, a longitudinal study conducted in a population-based cohort demonstrated that AMH may be used as a surrogate marker for identification of PCOM [37]. The samples in this study will be taken at any stage of the menstrual cycle; however, we anticipate that the small variation in cycle phases will not affect the diagnostic performance of the Elecsys AMH Plus assay. Furthermore, studies have shown that women with PCOS may have a higher body mass index, which could affect the precision of TVUS results [38,39]. In addition, the global COVID-19 pandemic may have caused selection bias during enrollment in the original NFBC 1986 population, although this factor applies to the entire cohort. The study results will be analyzed and interpreted in this context.

Benefits of the Study

By validating AMH levels in a large, population-based study, clinicians will be able to identify PCOM as part of PCOS diagnosis using a simple blood test. Thus, if TVUS is necessary only as a means to identify PCOM (rather than for other clinical reasons), this procedure can be replaced, thereby making the diagnosis of PCOM more accessible in a primary care setting. This would lead to much faster diagnoses for patients, as in some health care settings there would be no need to wait for referral, and only patients needing treatment for other specialized health care (eg, fertility, topical skin therapy, or psychological distress) would require referral to a specialist. This would also allow the common health impairments of the women affected to be viewed more holistically, rather than categorizing these women into an infertile population without further consideration of other adverse outcomes (eg, risk of developing type 2 diabetes mellitus or psychological distress). Testing AMH levels could also contribute to reducing missed diagnoses due to operator-dependent TVUS examinations. Following the validation of AMH levels in this study, we do not anticipate that PCOS guidelines will discard TVUS as a diagnostic method for PCOM, but rather advise that AMH testing be adopted as an alternative method.

Acknowledgments

The authors would like to thank Lotta Vuokila for coordination of the study, the study nurses and doctors for the data collection, the Northern Finland Birth Cohort staff for support, Antje Ziegler for data management support, Laura Schlieker and Chad Logan for statistical analysis and study conception support, and Anna-Maria Olziersky and Maria Schoedl for study setup and management support. We thank all study participants for the valuable resources they have offered. Third-party medical writing assistance, under the direction of the authors, was provided by Chloe Fletcher (MSc) and Pozisa Majaja (MSc) of Ashfield MedComms, an Inizio company, and was funded by Roche Diagnostics International Ltd. COBAS, COBAS PRO, and ELECSYS are trademarks of Roche. All other product names and trademarks are the property of their respective owners. This study was funded by Oulu University Hospital, the Academy of Finland (grant 321763), the Novo Nordisk Foundation (grant NNF21OC0070372), the Sigrid Jusélius Foundation, and Roche Diagnostics.

Data Availability

The data sets that will be generated or analyzed during this study will be available for academic research collaborations through the research group at the University of Oulu and the corresponding author on reasonable request. The Women's health study (WENDY) data can also be viewed [40].

Authors' Contributions

TP, DA, MH, JS, and RKA contributed to the study design and conception. TP and RKA acquired the data. TP, DA, MH, KB, JS, and RKA contributed to the data analysis and interpretation, provided critical review of the manuscript, and approved the final manuscript for submission.

Conflicts of Interest

TP received a research grant and honoraria from Roche, and fees or honoraria from Exeltis, MSD, Ferring, Gedeon Richter, and Organon. DA, JS, and MH are employees of Roche Diagnostics International Ltd. MH holds shares in F. Hoffmann-La Roche Ltd. KB is an employee of Roche Diagnostics GmbH. RKA has no competing interests.

Abstract

Background: Distal radius fractures are the most frequently encountered fractures in Western societies, typically affecting patients aged 50 years and older. Although this is a common injury, the best treatment for these fractures in older patients is still under debate.

Objective: This prospective study aims to compare the outcome of operatively and nonoperatively treated distal radius fractures in the older population. Only patients with distal radius fractures for which equipoise regarding the optimal treatment exists will be included.

Methods: This prospective international multicenter observational cohort study will be designed as a natural experiment. Natural experiments are observational studies in which treatment allocation is determined by factors outside the control of the investigators but also (largely) independent of patient characteristics. Patients aged 65 years and older with an acute distal radius fracture will be considered for inclusion. Treatment allocation (operative vs nonoperative) will be based on the local preferences of the treating hospital either in Switzerland or the Netherlands. Hence, the process governing treatment allocation resembles that of randomization. Patients will be identified after treatment has been initiated. Based on the radiographs and baseline information of the patient, an expert panel of 6 certified trauma surgeons from 2 regions will provide their treatment recommendation. Only patients for whom the experts disagree on treatment recommendations will ultimately be included in the study (ie, for whom there is a clinical equipoise). For these patients, both operative and nonoperative treatment of distal radius fractures are viable, and treatment choice is predominantly determined by personal or local preference. The primary outcome will be the Patient-Rated Wrist Evaluation score at 12 weeks. Secondary outcomes will include the Physical Activity Score for the Elderly, the EQ questionnaire, pain, the living situation, range of motion, complications, and radiological outcomes. By including outcomes such as living situation and the Physical Activity Score for the Elderly, which are not relevant for younger cohorts, valuable information to tailor treatment to the needs of the older population can be gained. According to the sample size collection, which was based on the minimal

important clinical difference of the Patient-Rated Wrist Evaluation, 92 patients will have to be included, with at least 46 patients in each treatment group.

Results: Enrollment began in July 2023 and is expected to continue until summer 2024. The final follow-up will be 2 years after the last patient is included.

Conclusions: Although many trials on this topic have previously been published, there remains an ongoing debate regarding the optimal treatment for distal radius fractures in older patients. This observational study, which will use a fairly new methodological study design, will provide further information on treatment outcomes for older patients with distal radius fractures for which to date equipoise exists regarding the optimal treatment.

KEYWORDS

distal radius fracture; older patients; natural experiment; study protocol; observational study

Introduction

Distal radius fractures are the most common fractures encountered in Western societies, and they typically occur in patients aged 50 years and older [1,2]. Despite being so common, there remains an ongoing discussion on the best treatment for these fractures, especially in older patients, ranging from nonoperative treatment to complex surgery [3].

Previous studies have used varying definitions of "older people" and based this only on chronological age. However, the spectrum of physical demands and capabilities is wide among patients of the same age, which will likely be reflected in the satisfaction and outcome after treatment of distal radius fractures. Additionally, even frail patients may rely on a good function of the wrist to maintain independence if they, for example, require walking aids, and therefore need to fully weight bear on the upper extremity.

This study aims to compare the outcome of operatively and nonoperatively treated distal radius fractures in the older population by evaluating functional and radiological outcomes as well as range of movement, quality of life, and change in independence or living situation. By evaluating the quality of life and patient independency or living situation, we aim to gain more insight into outcomes after distal radius fracture in older patients while considering their individual functional demands.

Therefore, we have designed this study as a prospective international multicenter cohort study in which only patients with distal radius fractures for which equipoise regarding the optimal treatment exists will be included. The primary objective will be to compare clinical outcomes between older patients with distal radius fracture treated operatively and those treated nonoperatively.

Methods

Study Design

Although randomized controlled trials are generally considered the gold standard to investigate the effects of medical treatments, both patients and surgeons can have a strong preference for a certain treatment, which may limit the feasibility of a randomized controlled trial and therefore the generalizability of its results [4,5]. Provided possible incomparability of patients who receive different treatment modalities (ie, confounding) is adequately controlled for, observational studies could provide an alternative source of information.

A natural experiment design uses existing variation in treatment allocation (eg, due to practice variation). Natural experiments are observational studies in which treatment allocation is determined by factors outside the control of the investigators but also (to a large extent) independent of patient characteristics [6,7]. We assume the decisions regarding the treatment of distal radius fractures are largely influenced by the training of the treating surgeons. Since patients with a distal radius fracture generally visit the nearest hospital, treatment allocation is dependent on which surgeon is on call, which is likely independent on patient characteristics. Hence, the process governing treatment allocation arguably resembles that of randomization. Practice variation therefore provides an opportunity to conduct a natural experiment of the effect of operative versus nonoperative treatment of distal radius fractures. In order to further minimize the influence of patient characteristics on treatment decisions, a selection could be made of those patients for whom a panel of physicians disagree regarding the preferred treatment option (ie, for whom there clearly is a clinical equipoise). For these patients, both operative and nonoperative treatment of distal radius fractures are viable, and treatment choice is predominantly determined by personal or local preference.

This study is an international multicenter prospective observational cohort study for which patients will be identified after treatment has been initiated. Outcome data will be prospectively collected. Patients will be recruited from 5 hospitals in countries with a predominant preference for operative (Switzerland) and nonoperative treatment (the Netherlands).

Patient Population

Local investigators will review the list of patients seen in the emergency departments of the participating hospitals to identify eligible patients. The inclusion criteria are all patients 65 years and older with an acute (<14 days after injury) distal radius fracture treated at one of the participating hospitals.

The exclusion criteria are no informed consent provided; patients transferred after initial operative treatment at a nonparticipating hospital; delayed presentation (>14 days after injury); insufficient follow-up (<12 months) or unavailable to follow-up due to residency in other hospital area; concomitant injury to the ipsilateral or contralateral upper extremity; cognitive impairment precluding answering questionnaires; non-German, non-English, and non-Dutch speaking; preexisting comorbidities that preclude operative treatment; pathological fractures; open fractures; and neurovascular injury requiring operative treatment.

Ethical Considerations

This study was approved by the ethics committee of Northwest and Central Switzerland (ID 2022-00142). It will be conducted in accordance with the Declaration of Helsinki and the principles of Good Clinical Practice. The study has been registered on ClinicalTrials.gov (ID NCT05631314). The protocol was written in adherence to the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) guideline. A signed informed consent form is required prior to patient inclusion. The patients will be informed about the aim, content, and requirements of the study by the study leader or delegate either during an initial presentation or at a routine outpatient clinic appointment and will receive an information and consent form. The patients will be given the opportunity to ask questions and clarify any issues prior to giving their consent. No compensation or payments will be provided to project participants. Project data will be handled with the utmost discretion. They will be coded and a file to decode these data will be saved in the research folder only accessible by the principal investigator and project leaders.

Expert Panel

Following the identification of eligible patients and obtainment of informed consent, anonymous radiographs including key images of computer tomography scans if available, and baseline characteristics including information regarding comorbidities and activity levels (details below) will be made available on a secure web-based platform. This will allow the members of the panel to reach a "clinical" decision regarding their treatment recommendation. The panel will be blinded to the actual treatment received and the origin of the case.

The comorbidities, which will be reported to the experts, are cardiomyopathy including valvular disease, history of stroke or other brain injury with persistent neurological deficit, diabetes mellitus, cardiovascular disease, active malignancy, rheumatoid arthritis, and history of alcohol or drug abuse.

Additionally, the experts will be provided with information regarding the usage of the following medications: anticoagulant agents (vitamin K antagonists and new oral anticoagulants), immunosuppressants, and current chemotherapy.

The activity levels are independent, independent with support from family or district nurse or nursing home, and use of a walking aid prior to injury (no, walking stick, frame, and not mobile).

The expert panel will consist of 3 representatives from each "school." All panel members will be certified trauma surgeons. Half of them are generally in favor of conservative treatment ("school A"), while the others are generally in favor of operative treatment ("school B"). Patients will ultimately be included in the study if clinical equipoise is achieved, meaning 2 or more of the experts disagree with the rest of the panel. This is expected to result in 2 comparable groups for which clinical equipoise exists. The actual treatment the patient receives will continue as initially planned by the treating physician (see below).

Intervention

The decision whether operative or nonoperative treatment is chosen is left to the treating trauma surgeon as per the local standard of the participating hospital. Treatment will be initiated before the patient is approached for recruitment. Nonoperative treatment will consist of immobilization in a below the elbow cast for 4-6 weeks with or without prior closed reduction.

Operative intervention will be based on the treating surgeon's experience and preference. It will consist of open reduction and internal plate fixation using volar, dorsal, spanning or a combination of plates, or reduction (open or closed) and fixation with an external fixator with or without Kirschner wires. The participating hospitals in Switzerland will use the 2.4-mm distal radius plate system (Arthrex) for internal plate fixation. Perioperative management including anesthesia, antibiotics, and thromboembolism prophylaxis will follow the national guidelines. Postoperative care and immobilization will be decided by the treating surgeon. When possible, functional aftercare without immobilization will be allowed. Physiotherapy will be provided according to the local standards.

All patients (operative and nonoperative) will be reviewed in the outpatient clinic at 6 and 12 weeks as well as 1 year after treatment or surgery. In addition, patients will be contacted by phone 2 years after treatment or surgery.

Outcomes

Primary Outcome Measure

The primary outcome is the Patient-Rated Wrist Evaluation (PRWE) score measured at 12 weeks. This is a 15-item questionnaire that measures wrist pain and disability in activities of daily living. The score ranges from 0 to 100 with the best score being 0 [8,9].

Secondary Outcome Measures

Functional Outcome

Secondary functional outcome measures will include the PRWE at 1 year, Physical Activity Score for the Elderly, the Numerical Rating Scale for pain, and the EQ-5D-5L questionnaire. The Physical Activity Score for the Elderly is a questionnaire with multiple choice and open questions. The score combines information on household, leisure, and occupational activities. Based on duration, frequency, and intensity level of activities performed the previous week, a score is calculated ranging from 0 to 793, with higher scores reflecting more physical activity [10]. The EQ-5D-5L questionnaire is a questionnaire that measures general health status, with higher scores reflecting a better quality of life. It is based on 5 dimensions (mobility,

self-care, usual activities, pain or discomfort, and anxiety or depression), which are rated on a scale with 5 levels. It also includes the EQ visual analogue scale for patients to state their self-rated health on a scale from 0 to 100, with 0 being the worst health imaginable [11]. The Numerical Rating Scale is a widely used scale to measure pain intensity, ranging from 0 (no pain) to 10 (worst pain imaginable) [4]. The living situation will be assessed at the first presentation, 6 weeks, 12 weeks, 1 year, and 2 years after injury. It will be defined as independent, independent with support from family, district nurse or similar, and nursing home. Range of motion of the wrist (dorsal extension, palmar-flexion, ulnar-, radial-abduction, pro-, and supination) as well as the finger-palm-distance will be assessed 12 weeks after injury. Additionally, the duration of surgery and the occurrence of intraoperative complications will be documented.

Complications

Complications will be assessed at every outpatient visit and after 2 years. They will include infection, nonunion, implant failure, complex regional pain syndrome, and any adverse event needing surgical intervention. For patients treated surgically, the need for implant removal will also be recorded. Infections will be defined according to the guidelines of The Centers for Disease Control and Prevention and subdivided into superficial incisional and deep infections. Deep infections will include both deep incisional and organ or space infections [5]. The diagnosis of complex regional pain syndrome is based on the Budapest clinical diagnostic criteria [12]. Nonunion is defined as a Radius union scoring system score greater than or equal to 6. It will be assessed 1 year after injury. The RUSS score evaluates union on dorso-volar and lateral radiographs by assigning a score of 0 to 2 on each cortex. Zero points are given if the fracture line is visible with no callus, 1 point if a callus is present but the fracture line is still visible, and 2 points if the fracture line is not visible and a bridging callus is present. In surgically treated cases, where the cortex is not visible due to the implant, a score of 0 is given to that cortex [13]. In case of doubt with regard to union, a computer tomography scan will be acquired. Patients with nonunion will be divided into 2 groups based on their symptoms (symptomatic vs asymptomatic).

Radiological Outcome

X-rays will be obtained as per standard hospital protocol at 6 and 12 weeks as well as 1 year after injury. The final radiological outcome will be determined 1 year after injury and will include union, radial inclination, volar tilt, carpal alignment, ulnar variance, and the presence and size of any step or gap in the articular surface.

Timeline and Recruitment

The recruitment procedure is visualized in Figure 1. The follow-up schedule for the patients and time point for the assessment of each outcome are listed in Table 1.

Data Collection

In every participating institution, a project leader will fill in all the patient information in the secure web-based database on REDCap (Research Electronic Data Capture; Vanderbilt University). The original data will be collected from the institution's electronic patient records, the picture archiving and communication system, the different questionnaires, and pseudonymized prior to entry in the database.

Health care workers from the participating institutions will get access to REDCap, which enables centralized tracking of potentially eligible patients in compliance with the good clinical practice guidelines for electronic data collection. Every 2-4 weeks, this list of patients will be screened by the project leader, and explanatory and response variables will be entered on the study website. All data will be saved in a research folder that can only be accessed by the principal investigator and the project leader or leaders.

Sample Size Calculation

This study will be a noninferiority study, for which we assume that conservative treatment in older patients with a distal radius fracture is noninferior to operative treatment. The reason for choosing a noninferiority design is as follows. Operative treatment for distal radius fractures inherently exposes patients to additional risks of operation-related complications and costs. This is not the case for conservative treatment. If the study would demonstrate that both treatments are equal with regard to the primary outcome, it would automatically imply that patients should be treated with the lesser invasive treatment of the 2 (in this case, conservative treatment).

The sample size is based on the minimal important clinical difference of the PRWE score, which is 11.5 points (with an average SD 14). Using the minimal important clinical difference (11.5 points) as the noninferiority margin, a statistical significance threshold (α) of 5%, and a power of 90%, 32 patients per group are needed [14]. Taking into account a 30% loss to follow-up (due to the considerable age of the included study population), a total of 92 patients will have to be included, with at least 46 patients in each treatment group.

Statistical Analysis

The statistical software package SPSS (IBM Corp) will be used for analysis. All analyses will be performed according to the intention-to-treat principle. Multiple imputation will be used for missing values. Depending on their distribution, baseline characteristics will be described as means and SDs or median and IQR for continuous variables. Categorical variables will be reported as counts and percentages. Treatment groups will be compared using an independent Student *t* test (2-tailed) or chi-square test, as appropriate.

The primary outcome will be analyzed using a regression analysis with the 12 weeks PRWE score as dependent and treatment as independent variable. Potential confounders (notably age and fracture type) will be included as covariates in the model. Regression coefficients will be calculated with corresponding 95% CI. Regression analysis will also be used for analyzing the secondary outcomes with correction for the previously mentioned confounders.

Results

Patient enrollment started both in the Netherlands and Switzerland in July 2023. To date, 23 patients have given their consent in Switzerland and 59 in the Netherlands. The results of the first expert panel decisions are currently pending. Depending on the rate of equipoise, enrollment is expected to be completed after approximately 1 year. The final follow-up will be 2 years after the inclusion of the last patient.

Discussion

Despite many trials on this topic, the optimal treatment for distal radius fractures in older patients remains debated, and regional preferences continue to influence the treatment chosen. This

provides the perfect situation to perform a natural experiment [6]. The Let's Agree to Disagree on Operative Versus Nonoperative radius study is a prospective international multicenter cohort study that will use a fairly new methodological study design [6]. One of the main benefits of this study design is that patients will be treated as per the local standards. We expect this to lead to high participation rates and prevent the negative effects of a learning curve. By limiting inclusion to those patients, for whom the expert panel disagrees on the treatment method, only those cases in which equipoise is attained are evaluated. We anticipate the 2 patient groups to be comparable as natural randomization based on geographical location will occur. Therefore, confounding is expected to be minimal. Additionally, multivariable analysis will be performed.

Many studies on the treatment of distal radius fractures in older patients have been published and yet no sound conclusion can be drawn. While some authors demonstrated a benefit of volar plating, others were unable to show a difference in functional outcomes between operative and nonoperative treatment [15-19]. Previous studies examined functional outcome based on patient-reported outcome measurements such as the PRWE score or Disabilities of the Arm, Shoulder, and Hand score. None of the studies used a score derived specifically for the older population or evaluated changes in independence or living situation despite the fact that these are very relevant issues for older patients. Additionally, information on the quality of life after treatment is lacking. This study aims to compare the outcome of surgically and nonoperatively treated distal radius fractures in older patients by not only evaluating functional and radiological outcomes but also quality of life and change in independency or living situation. Furthermore, a functional score that was specifically designed to assess the physical activity level of older patients will be used.

One limitation of this study to consider is the relatively new study design. The ratio of opposing opinions among the expert panel to define equipoise was set at 2:4. One could argue that a ratio of 1:5 or 3:3 might be a better choice. A previous study performed with ethical committee members examined which proportion of agreement on the merit of a new treatment was perceived by the members as ethically justifiable to perform a trial investigating the new treatment. This study showed a distribution of 1:4 to suffice for the members to deem the trial ethically justifiable [20]. Based on the findings of that study in combination with an equal number of experts from both regions, the ratio of 2:4 was chosen for this study.

In conclusion, this observational study, designed as a natural study, will provide valuable information on treatment outcomes for those older patients with distal radius fractures for which to date equipoise exists regarding the optimal treatment. By evaluating outcomes pertinent to the older population, such as quality of life and changes in living situation or independence, this study will help tailor treatment to the specific needs of older patients.

Abstract

Background: Health organizations and countries around the world have found it difficult to control the spread of COVID-19. To minimize the future impact on the UK National Health Service and improve patient care, there is a pressing need to identify individuals who are at a higher risk of being hospitalized because of severe COVID-19. Early targeted work was successful in identifying angiotensin-converting enzyme-2 receptors and type II transmembrane serine protease dependency as drivers of severe infection. Although a targeted approach highlights key pathways, a multiomics approach will provide a clearer and more comprehensive picture of severe COVID-19 etiology and progression.

Objective: The COVID-19 Response Study aims to carry out an integrated multiomics analysis to identify biomarkers in blood and saliva that could contribute to host susceptibility to SARS-CoV-2 and the development of severe COVID-19.

Methods: The COVID-19 Response Study aims to recruit 1000 people who recovered from SARS-CoV-2 infection in both community and hospital settings on the island of Ireland. This protocol describes the retrospective observational study component carried out in Northern Ireland (NI; Cohort A); the Republic of Ireland cohort will be described separately. For all NI participants (n=519), SARS-CoV-2 infection has been confirmed by reverse transcription-quantitative polymerase chain reaction. A prospective Cohort B of 40 patients is also being followed up at 1, 3, 6, and 12 months postinfection to assess longitudinal symptom frequency and immune response. Data will be sourced from whole blood, saliva samples, and clinical data from the electronic care records, the general health questionnaire, and a 12-item general health questionnaire mental health survey. Saliva and blood samples were processed to extract DNA and RNA before whole-genome sequencing, RNA sequencing, DNA methylation analysis, microbiome analysis, 16S ribosomal RNA gene sequencing, and proteomic analysis were performed on the plasma. Multiomics data will be combined with clinical data to produce sensitive and specific prognostic models for severity risk.

Results: An initial demographic and clinical profile of the NI Cohort A has been completed. A total of 249 hospitalized patients and 270 nonhospitalized patients were recruited, of whom 184 (64.3%) were female, and the mean age was 45.4 (SD 13) years. High levels of comorbidity were evident in the hospitalized cohort, with cardiovascular disease and metabolic and respiratory disorders being the most significant (P<.001), grouped according to the International Classification of Diseases 10 codes.

Conclusions: This study will provide a comprehensive opportunity to study the mechanisms of COVID-19 severity in recontactable participants.

KEYWORDS

COVID-19; clinical research; multiomics; comorbidity; severity; electronic health record

Introduction

Background

COVID-19 has a wide spectrum of clinical severity, with approximately 60% of cases thought to be asymptomatic or mildly symptomatic and approximately 5% being critically ill [1]. A severe infection is characterized by respiratory and multiorgan failure [2]. There are several known demographic risk factors, such as age, male sex, diabetes mellitus, and obesity [3], and recently, high-risk genes and genetic variation have gained extensive attention [4-8]. Identifying further biomarkers that reflect the pathophysiology of the disease and aid clinical staff in recognizing COVID-19 severity is critical [9]. This would also help in the development of clinical management systems that can improve patient outcomes [10]. Early work focused on easily accessible laboratory indices, such as elevated C-reactive protein and D-dimer, among others, which have been helpful in the early management of high-risk patients [9,11]. These biomarkers are commonly recorded in electronic care records (ECRs), a technological development that allows the exchange of health information electronically, facilitating effective diagnosis, reducing medical errors, and providing safer care and research [12]. However, the limitations of routine laboratory biomarkers are well documented [13].

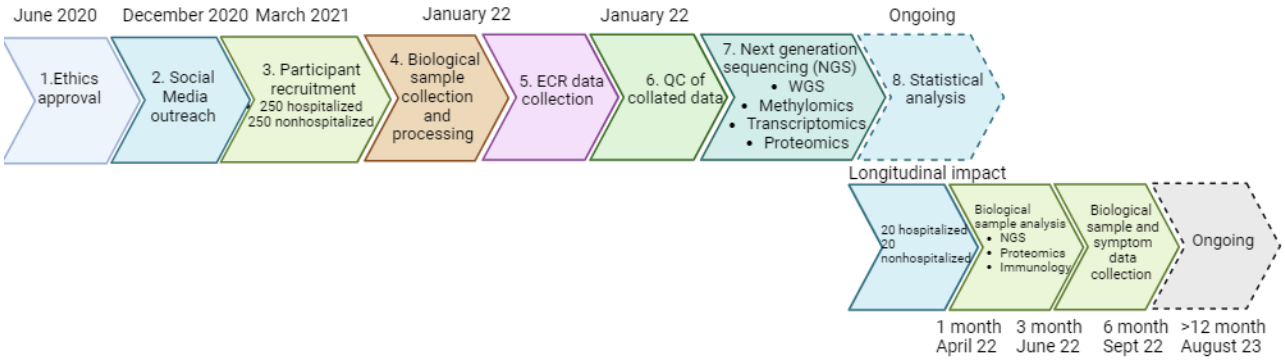
Early work also implicated angiotensin-converting enzyme 2 (ACE2) receptors and type II transmembrane serine protease in viral entry [14,15]. A recent genome-wide association study of 2000 critically ill patients [5] identified dipeptidyl peptidase 9, tyrosine kinase 2, and the antiviral restriction enzyme activators OAS1, OAS2, OAS3. To date, singleomic approaches have been used to identify genomic markers of COVID-19 severity [5,16-18]. Here, we seek to use multiomics analysis using 2 tissue types (blood and saliva) in combination with comprehensive ECRs and self-reported data to build one of the most extensive pictures yet.

Study Aims and Overview

The COVID-19 Response Study (COVRES; NCT05548829) aims to carry out an integrated multiomics analysis of factors contributing to host susceptibility to SARS-CoV-2 among a patient cohort of 1000 people from the geographically isolated island of Ireland. Because of differences in site, governance, and timelines, the protocol in the subsequent section describes the study to be carried out in Northern Ireland (NI-COVRES) by Ulster University and the Western Health and Social Care Trust (WHSCT) only. The Republic of Ireland component (Trinity College Dublin and St James Hospital Dublin) will be described separately.

Figure 1 shows an overview of the main stages and timeline with data for each participant (n=519) on the following: (1) disease status, (2) genome analysis, (3) transcriptome analysis, (4) proteome analysis, (5) methylome analysis, (6) microbiome analysis, (7) immune response, (8) patient history, (9) mental health, and (10) ECR and prospectively on 40 participants at 1, 3, 6, and 12 months postpositive polymerase chain reaction (PCR) analysis to assess persistent inflammatory and immune responses.

Figure 1. Stages of the COVID-19 Response Study implementation. ECR: electronic care record; NGS: next generation sequencing; QC: quality control; WGS: whole genome sequencing.

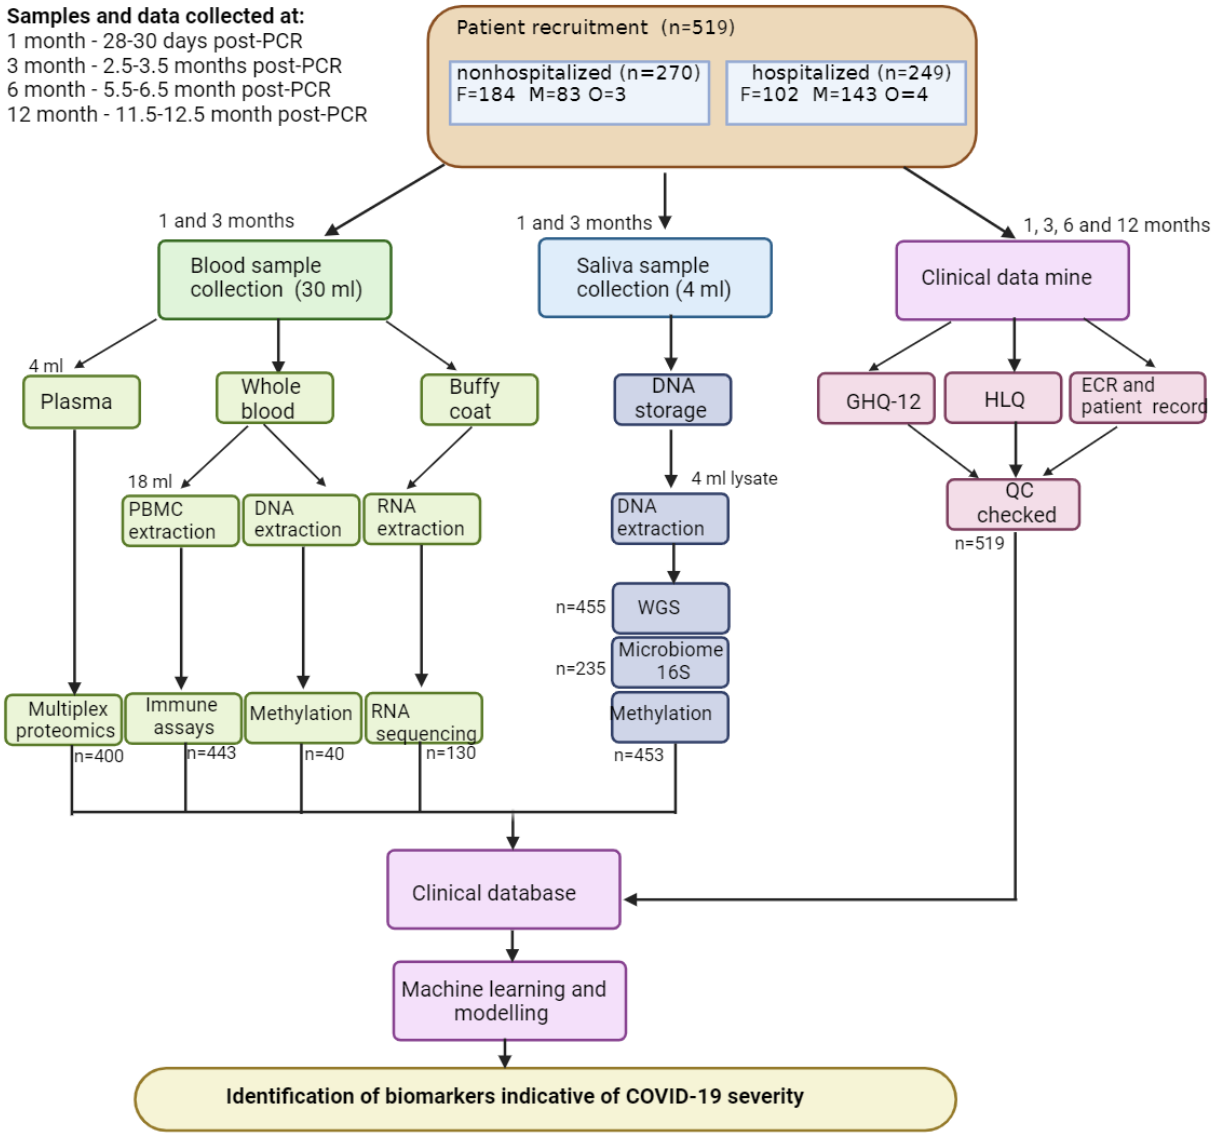


Methods

Status and Timeline of the Study

The main retrospective Cohort A recruitment commenced in December 2020 and was completed in March 2021 (trial registration; NCT05548829), except for the prospective Cohort B (ongoing). Integration of ECR record data was completed in January 2022 at the time of writing, and omics samples are being processed (Figure 2).

Figure 2. Overview of the COVID-19 Response Study sample processing work flow. ECR: electronic care record; FBC: full blood count; GHQ-12: 12-item General Health Questionnaire; HLQ: Health Life Style Questionnaire; MSD: Meso Scale Discovery; PBMC: peripheral blood mononuclear cell; PCR: polymerase chain reaction; TCR: T-cell receptor; QC: quality control; WGS: whole genome sequencing.



Ethical Considerations

Standard operating procedures and participant response questionnaires included standard operating procedures for saliva sample kit preparation, blood collection and processing, downstream sample processing, website management, data protection and participant contact. The COVRES was subsequently approved by the Health and Care Research Wales Ethics Service on July 14, 2020 (Research Ethics Committee ref 20/WA/0179). All the participants provided informed consent to participate.

Social Media Outreach

Social media content (on Twitter [subsequently rebranded X; Twitter, Inc] and Facebook [Meta Platforms, Inc]) and web page visuals were designed, with input from recovered patients, by the project principal investigators, including a range of infographics and short explanatory texts. Information was circulated to local and national news outlets (television, radio, and newspapers) across NI for recruitment purposes. Interested patients contacted the research team and were sent a patient information sheet. Appointments were then organized at least 24 hours later to obtain informed consent and samples.

Participant Recruitment With Inclusion and Exclusion Criteria

Inclusion criteria: patients had to be aged >18 years but could have any BMI or ethnic origin. Exclusion criteria: patients were excluded if they were aged <18 years and had any intellectual disabilities. Hospitalization status was determined if a patient attended or was admitted to the hospital within 14 days of a positive PCR result. Patients were also classified based on the World Health Organization (WHO) scale [19], which reflects severity over the duration of the patient's infection, regardless

of hospitalization status. For example, a patient may have an overall WHO score of 5 and be classified as nonhospitalized as they attended the hospital >14 days from their positive PCR result. After receiving a participant information sheet, patients interested in participating provided written informed consent and were enrolled in the study. A self-report questionnaire established demographic information, lifestyle choices, family history of clinical disorders, and COVID-19 severity and symptoms. This was followed by a 12-item general health questionnaire to help ascertain the patient's mental health after the COVID-19 infection (Figure 2). This data was securely digitalized onto a bespoke database, CovresNIdb, generated on the REDCap (Research Electronic Data Capture; Vanderbilt University) platform [19], to comply with the terms of the ethical considerations, the Human Tissue Act 2004, and general data protection regulations. This process is being repeated for Cohort B (prospective), consisting of 40 participants with stricter timelines followed (1, 3, 6, and 12 mo).

Biological Sample Processing

The WHSCT recruitment team coordinated sample collection appointments at hospital wards, Clinical Translational Research and Innovation Centre clinic rooms, or home visits. Participants and related study code numbers were predetermined depending on hospitalization and logged into encrypted clinical data sheets on a secure server to ensure full data traceability. All whole blood and saliva processing carried out includes recruitment numbers, sample collection types, sample processing, and downstream analysis; n numbers refer to patient numbers for specific omics analyses.

Isolation was carried out in a Category III containment hood with full personal protective equipment. Samples were not deactivated upon receipt or before processing. The participants provided 3×10 mL of whole blood and 2× saliva samples of approximately 2 mL each (Figure 2). Blood was extracted using 21G Vacuette safety needles (Greiner Bio-One Ltd, Gloucestershire) into 3×10 mL ethylenediaminetetraacetic acid–coated Vacuette tubes and centrifuged at 4000 rpm (4 °C) for 15 minutes. The buffy coat was extracted, washed, and stored for RNA sequencing (Figure 2). All samples were frozen at −80 °C; the time to freeze was <2 hours, and none showed signs of hemolysis. Saliva was collected using 1×DNA Genotek (DNA Genotek, Ottawa), Oragene DNA (OG-500), and 1×RNA (CP-190) collection tubes per participant. Samples were considered deactivated once lysed. Peripheral blood mononuclear cells were isolated using the Ficoll gradient separation methods as per [20].

Immune Assays

Whole blood was analyzed at 1 and 3 months post–positive PCR tests. Using the FACSAria III high-speed cell sorter (Becton Dickinson, Oxford, United Kingdom, software version 9) with an 85-µm nozzle fitted, whole blood and peripheral blood mononuclear cell samples were stained for T, B, and natural killer cell populations using CD45 PerCP-Cy5.5, CD3 FITC, CD8 APC-Cy7, CD4 PE-Cy7, CD19 APC, and CD16+CD56 PE (BD Biosciences) before erythrocyte lysis by PharmLyse (BD Biosciences) according to the manufacturer's instructions. T-cell subpopulations were measured using 2 defined panels: panel 1: CD3 FITC, CD4 PE-Cy7, CD8 BV605, CD30 APC, CD45RA V450, CD45RO BV786, and CD183 BB700; panel 2: CD3 FITC, CD4 PE-Cy7, CD8 BV605, CD69 APC, CD45 V450, CD127 BV786, CD152 BB700, CD25 R718, and FoxP3 PE. Cell surface staining was performed before fixing, permeabilizing, and FoxP3 labeling using the Transcription Factor Buffer Set (BD Pharmingen).

DNA Isolation

Saliva samples (whole-genome sequencing [WGS], methylome, and microbiome) were incubated for 2 hours at 56 °C, followed by DNA isolation using PrepIT L2P (DNA Genotek). DNA from whole blood (methylome) was isolated using the DNA Blood 200,360 prefilling H96 Kit (CMG-717, PerkinElmer), and 200 µL of whole blood on the Chemagic 360 system (PerkinElmer) was used. Microbial DNA was extracted from saliva aliquots using a modified protocol from Teng et al [21] using the DNeasy Blood and Tissue Kit (Qiagen). All extracted DNA was evaluated using the Qubit 3.0 fluorometer (Thermo Scientific) and the Nano Drop 1000 spectrophotometer (Thermo Scientific) and sequenced using the Invitrogen Quant-iT PicoGreen dsDNA Assay Kit (P7589) on the Hamilton Microlab Star before storage at −80 °C.

RNA Isolation

RNA was isolated from saliva using the Oragene RNA purification protocol and Qiagen RNeasy Micro Kit (Qiagen), and RNA was extracted from whole blood using the Chemagic 360 system (PerkinElmer) with the Chemagic RNA tissue 360 H96 Kit (CMG-1212). Purity and quantity were assessed, as described in the preceding section for DNA, but with the Invitrogen Quant-iT RiboGreen Assay Kit (R11490). Integrity (RIN) was determined using the Agilent 4200 TapeStation and the RNA ScreenTape (5067-5366), before storage at −80 °C.

Clinical Data

Self-Reported Data on Physical and Mental Well-Being

All participants completed 2 surveys as part of the trial. The 12-item general health questionnaire is a self-administered screening tool designed to detect current mental state disturbances in primary care settings; a score of ≥2 indicates a disorder. The health and lifestyle questionnaire is a survey tool designed by Ulster University to capture key health-related data not present in the ECR. The fields included COVID-19 risk factors, medications, comorbidities, hospitalization information, symptoms at admission, laboratory tests, family history, drinking status, and occupation. The same protocol is being followed for all prospective appointments (ongoing).

Clinical Database Development

The participants' consent forms, as well as data from the self-reported questionnaires, but with all personally identifiable information removed by the project's data controller as per general data protection regulations guidelines, were also recorded in the CovresNIdb database. The data were subjected to quality control (QC) by 2 independent researchers against the original sources. The same protocol is being followed for all prospective appointments (ongoing).

Electronic Care Records

In addition to the self-reported data, consent was also provided by each patient to enrich the database by accessing their NI Electronic Care Record information held by the National Health Service. PCR positive dates, severity (hospitalized because of COVID-19 infection or recovered from COVID-19 infection at home), laboratory results (full blood count, blood pressure, lipids, C-reactive protein, glomerular filtration rate, and troponin), treatment administered, drugs prescribed within the last 6 months, and comorbidity and multimorbidity were recorded for each patient.

Omics Analyses

Genome Analysis

Whole-genome library preparation was performed using the Illumina TruSeq PCR Free Library Prep protocol (20015963) with an input amount of 1 µg on a Hamilton next-generation sequencing Star robotic workstation, and quality was assessed using the Roche KAPA Library Quantification Kit (7960298001) before pooling and sequencing (150bp PE) on an Illumina NovaSeq 6000 instrument using NovaSeq 6000 S4 Reagent Kit v1.5 (20028312), with a mean coverage of 30× as described previously [22]. Sequences are being uploaded to the European Genome-phenome Archive (EGA).

Methylome Analysis

Methylation analysis was performed on DNA samples from saliva (n=450) and whole blood (n=40) using the Illumina Infinium Methylation EPIC, largely as described previously [22]. Data were adjusted for known epigenetic covariates, and surrogate variable analysis was performed via the *sva* inference module [23]. Our in-house-developed tool, CandiMeth [24], will be used to streamline the methylation analysis of gene lists of interest.

Transcriptome Analysis

RNA sequencing library preparation was performed using the Illumina TruSeq Stranded Total RNA Library Prep Globin Kit (20020612) with an input amount of 100 to 1000 ng. Library preparation was automated and processed using a Hamilton next-generation sequencing Star, and quality was assessed using the Roche KAPA Library Quantification Kit (7960298001) and GX Caliper HS Assay (CLS 760,672, 760,517), run on Roche Lightcycler 480 II and PerkinElmer LabChip GX Touch analyzers, respectively. Libraries were pooled and sequenced (75bp PE) on an Illumina NovaSeq 6000 instrument using NovaSeq 6000 S2 Reagent Kit v1.5 (20028314), targeting 50M paired reads. Raw data binary base call format was demultiplexed and converted to the FASTQ format using BCL2FastQ (Illumina). Adapters were trimmed using Skewer [25], and QC was assessed using FASTQC. Spliced Transcripts Alignment to a Reference [26] was used to align reads to the reference genome (GRCh38/hg38) as well as to the transcriptome (version 25; GENCODE). The quality of the RNA alignment was assessed using Picard QC. Gene and isoform quantification will be performed using RNA-Seq by Expectation-Maximization [27], with prospective patient (1 and 3 mo) T-cell receptor sequencing completed following flow cytometry.

Microbiome Analysis

16S ribosomal RNA gene amplicons for sequencing by the Illumina MiSeq system (Illumina) were prepared using the V3 and V4 regions as described by Klindworth et al (2013), with sequencing performed in-house.

Proteome Analysis

Protein analysis of 400 plasma samples (baseline; 186 nonhospitalized and 214 hospitalized), 40 prospective (20 nonhospitalized and 20 hospitalized; 1 and 3 months postinfection), was outsourced to OLINK proteomics (OLINK, Uppsala, Sweden) using the Explore 384 Inflammation panel (Protein Proximity Extension Assay). Ethylenediaminetetraacetic acid plasma samples were thawed at room temperature (20 °C), and 45 µL of each plasma sample was (at random) pipetted into a LightCycle 480Multiwell Plate 96-well white PCR plates (product no. 04729692001; Roche Molecular Systems Inc) with 8 × wells left empty on each plate for internal controls to be added at OLINK. The samples were inactivated as per OLINK's protocol and shipped on dry ice (CO2, −78 °C). Only samples above 0.2 Normalized Protein eXpression and samples that deviated less than 0.3 Normalized Protein eXpression passed QC.

The Meso Scale Discovery plasma multispot assay system comprising V-PLEX COVID-19 serology panel 11, *total IgG*, and *ACE2 neutralization* assays was used to determine viral variant prevalence. Samples were prepared at 1:10 (ACE2) and 1:5000 (neutralization) for specific assays and then treated as described in [28].

The Roche COBAS Elecsys SARS-CoV-2 spike (S) protein receptor binding domain assay was used to determine SARS-CoV-2 antibody presence as per manufacturer's instructions.

Statistics

Univariate and Multivariate Analysis

Only patients from Cohort A (n=507) who had their BMI recorded in the database were selected for the odds ratio analysis. We considered the following risk factors: sex, age, BMI, and disease subgroups. First, univariate analyses (Fisher exact test) were performed to identify risk factors associated with COVID-19 severity.

P values for univariate analyses were generated using the Fisher exact test to compare the frequencies of each potential risk factor between nonhospitalized and hospitalized participants. Variables with a *P* value <.001, that is, sex, age <50 years and >50 years, and cardiovascular, respiratory, endocrine, and musculoskeletal comorbidities, were considered clinically relevant and entered into the multivariable logistic regression model. This and further analysis are being undertaken on Base-R software (R Project for Statistical Computing; version 4.2.2) using the Visdat library.

Demographics Table

The demographic table of the COVRES data (n=519) was generated using IBM SPSS Statistics for Windows (version 27; IBM Corp) [29]. Statistical analysis for the contingency table

was undertaken using a Fisher exact 2-sided test to obtain the required *P* values, and CI rates were set at 95%.

Bioinformatic Analyses

Bioinformatic analyses will focus on using computational approaches to identify genomic, transcriptomic, proteomic, and clinical correlates of severity. Planned analyses primarily include the identification of clinical features, gene variants (host) or Expression quantitative trait loci, transcriptomic signatures, and cytokine profiles associated with disease severity, as well as the differential methylation among the host genomes of the severity groups.

Variant calling will use mathematical models from the Best Practices Genome Analysis Toolkit. Data are being stored according to genomic position in the Genuity Science Genomically Ordered Relational Database to facilitate rapid access by the Clinical Sequence Analyzer user interface and Sequence Miner visualization software. Initial data processing for methylome analysis will be carried out in *GenomeStudio* (version 3.2; Illumina) before the import of idat files into the RnBeads package [30] using RStudio (version 2022.02.0+443) on the R platform (version 4.1.2). QC will be performed using the *greedycut* algorithm, which involves the removal of probes with missing values and poor quality. For RNA-seq, gene and isoform quantification will be performed using RNA-Seq by Expectation-Maximization [27] before further analysis is carried out. 16S ribosomal RNA analysis has been previously described (refer to the preceding section), and OLINK data will be processed in R as per standard pipelines. WGS and transcriptomics data are to be deposited in the EGA pending and shared in collaboration with the International COVID-19 Host Genetics Initiative.

Results

Retrospective Cohort A Demographics

The main demographic characteristics are summarized in Table 1.

Table 1. COVID-19 Response Study Cohort A demographic information.

Cohort A demographics	Nonhospitalized (n=270)	Hospitalized (n=249)	Total (n=519)	*P* value[a]
Sex, n (%)				
Female	184 (64.3)	102 (35.7)	286 (55.1)	<.001
Male	83 (36.7)	143 (63.3)	226 (43.5)	<.001
Other	3 (42.9)	4 (57.1)	7 (1.3)	.72
Age (y) at diagnosis				
Age, mean (SD)	45.4 (13)	56.5 (12.7)	50.7 (14)	<.001[a]
<50, n (%)	169 (62.6)	67 (26.9)	236 (45.5)	<.001
>50, n (%)	101 (37.4)	182 (73.1)	283 (54.5)	<.001
Disease subgroup, n (%)				
Autoimmune[b]	12 (4.4)	26 (10.4)	38 (7.3)	.01
Metabolic[c]	33 (12.2)	94 (37.8)	127 (24.5)	<.001
Respiratory[d]	39 (14.4)	83 (33.3)	122 (23.5)	<.001
Cardiovascular[e]	32 (11.9)	100 (40.2)	132 (25.4)	<.001
Cancer[f]	7 (2.6)	21 (8.4)	28 (5.4)	.003
Gastrointestinal[g]	13 (4.8)	21 (8.4)	34 (6.6)	.11
Musculoskeletal[h]	23 (8.5)	58 (23.3)	81 (15.6)	<.001

[a]*P* value calculated using 2-sided Fisher exact test between nonhospitalized versus hospitalized patients. *P*<.05 was set as statistically significant (n=519); continuous variables used a 2-sided *t* test.

[b]Autoimmune or rheumatic diseases including rheumatoid arthritis, systemic lupus erythematosus, and multiple sclerosis.

[c]Metabolic and endocrine diseases including thyroid conditions, hypercholesterolemia, or other hyperlipidemia, gout, diabetes, and kidney disorders.

[d]Respiratory disorder and chronic lung diseases including chronic obstructive pulmonary disease, asthma (moderate to severe), interstitial lung disease, cystic fibrosis, sleep apnea, and pulmonary hypertension.

[e]Cardiovascular system disorders including angina, hypertension, stroke, peripheral vascular disease, balloon angioplasty or percutaneous coronary intervention, atrial fibrillation, venous thromboembolism, anemia, and chronic cardiac diseases other than hypertension.

[f]Cancer including leukemia, lymphoma, and malignant solid tumors, and to include current, past, and remission.

[g]Gastrointestinal disorders including gallbladder, liver disease, pancreatic disease, and Inflammatory bowel syndrome.

[h]Musculoskeletal diseases including osteoarthritis and ankylosing spondylitis, excluding subgroup 1 conditions.

As expected, there was a significant difference in the mean age between hospitalized and nonhospitalized patients, as well as between sexes (both $P<.001$). Age bias was also evident, with 62.6% (169/270) of patients aged <50 years in the nonhospitalized subgroup ($P<.001$) and 73.1% (182/249) of patients aged >50 years in the hospitalized subgroup ($P<.001$). As expected, comorbidity incidence was higher in the hospitalized subgroup than in the nonhospitalized subgroup, with autoimmune (12/270, 4.4% nonhospitalized and 26/249, 10.4% hospitalized; $P<.001$), metabolic (33/270, 12.2% nonhospitalized and 94/249, 37.8% hospitalized; $P<.001$), respiratory (39/270, 14.4% nonhospitalized and 83/249, 33.3% hospitalized; $P<.001$), cardiovascular (32/270, 11.9% nonhospitalized and 100/249, 40.2% hospitalized; $P<.001$), and musculoskeletal (23/270, 8.5% nonhospitalized and 58/249, 23.3% hospitalized; $P<.001$) disorders of note. There were no differences between the cohorts for gastrointestinal disorders (Table 1).

Prospective Cohort B Demographics

Data collection is ongoing for 40 participants who are being followed up over 12 months: 20 (8/20, 40% female) hospitalized and 20 nonhospitalized (12/20, 60% female); sex distribution is not significantly different between subgroups ($P=.21$) but average age is (hospitalized: mean 52, SD 17.2 years; nonhospitalized: mean 45.2, SD 13.5 years; $P<.001$; Table 2).

In contrast to the initial recruitment, within this follow-up Cohort B, there was no age bias toward participants older than 50 years ($P=.20$). There was also no significant difference in vaccination status between hospitalization subgroups ($P=.55$), and only cardiovascular disease as a comorbidity was more prevalent in hospitalized patients ($P=.02$), although the numbers are small.

Table 2. COVID-19 Response Study Cohort B multivariate analysis of hospitalized versus nonhospitalized patients analyzing risk factors for COVID-19 severity.

Prospective Cohort B demographics	Nonhospitalized (n=20)	Hospitalized (n=20)	Total (n=40)	*P* value[a]
Female, n (%)	12 (60)	8 (40)	22 (50)	.21
Age (y) at diagnosis				
Age, mean (SD)	45.2 (13.5)	52 (17.2)	48.6 (15.6)	<.001[b]
>50, n (%)	7 (35)	11 (55)	18 (45)	.20
Vaccine status, n (%)	19 (95)	18 (90)	37 (93)	.55
Comorbidity, n (%)				
Autoimmune[c]	3 (15)	6 (30)	9 (23)	.26
Metabolic[d]	4 (20)	9 (45)	13 (33)	.91
Respiratory[e]	2 (10)	7 (35)	9 (26)	.58
Cardiovascular[f]	2 (10)	11 (55)	13 (33)	.02
Cancer[g]	0 (0)	4 (20)	4 (10)	.35
Gastrointestinal[h]	2 (10)	4 (20)	6 (15)	.38
Musculoskeletal[i]	3 (15)	7 (35)	10 (25)	.14

[a]*P* value calculated using 2-sided Fisher exact test between nonhospitalized versus hospitalized patients. $P<.05$ set as statistically significant (n=40); continuous variables used a 2-sided *t* test.

[b]Inclusion criteria for analysis: participants (n=40) were required to have a BMI score recorded.

[c]Autoimmune or rheumatic diseases including rheumatoid arthritis, systemic lupus erythematosus, and multiple sclerosis.

[d]Metabolic and endocrine diseases including thyroid conditions, hypercholesterolemia, or other hyperlipidemia, gout, diabetes, and kidney disorders.

[e]Respiratory disorder and chronic lung diseases including chronic obstructive pulmonary disease, asthma (moderate to severe), interstitial lung disease, cystic fibrosis, sleep apnea, and pulmonary hypertension.

[f]Cardiovascular system disorders including angina, hypertension, stroke, peripheral vascular disease, balloon angioplasty or percutaneous coronary intervention, atrial fibrillation, venous thromboembolism, anemia, and chronic cardiac diseases other than hypertension.

[g]Cancer including leukemia, lymphoma, and malignant solid tumors, and to include current, past, and remission.

[h]Gastrointestinal disorders including gallbladder, liver disease, pancreatic disease, and Inflammatory bowel syndrome.

[i]Musculoskeletal diseases including osteoarthritis and ankylosing spondylitis, excluding subgroup 1 conditions.

Discussion

Principal Findings

The COVRES provides a novel opportunity to identify multiomics biomarkers from blood and saliva indicative of COVID-19 severity in NI and may provide unique insights into disease mechanisms and identify potential therapeutic targets. The maximum recruitment number (n=519) was reached, and various analyses are ongoing, including WGS and RNA sequencing, proteomic, microbiome, and methylation experiments. We have also collected detailed medical data using the NI Electronic Care Record that will be used to enrich the biomarker data [31]. All Cohort A participants were recruited over a 4-month period (December 1, 2020-March 31, 2021) during the pandemic peak, allowing homogeneous data collection from the same viral variant (B.1.1.7; Figure 1). Compared with other studies, the COVRES has a higher participant number and uses a significantly wider biomarker identification approach. This was achieved while significant pandemic restrictions were in place and was only possible because of our local health trust (WHSCT, National Health Service) collaboration, which facilitated patient access and enabled the recording of laboratory parameters that have not been possible in other studies [32]. A recent multiomics COVID-19 study used proteomics and metabolomics to screen 13 samples at 2 time points and found 10 significant proteins, 32 significant peptides, and 5 metabolites that were dysregulated in severe patients [33]. Recruitment for this study also occurred in early 2021, but the small sample size (n=13) brings into question the generalizability of the findings. Another multiomics study based in the United States sampled 128 individuals between April 6, 2020, and May 1, 2020, and conducted follow-up until June 2020. The authors quantified transcripts, proteins, metabolites, and lipids and made associations with clinical outcomes [34]. Links were made between platelet function, blood coagulation, endotheliopathy, and COVID-19 severity. Our study builds on these smaller studies and may offer increased statistical power and the potential to validate or compare the markers identified.

The COVRES was designed to recruit hospitalized (n=250) patients with COVID-19, classified as having a severe infection, and nonhospitalized (n=250) patients with COVID-19, classified as having a mild infection, within 3 months of sampling. It is worth noting that the recruitment of nonhospitalized patients with COVID-19 makes this cohort particularly valuable, as most trials have only involved patients who have been admitted to the hospital or those who have not [35,36], and few have investigated earlier stages of the disease process, such as preexposure or postexposure and outpatient treatment.

To maximize the impact and benefit to the scientific and health care communities, this study was designed to be cross-border, covering both NI and the Republic of Ireland. The global drive to identify clinical biomarkers of COVID-19 severity has led to many clinical studies and trials that have varied methodologies regarding different control groups, follow-up periods, omics of interest, and laboratory methodologies [37-39]. Studies have also been carried out in different geographic regions without any standardized operating procedures and have been powered according to different end points [40]. This variation makes reproducibility questionable, and it is difficult to apply the findings across geographic regions and variant periods. To align with as many studies as possible, COVRES participants have been classified according to the WHO [41], and to facilitate cross-border collaboration, we coordinated with Trinity College Dublin. We also plan to share our WGS data with the EGA for the advancement of science and improved public health outcomes.

The recruitment of nonhospitalized and hospitalized patients with COVID-19 in NI is the main strength of the COVRES and adds novelty to existing research regarding COVID-19 severity, with the majority recruiting patients based on a positive PCR test result regardless of hospitalization. Sex and age matching was considered, but an exact match was not achieved because of the complexities and limitations of COVID-19 presented regarding patient access [5]. The mean age of the hospitalized COVRES subgroup was 56.5 years (Table 1), which was slightly younger compared with a large UK-wide observational study [42] (20,908 hospitalized), which had a mean age of 62 years. There was no difference between sex (male 49%, female 51%), compared with our sample comprising 43.5% (226/519) men. Another smaller (n=429) UK study found the average age of hospitalized patients with COVID-19 to be 70 years and a male bias of 57%, which is close to our study. Corresponding with our study, they also found the average BMI to be 28 kg/m^2 (overweight-obese) and highly comorbid (Table 2), with the most common comorbidities being type-2 diabetes, hypertension, and respiratory disorders [42,43]. A previous study [43] in England is a good comparison for COVRES NI, as the recruitment protocols and cohort demographics are similar. The similarities in the data are promising and may indicate that our findings could be useful to the wider United Kingdom.

Limitations

COVRES participants were all sampled at a single time point, limiting our ability to assess genomic, proteomic, and immune biomarkers as the disease progresses. Future work will focus on obtaining follow-up samples to enable longitudinal analysis and assess the prognostic capability of markers of interest. Manual data input at some points increases the risk of human error [44], and although QC checks were carried out between 2 WHSCT staff members, there is an inherent risk of incorrect data.

It also needs to be considered that the COVRES cohort represents a COVID-19 population recruited in NI, and the demographics show a low representation of ethnic minority groups; therefore, data may not be able to be generalizable beyond White Irish and UK populations.

Conclusions

The COVRES offers a novel opportunity to study the multiomics mechanisms of COVID-19 severity in recontactable participants. This research has the potential to impact COVID-19 clinical decision-making and therapeutic development. Our WHSCT and industry collaborators enabled rapid and effective

recruitment, allowing us to reach our goal of 500 participants and begin the analysis pipelines immediately. We hope that this paper will not only demonstrate the effectiveness of the study methodology but also raise awareness of the availability of this cohort among researchers in the field and promote future collaboration.

Acknowledgments

This work was supported by a research grant to AJB (principal investigator) and coauthors from the Department for the Economy Northern Ireland under its contribution to Science Foundation Ireland's COVID-19 Rapid Response Call (phase 2), Opportunity-Led Research Awards to TSR and DSG from HSC Research and Development Division, Public Health Agency (COM/5618/20 and COM/5631/20, respectively), and National Core Study: Immunity (NCSi4P program) funding from United Kingdom Research and Innovation to DSG and PS.

The authors would like to extend their sincere gratitude to the participants of this study for their invaluable contribution and to the Western Health Social Care Trust (WHSCT), Northern Ireland, for facilitating access to patients and clinics, Dr Maurice O'Kane for enabling Western Health Social Care Trust laboratory completion of Roche anti–SARS-CoV-2 antibody assays, and Genuity Science (Ireland) Ltd for their funding in kind for the completion of the whole-genome sequencing and methylation analysis.

Data Availability

Data and metadata will be stored according to the Ulster University policy on data management and sharing. Data will be available via Ulster University's Research Data Repository and in accordance with their Research Data Management Policy. Any personal and identifiable information will be redacted, and data queries will be addressed on an individual basis by the research team. Genomics data are being deposited in the European Genome-phenome Archive and will be available upon request.

Authors' Contributions

AE contributed to investigation, formal analysis, writing, resources, and supervision; DM, EC, BW, REI, M Bhavsar, SDZ and PS contributed formal analysis and data curation; SML contributed formal analysis and investigation; JM contributed to investigation, formal analysis and writing; MK and M Bhavsar contributed to conceptualization and project administration; VM contributed to conceptualization, project administration and supervision; TSR contributed to conceptualization, project administration, supervision, and funding acquisition; AJB contributed to conceptualization, project administration, supervision, funding acquisition and resources; EM contributed to conceptualization, project administration, supervision, and funding acquisition; DSG and CW contributed to conceptualization, project administration, supervision, funding acquisition, resources, and writing.

Abstract

Background: Vulnerable older adults have a high risk of morbidity and mortality. Regular physical activity (PA) can have a positive effect on the health and health-related behavior of this specific target group. However, evidence of the impact and feasibility of community-based PA promotion interventions for vulnerable older adults is still limited.

Objective: The BeTaSen (Bewegungs-Tandems in den Lebenswelten Chemnitzer Seniorinnen und Senioren: ein Beitrag zur kommunalen Gesundheitsförderung) study aims to evaluate the (1) impact as well as the (2) feasibility, acceptance, and usefulness of a 12-month low-threshold PA intervention program for community-dwelling vulnerable older adults.

Methods: For our population-based prospective observational cohort study, a total of 120 vulnerable older adults (aged 75 years or older) in the area of Chemnitz (Germany) will be recruited to participate in (1) weekly neighborhood-based low-threshold PA meetings with trained mentors (activity tandems) and (2) monthly exercise meetings led by trained exercise instructors. Within the intervention, participants will be encouraged to perform the PA independently. Participants will complete assessments, which will include questionnaires as well as objective measurements of their physical, cognitive, and psychosocial health at 3 different time points (baseline, 6 months after the start, and 6 months after the end of the intervention). Additionally, a process evaluation will be performed, including questionnaires and qualitative interviews, involving the participants, mentors, and municipal project partner representatives.

Results: The BeTaSen project process began in October 2021, with the start of data collection and intervention in August 2022 in the first neighborhoods of the city of Chemnitz. A total of 86 participants were recruited at the time of submission of the manuscript. Longitudinal results are expected by 2025.

Conclusions: This study's results will provide insights on (1) the PA behavior of vulnerable older adults as well as the impact of PA interventions on health-related outcomes such as cognitive, physical, and psychosocial health, and (2) the feasible and useful components of community-based PA interventions. Thus, this pilot study contributes to future recommendations and provides a basis for further research, such as the development of feasible and sustainable target group–specific interventions in community settings.

Introduction

Overview

The share of older adults in many European countries' total population is increasing [1]. Aging is associated with a number of physical and health-related changes, including a decline in physical and cognitive performance and an increase in neurodegenerative as well as cardiovascular diseases [2]. Furthermore, demographic developments and age-related increases in individual disease risk pose significant (health-related) economic and social challenges for aging societies. This manifests itself in increased hospitalizations [3] and financial burdens on both the health care system and private households due to rising health care costs [4]. Thus, healthy aging, for example, years of life spent in good health and the maintenance of well-being in old age, has enhanced attention in social and health systems [2]; investments in and programs to promote health are increasing in importance. According to current research, vulnerability in older adults (eg, poverty, loneliness, and a low level of education) can adversely affect the health behavior, morbidity, and mortality of older adults [5-9]. German adults with an income of less than 60% of the national average, for example, have a significantly reduced life expectancy compared to those with above-average incomes [8]. Consequently, it is crucial to focus, especially on these target groups, on health promotion programs.

Among other health-promoting interventions, recent studies confirm that regular physical activity (PA), for example, daily walks, can improve individual and biopsychosocial health among healthy as well as vulnerable older adults [10-16]. Moreover, regular PA can also have a positive impact on social connectedness [13], which in turn can improve older adults' cognitive and mental health and seems to be a relevant factor in successful aging [14]. Accordingly, regular PA can be considered a beneficial investment in individual health capital [15] and in healthy aging in general [11]. Furthermore, previous studies and systematic reviews have shown that PA interventions in community settings can improve older adults' physical function and level of PA [16-20], even in those who are vulnerable [16,20]. For example, Giné-Garriga et al [16] find that physical exercise interventions can improve physical function in frail older adults. Other studies conclude that such programs can have positive effects on older adults' cognitive and mental health [21,22]. Recently, studies investigated the impact of community-based PA interventions on older adults' cognitive, psychosocial, and physical health and on their PA behavior in German communities [23,24]. However, many studies involved mostly healthy older adults who did not belong to a vulnerable group, and current research does not address long-term implications or specific group differences.

Thus, more evidence is needed to confirm these positive impacts, especially on vulnerable older adults, and to implement subsequent health promotion programs. Furthermore, despite the well-known positive effects of regular PA, only a small fraction of older adults in Germany are sufficiently physically active in line with the recommendations of the World Health Organization (WHO) [25]. The WHO and the American College of Sports Medicine recommend adults aged 65 years or older perform moderate to vigorous endurance training for a minimum of 150 minutes per week (in bouts of at least 10 minutes each) [26], in addition to flexibility, strength, and balance training twice per week [25]. Among adults aged 65 years or older, 42% meet the recommendations for endurance training, while only 29% meet those for strength training [25]. In a German health monitoring survey, 36% of older adults aged between 60 and 69 years and nearly 45% of older adults aged between 70 and 79 years reported that they do not engage in any regular PA or exercise [27]. Several studies find that vulnerability, for example, a low level of education, physical restrictions, and poor health status, is negatively associated with older adults' PA level (eg, meeting the WHO's recommended level of PA) [25]. This specific group is thus exposed to severe health risks and potentially early care dependency [5-8]. Due to the high share of older adults who are physically inactive, feasible PA promotion programs targeted specifically at previously physically inactive or vulnerable older adults are especially relevant. To determine the feasibility and sustainability of PA programs targeted specifically at vulnerable older adults, further research on contributing factors and barriers is needed. The literature identifies several internal and external barriers for older adults' participation in PA programs: lack of information about PA offers, physical restrictions, lack of social support to begin with PA, lack of language skills and local accessibility, as well as financial costs [28]. Vulnerable older adults (eg, poverty, loneliness, and a low level of education) perceive high barriers to participation in health-related promotion programs, for example, PA programs [29]. In a systemic review, Franco et al [30] identified six major themes that may influence older adults' participation in PA: (1) social influences, (2) physical restrictions, (3) competing priorities, (4) access difficulties, (5) lack of awareness of the personal benefits of PA, and (6) motivation and beliefs [30]. Furthermore, current research recommends providing PA interventions in community settings for vulnerable older adults that are specifically tailored to the target group and embedded in their immediate social-spatial context (districts and neighborhoods) [31-33]. Moreover, previous studies have shown that personal interventions are particularly effective in promoting PA [34] and that motivators such as social and environmental support, convenience of location, and enjoyment of the activity seem to be relevant factors in interventions targeted at community-dwelling older adults [35]. These influencing factors should be considered when developing exercise interventions to promote PA and its associated positive health benefits among vulnerable community-dwelling older adults.

Some studies conclude that community-based PA programs for older adults are feasible, even over a longer period [36-38]. A systematic review carried out by Farrance et al [39], for example, finds long-term adherence rates of nearly 70% for community-based group exercise programs. Nevertheless, there is limited evidence about the long-term adherence measures included in these programs as well as participants' views [39]. Shvedko et al [40] assert that a PA intervention for community-dwelling older adults at risk of loneliness is accepted by older adults and is feasible. Crombie et al [41] also show that a community-based PA intervention is feasible for sedentary

older adults. However, recent evidence about the feasibility and acceptance of community-based PA interventions and of the different components of such interventions, especially among vulnerable older adults, is limited.

In summary, evidence of the impact and feasibility of PA interventions on the health and health-related behavior of vulnerable community-dwelling older adults remains sparse. Therefore, research should focus on the health-related benefits of intervention programs that promote PA among vulnerable older adults as well as on how intervention programs tackle (internal and external) barriers that discourage the participation of vulnerable older adults in PA programs.

For this reason, the aim of this study is to investigate the impact and feasibility of a 12-month low-threshold targeted PA intervention program on community-dwelling vulnerable older adults. This study protocol describes the study's objectives, the design of the intervention, method, data collection, and considerations for analyzing the data from the PA intervention program of the study BeTaSen (Bewegungs-Tandems in den Lebenswelten Chemnitzer Seniorinnen und Senioren: ein Beitrag zur kommunalen Gesundheitsförderung).

Research Objectives and Research Questions

The main goal of the BeTaSen study is to initiate, sustainably maintain, and promote an active and healthy lifestyle for vulnerable older adults who reside in Chemnitz.

The objectives of the BeTaSen study are described in subsequent paragraphs.

Evaluation of the impact of a 12-month low-threshold PA intervention program on health-related outcomes of vulnerable community-dwelling older adults. In this context, the main research questions are as follows: (1) What are the long-term outcomes for older adults after completing a 12-month, target group-specific community-based PA program? Older adults' PA behavior as well as their physical, cognitive, and psychosocial health are of particular interest in this regard. (2) Are any group differences evident in the long-term outcomes of a 12-month target group-specific community-based PA program among older adults (eg, gender, previous disease, and vulnerability)?

Analyzing the feasibility, acceptance, and usefulness of aspects of a community-based PA intervention for vulnerable community-dwelling older adults. In this context, the main research questions are as follows: (1) Which PA-promoting exercises and activities are considered useful by older adults? (2) Is a target group-specific 12-month PA program feasible for vulnerable community-dwelling older adults and the community setting? and (3) What factors promote or inhibit the successful implementation of a target group-specific PA program for vulnerable community-dwelling older adults?

Methods

Participants and Procedure

The pilot study is being implemented in the German city of Chemnitz. Chemnitz is the third-largest city in the federal state of Saxony in the southeastern part of Germany, with a population of 250,398 (in 2023) [42]. In 2022, nearly 30% of the population of Chemnitz was aged 65 years or older; 15% were aged 75 years or older [43]. In 2020, Chemnitz was the city with the highest median age in Europe (52 years) [44]. Forecast calculations expect that by 2030, the Chemnitz region will have the highest share of people aged 65 years or older (nearly 38%) in Europe [1]. According to population forecasts, the share of Chemnitz residents aged 80 years or older will also rise from 8% in 2018 to nearly 11% in 2030 [45]. Due to these demographic developments, there is an urgent need for target group-specific and low-threshold community health promotion programs (eg, PA interventions) to support the healthy aging of vulnerable older adults who live in the city of Chemnitz. This city was furthermore chosen due to its immediate proximity to the Technical University of Chemnitz, which is conducting the study, and its collaboration with the city of Chemnitz's health department, as well as support from various local partners (eg, citizen platforms).

The aim during the study period is to cover at least 4 out of 39 districts in Chemnitz, representing the city's average demographic age (>50 years) and lower socioeconomic districts (compared to the city of Chemnitz's average) [46,47]. The recruitment of participants is planned primarily due to collaboration with local partners. Announcements will be conducted in different communal facilities for older adults (eg, citizen online platforms, assisted living facilities, and citizens' meeting points) through flyers, at information events, in institutional newspapers, and in the personal conversations of the research team with targeted older adults as well as with staff of different social institutions. The study will be announced in various local and district newspapers, and flyers will be distributed in shops, for example, in bakeries and pharmacies. Additionally, older adults who had participated in previous studies and had consented to being informed about future studies will be contacted.

Eligibility to participate in the study will be determined in personal interviews by qualified staff based on the inclusion and exclusion criteria described below.

Inclusion and Exclusion Criteria

The study primarily targets older adults aged 75 years or older who can be considered vulnerable (eg, poverty, loneliness, physical restrictions, and a low level of education) and who reside in the city of Chemnitz.

Residents are eligible to participate in the study if they (1) have at least basic knowledge of the German language, (2) can independently travel to the assessment and intervention locations, which will be meeting points in close proximity to their home, and (3) provide informed consent to participate in the study.

Participants will be excluded from the study if they have a medical condition preventing them from engaging in regular PA or if they had a severe adverse health event within the last 6 months (eg, myocardial infarction, stroke, fracture, surgery, or pneumonia) to ensure their safety during the PA sessions. Additionally, participants will be excluded if they participate in other clinical trials as well as in regular PA programs at least

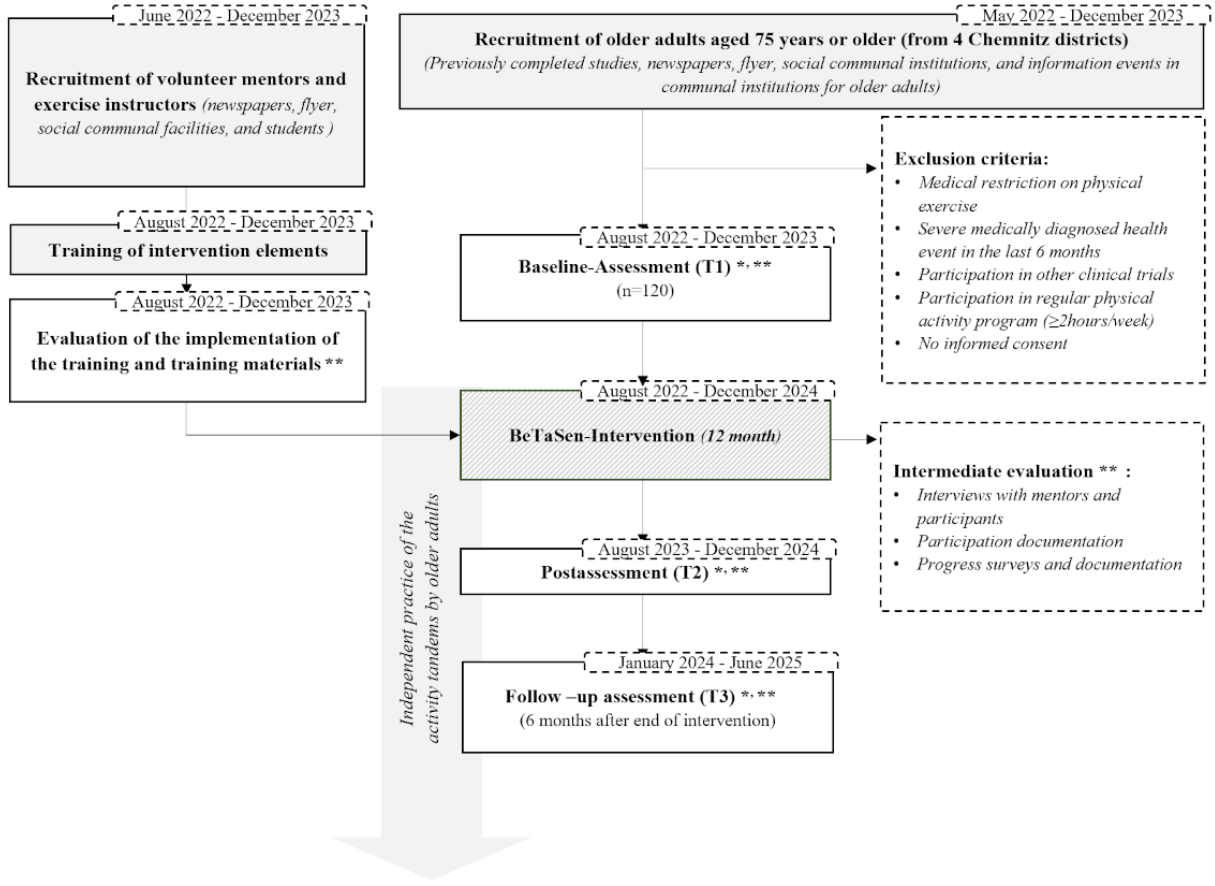
twice a week (eg, regular gym visits or rehabilitation exercise programs) to address older adults who are less physically active and to analyze solely the impact of the intervention.

Study Design

The pilot study is designed as a population-based prospective observational cohort study and is being carried out in 4 different districts in the city of Chemnitz. The first screening for study eligibility will be assessed through a standardized telephone interview with, for example, questions about older adults' age, health conditions, and regular weekly PA exercises. Afterwards, participants will complete an assessment conducted by the research team in their direct neighborhood (eg, in the facilities of community centers), which includes questionnaires and objective measurements of physical and cognitive function and of psychosocial health. In addition to these measurements, participants will wear a pedometer for 7 consecutive days to assess their PA behavior. Measurements will take place at 3 different time points over an 18-month period, namely at the beginning (T1), at the end (T2), and 6 months after the end of the intervention (T3) (Figure 1).

The project was launched in October 2021 and will be completed in September 2025. The first participants were recruited in August 2022.

Figure 1. Study flow of the population-based prospective observational cohort study BeTaSen (Bewegungs-Tandems in den Lebenswelten Chemnitzer Seniorinnen und Senioren: ein Beitrag zur kommunalen Gesundheitsförderung) with a study population of older adults (aged 75 years or older) living in Chemnitz, Germany. *Outcome evalution. **Process evaluation.



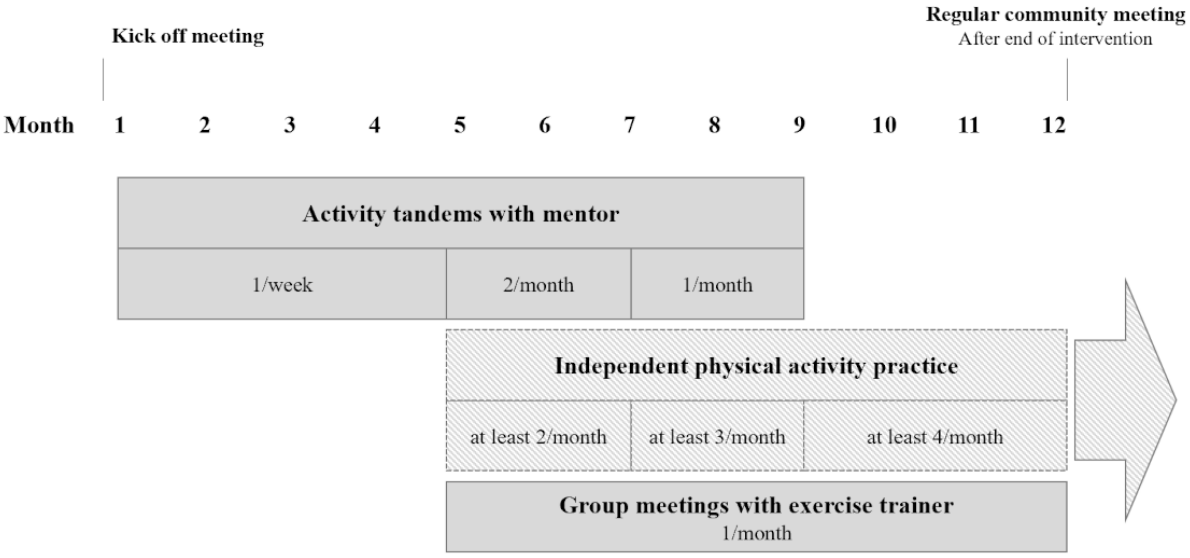
Design and Organization of a Physical Activity–Promoting Intervention

All participants will participate in the target group-specific community-based PA intervention. The pilot study's intervention period is 12 months per participating neighborhood. The participants will be encouraged to continue to engage in PA independently (Figure 2).

The intervention's main component will comprise regular PA meetings organized in so-called "activity tandems," which take place once a week for 30-45 minutes. One activity tandem will include 1 trained voluntary mentor and 3-4 older adults living in the same neighborhood. These activity tandems will primarily engage in low-threshold outdoor PA and exercise together in their neighborhood. For this, easily accessible locations such as urban lawns, walking paths, parks, and fitness trails will be used. In case of bad weather, the PA meetings will be organized in the meeting places of collaborating partners, for example, community centers. Due to the small group size, the content of each tandem lesson can be flexible and tailored to the individual participant's needs. For example, the exercises can be performed at different levels of intensity, or alternative exercises can be selected from a large PA-exercise pool. Additionally, monthly group meetings (eg, 3-4 activity tandems with a total of 12-16 older adults) will be organized in each neighborhood district in the intervention months 5-12 (Figure 2), which will be delivered by trained exercise instructors. In these group meetings, in addition to PA exercises, the following contents will be covered:

knowledge about the positive effects of PA, goal setting and planning, barrier management, and motivational aspects, as well as the sustainable implementation of regular PA in everyday life. Measures like small group sizes, qualified mentors, support material (eg, first aid kits, pulse oximeters, Borg scales), and the accessible, familiar environment of the activity sessions ensure the safety and well-being of participating older adults.

Figure 2. Procedure of the population-based prospective observational cohort study BeTaSen's intervention over a period of 12 months; an example is shown for 1 district (study population: older adults aged 75 years or older living in Chemnitz, Germany). BeTaSen: Bewegungs-Tandems in den Lebenswelten Chemnitzer Seniorinnen und Senioren: ein Beitrag zur kommunalen Gesundheitsförderung).



In total, around 6-8 activity tandems will be created in each of the 4 local districts (approximately 24-32 older adults per district). Thus, the goal is to reach a total of approximately 120 older adults residing in the city of Chemnitz during the project period.

Voluntary mentors (eg, volunteers from Chemnitz, students, and community center staff) will be recruited through various public channels (eg, newspapers, flyers, and mailing lists) in cooperation with municipal partners. The trained mentors should guide the activity tandem groups (eg, demonstrate PA exercises with the help of the manual and walk paths), ensure safety and well-being (eg, through individualized feedback), and encourage the older adults to do independent regular PA exercises. The mentors will also be responsible for communication and the planning of the activity tandem meetings. Researchers on the project team will instruct mentors in a workshop about how to conduct PA meetings, how to appropriately deal with the target group, and how to perform basic first aid procedures. In addition, mentors will be equipped with support materials, such as a manual that includes a range of various low-threshold PA exercises, an overview of district walkways, and additional exercise materials (eg, resistance bands and everyday objects).

The mentors will supervise and support the activity tandems once a week initially at the start of the intervention (intervention months 1-4), later once every 2 weeks (intervention months 5-6), and then once a month (intervention months 7-9). The older adults will thus be gradually encouraged to independently engage in weekly PA activity meetings, as from intervention month 10 onward, they will be prepared for basically independent implementation. Furthermore, older adults will be encouraged to actively participate in the activity tandems, for example, by choosing walkways or suggesting individual exercises. During the intervention period, participants will be given exercise material (eg, brochures) to continue regular PA in their activity tandem and on their own. To ensure that older adults do not overexert themselves as well as to enable them to get a better sense of their exercise limits, their oxygen saturation and heart rate (using a pulse oximeter; Orbisana Healthcare GmbH) as well as a subjective exertion rate (based on the Borg scale; [48]) will be measured at the beginning, middle (during physical exertion), and end of each activity tandem meeting. Based on these measures, participants will receive direct feedback, and the PA exercise intensity can be adjusted individually.

In line with previous literature and findings, the vulnerable target group's potential barriers should be carefully considered when developing the pilot study. To ensure low-threshold accessibility, the activity tandems and monthly group meetings will take place in the older adults' neighborhoods. District plans will be drawn up to identify sitting areas and public toilets, for example, and to pinpoint accessible walkway plans. The activity tandem's PA content will be designed to reflect daily life activities in a very playful, individualized, ability-oriented, and motivational way. Each unit can be freely designed by the mentors and older adults based on the PA, exercise materials, and recommendations provided. Each activity tandem unit should begin with a warm-up, and the components of strength, endurance, coordination, stretching, and relaxation should be addressed regularly in different sessions. In addition, the mentor should include knowledge transfer in each unit, for example,

about the positive effects of PA. Moreover, participation in the PA intervention does not entail any financial costs (eg, materials and participation fees). To promote sustainable participation in the neighborhood meetings and to ensure that the PA meetings are tailored to the vulnerable target group, the activity tandems are purposely organized for a smaller number of older adults. The older adults and mentors of the activity tandems can coordinate the time and location of their weekly meetings flexibly on their own.

Measures

All participants will complete an assessment at baseline (T1), at the end of the 12-month intervention (T2), and 6 months after the end of the intervention (T3). Before each assessment, participants will be asked to fill out a self-administered questionnaire and, for the detection of objective PA behavior, will be given a pedometer to wear for 7 consecutive days. The questionnaire will assess the older adults' psychosocial and physical health and evaluate motivational aspects related to PA in a community setting. Sociodemographic information will be assessed within the questionnaire at T1 only, comprising target group-specific items from the German Health Interview and Examination Survey for Adults [49].

Further measurements will take place in communal facilities in the older adults' neighborhood and will be carried out by qualified staff members. Each assessment will start with the measurement of anthropometric data (height and weight) as well as the registration of current medication intake and existing diagnosed diseases via interview. Using the EQ-5D-3L questionnaire, the participants' subjectively perceived health status in terms of mobility, self-care, regular daily activities, pain, discomfort, anxiety, and depression will then be determined by interview (3 response options: no problems, some problems, and serious problems) [50]. Additionally, their general self-rated health status will be recorded using the vertical visual analog scale EQ-VAS (1-100) [50].

An additional process evaluation will be performed during the intervention period using questionnaires for participants (after a period of 4 weeks) and mentors (after the workshop, 3 months after the intervention). Furthermore, qualitative interviews and informal notes, reports, and documentation of the PA groups will also be obtained from the activity tandems as well as from group meetings (Table 1 for a summary of outcomes).

Table 1. Outcome measurements of the population-based prospective observational cohort study BeTaSen (Bewegungs-Tandems in den Lebenswelten Chemnitzer Seniorinnen und Senioren: ein Beitrag zur kommunalen Gesundheitsförderung). T1 is baseline, T2 is the end of the intervention period (12 months), and T3 is 6 months after the end of the intervention (study population: older adults aged 75 years or older living in Chemnitz, Germany).

Assessment	Instrument or scale	Time of measurement
Outcome		T1, T2, T3
Physical function	• Short Physical Performance Battery (SPPB) • Handgrip strength (handgrip dynamometer)	
Physical activity	• OMRON Walking Style One 2.1. Pedometer (7 days) • PRISCUS-PAQ	
Psychosocial health	• German Depression Scale (DIA-S) • Items of Tilburg Frailty Indicator (TFI) • Items of social support questionnaire (F-SozU)	
Cognitive function	• Montreal Cognitive Assessment (MoCA)	
Process		
Feasibility	• Documentation of activity tandems and group meetings adherence rates • Qualitative interviews and self-administered questionnaire with older adults, mentors, exercise trainers, and communal partners	• Each activity tandem or group session • Monthly during the activity tandem period and after the end of the individual intervention period (older adults); after the end of intervention in the respective neighborhood (mentors, communal partners)
Usefulness	• Qualitative interviews and self-administered questionnaire with older adults, mentors, and exercise trainers	• Monthly during the activity tandem period and after the end of the individual intervention period (older adults); after the end of intervention in the respective neighborhood (mentors, communal partners)
Implementation (barriers and facilitators)	• Qualitative interviews and self-administered questionnaire with mentors, exercise trainers, and communal partners	• Monthly during the activity tandem period and after the end of the individual intervention period (older adults); after the end of intervention in the respective neighborhood (mentors, communal partners)

The main activity and health-related outcomes will be addressed in the following subsections.

PA Behavior

PA behavior will be objectively assessed using the OMRON walking style one 2.1. pedometer (OMRON Cooperation) that records a person's steps, walked kilometers, kilocalories used, and aerobic steps per day over 7 consecutive days. Participants will be instructed to wear the pedometer on their hip during waking times as well as get information about the use and purpose of the pedometer. After the pedometer has been returned, the data will be transferred by study assistants to a Microsoft Excel (Microsoft Corporation) spreadsheet. Activity data for days with at least 500 steps will be included for further analysis, according to Meyer et al [51].

For a subjective evaluation of PA behavior, the PRISCUS-Physical Activity Questionnaire (PRISCUS-PAQ) for older adults aged 70 years or older will be assessed based on interviews during T1, T2, and T3 measurements [52]. PRISCUS-PAQ consists of 10 main items on sedentary behavior, daytime naps, cleaning, and other housework, cycling, gymnastics, group exercise, other PA, walks, and gardening. The total score of the PRISCUS-PAQ reflects the individual's energy expenditure (metabolic equivalent) during the previous week [52].

Physical Performance

The digital grip dynamometer (JAMAR Smart Hand Dynamometer; Performance Health Supply Inc) will be used to assess the participants' handgrip strength. During this test, participants sit upright in a chair without an armrest with their arm bent to 90°. A total of 3 trials are performed per hand, alternating between right and left, with a test duration of 3-5 seconds for each trial. The mean and highest values of the 3 trials for each hand will be analyzed [53]. Additionally, the dominant hand will be queried.

To prove the impact of the exercise intervention on participants physical performance, the widely used, highly reliable, and valid Short Physical Performance Battery (SPPB) will be used [54]. The SPPB includes balance (Romberg, Semi-Tandem, and Tandem), gait speed (4-meter walk), and chair rise tests. Each of these 3 SPPB components is scored from 0 (inability to carry out) to 4 (best performance). There is a potential range between 0 and 12, with higher scores indicating higher functional performance. Participants with cut-off points of less than or equal to 6 points will be classified as "poor performers." Whereas a score of 7-9 points will define the "moderate performers," and the "good performers" will have scores of 9 points or more [55]. In a systematic review and meta-analysis, the SPPB has been shown to be a predictive tool for all-cause mortality [56].

The 2-minute step test (TMST) [57] will be used to assess the participants' endurance capacity. The test starts with a 2-minute rest period. Participants will then stand in front of a wall and raise their thigh to be horizontal to the floor; a mark (strip) will be placed in the position corresponding to the middle of their thigh bone, between the kneecap and frontal prominent pelvis bone. Participants will be instructed to alternately lift their knees as often as they can over a 2-minute period, such that their knees reach the marked location. After completing the TMST, the researcher will record the participants' number of steps, or "steps," as an outcome measure. Before the start of the test, directly after, and 30 seconds after the end of the test, the participant's heart rate in beats per minute and measurement of oxygen saturation in percent (through a pulse oximeter) as well as a subjective rating of perceived exertion (through the Borg scale [48]) will be recorded.

Cognitive Function

The short screening tool Montreal Cognitive Assessment (MoCA) will be used to evaluate the participants' cognitive functions (eg, memory, attention, and basic functions). Participants who achieve a MoCA score between 26 and 30 points will be classified as cognitively healthy; those with a MoCA score of 19-25 will be considered to have mild cognitive impairment; and participants with a MoCA score of less than 19 will be defined as severely cognitively impaired [58].

Psychosocial Health

Psychosocial health outcomes will be assessed using modified, validated, and reliable instruments included in a self-administered questionnaire. Thus, the psychological and social domains of the Tilburg Frailty Indicator [59], the German depression scale for older adults, namely Depression im Alter Skala [60], and modified items of the Fragebogen zur sozialen Unterstützung (social support) [61] will be implemented.

Feasibility and Usefulness

The intervention's feasibility for older adults will be assessed quantitatively based on the adherence rate (number of completed activity tandems and group meetings) during the intervention period. Additionally, participants will be given their own documentation sheet to record their subjective well-being (using a 5-level smiley scale at the beginning, middle, and end of each session) and their level of satisfaction (using a 5-point Likert scale) with each activity tandem meeting. Additional self-administered questionnaires with items to subjectively rate the activity tandem's components will be implemented after every fourth unit. Using a 3-point Likert scale, participants will rate the difficulty of the particular intervention content (eg, strength, endurance, and coordination). In addition, they will be able to use the open response section to indicate which parameters they want to improve and what they want to achieve over the next 4 weeks. Six months into, at the end, and 6 months after the end of the intervention, participants will receive another self-administered questionnaire to assess the intervention's feasibility and sustainability and to identify the optimizing factors of the activity tandems and group meetings.

To evaluate the feasibility of volunteer mentors and the communal context, (1) mentor workshops will be anonymously evaluated using a self-administered questionnaire, and (2) mentors and community project partner representatives will be asked to fill out a self-administered questionnaire (eg, questions on perceived feasibility and sustainability).

Implementation

To assess the implementation of the PA intervention, (1) self-administered questionnaires and (2) qualitative interviews will be conducted with mentors, participants, and community project partner representatives.

Data Management

Participant information will be recorded using an individual identification code. All hard copies will be stored at Chemnitz University of Technology in locked cabinets accessible only to project staff members. Electronic data will be stored on a secured, password-protected computer. The databases will not contain participant identifiers. The data linking participant identifiers and the individual identification codes will be stored separately. Data quality will be ensured through double data entry and range checks for data values. Only project staff members will have access to the final trial data set.

Statistical Analysis

SPSS Statistics (version 29; IBM Corp) and AMOS (version 29; IBM Corp) will be used for all quantitative statistical analyses. To determine the primary outcome at baseline (T1), the study population will be descriptively characterized using the following outcomes: demographics (eg, age, gender, family status, and income), anthropometric comorbidities, PA and health-related behavior (eg, smoking status and alcohol consumption), as well as physical, functional, cognitive, and psychosocial health status. Furthermore, participants' data at the end of the intervention period (T2) and 6 months after its end (T3) will be analyzed to evaluate the long-term impacts, feasibility, and usefulness of the PA intervention. Time effects, group differences (eg, age, gender, vulnerability, and sociodemographic conditions) in terms of physical, cognitive, and psychosocial health, interaction effects, as well as the intervention's feasibility and sustainability, will be analyzed using different parametric or nonparametric statistical methods such as the *t* test, Mann-Whitney *U* test, ANOVA, or Kruskal-Wallis test, depending on the number and size of the group, normal distribution, and homoscedasticity of the sample. Based on current evidence [6-8,25], associations and the strength of the relationship between 2 variables (eg, PA behavior and monthly income and adherence rate and level of education), correlation and regression analyses as well as adjustments for relevant covariates (eg, age, gender, and vulnerable criterion) will be performed. Additionally, multilevel analyses are planned to estimate, for example, the within-person impacts of the intervention program (eg, the impact of PA on well-being).

Qualitative interviews and focus group discussions will be protocolized by researchers and audio recorded, which will be transcribed afterwards. Qualitative data will be analyzed using a qualitative content analysis, according to Mayring and Fenzl [62], with the aim of structured processing of the material by coding relevant interview passages deductively in a theory-driven system of categories. Frequent text material that cannot be assigned to a deductive main category will result in the creation of new (inductive) main categories or subcategories [62]. The coding scheme will subsequently be supplemented with additional categories that emerge from the text material. These newly added categories will either be treated as subcategories of already existing categories or as new main categories. The text material will be coded with the help of MAXQDA (VERBI GmbH).

For this pilot study in the municipal area, the number of participants was calculated based on the project period and the project funding type in terms of feasibility within the study period.

Ethical Considerations

This study was approved by the Ethics Committee of the Chemnitz University of Technology, Faculty of Behavioral and Social Sciences, on May 19, 2022 (101547973). All study participants will be fully informed about the objectives and procedures of the study in German and will be requested to give written informed consent. Additionally, the informed consent contains information about the pseudonymized data collection for the study. Furthermore, the original informed consent allows the secondary analysis without additional consent.

Results

The intervention period of the BeTaSen study started in August 2022 in the first neighborhoods of the City of Chemnitz. Due to the planned staggered launches of the different activity tandems, cross-section data of all participants at T1 (approximately 120 older adults) and initial feasibility data 6 months into the intervention (approximately 60 older adults) will be collected until December 2023. Longitudinal results are expected in the first quarter of 2025. Qualitative and quantitative data on sustainable components for PA interventions among all participating vulnerable older adults are expected in December 2024, after T2, and 6 months after the end of the intervention (T3).

Discussion

The aim of the BeTaSen study is thus to develop, implement, and evaluate a target group-specific PA intervention for community-dwelling older adults living in Chemnitz, the city with the highest median age in Europe [44].

The intervention program was developed especially for the target group of vulnerable community-dwelling older adults on the basis of theoretical aspects [29-35] and considers potential barriers and facilitating factors for initiating and maintaining regular PA. Furthermore, the specific intervention design contains elements promoting long-term use (eg, increasing independent activity sessions over the intervention period, individual goal setting, and knowledge transfer of the effects of PA). Therefore, the intervention concept and their implementation are expected to contribute to (1) increasing or maintaining PA behavior, cognitive and physical function, as well as psychological parameters of older adults, and (2) the feasibility and sustainability of healthy aging in municipalities.

The results of the study will provide insights into (1) the PA behavior of vulnerable older adults as well as the impact of PA interventions on health-related outcomes such as cognitive, physical, and psychosocial health, and (2) feasible and useful

components of community-based PA interventions. Thus, this pilot study bridges a research gap as it focuses on the PA-promotion of vulnerable community-dwelling older adults and implements a low-threshold health promotion concept that may have a sustained impact on the health and health-related behavior of this specific target group. Furthermore, the BeTaSen study will make an important contribution to the state of knowledge of average PA levels and health outcomes, as well as the impact, feasibility, and sustainability of such interventions. As the results of the study will provide insight into the demands, needs, and possible barriers of programs, it can provide a foundation for new interventions and how to deal with difficulties in their implementation.

During and at the end of the project period, interim results and findings will be summarized in information brochures and presented at municipal information events or scientific congresses. When interpreting the results, it should be considered that this research project does not have a randomized, controlled study design since the accessibility of the target group is very restricted and community-based PA programs should be accessible to vulnerable older adults over the entire study period. Nonetheless, the results of the study will provide insights into the within-person impacts of regular PA over a longer time period, and the study design comprises a low-threshold intervention for a highly relevant target population and allows "real-world" applicability. The results of the study will make an important contribution to the research field of aging and movement sciences as well as to the development of health-promoting structures, providing insights into the impact and implementation strategies of community health promotion programs for specific target groups like vulnerable older adults. In addition to publications in scientific journals, the impulses of the study will be implemented into municipal health policies and structures (eg, other neighborhoods, community centers, and health departments) after the end of the project period. Furthermore, the PA program can be distributed throughout Germany through cooperation with the Federal Centre for Health Education and thus shows a high potential for expansion.

Finally, the results will contribute to future recommendations and provide a basis for further research, such as the development of feasible and sustainable target group-specific interventions in community settings.

Acknowledgments

This study is funded by the Federal Centre for Health Education with funds from the statutory health insurance funds as part of the GKV Alliance for Health [63]. The publication is funded by the Deutsche Forschungsgemeinschaft (491193532) and the Chemnitz University of Technology. The authors would like to thank Niki Rodousakis for proofreading the manuscript.

Data Availability

Participants information and data sets generated during and/or analyzed during this study will be stored securely and identified by a coded ID number only to maintain participants' confidentially. Data will be available from the corresponding author on reasonable request.

Authors' Contributions

TA and KM conceptualized the study and conducted the project administration. TA conducted the visualization of the manuscript. TA, KZ, TS, and KM wrote and edited the original draft. TA and KM conducted methodology, investigation, and funding acquisition. KM is responsible for the supervision of the BeTaSen project. All authors read, critically revised, and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The burden of alcohol use among patients with trauma and the relative injury risks is not routinely measured in South Africa. Given the prominent burden of alcohol on hospital trauma departments, South Africa needs practical, cost-effective, and accurate alcohol diagnostic tools for testing, surveillance, and clinical management of patients with trauma.

Objective: This study aims to validate alcohol diagnostics for injury-related trauma and assess its use for improving national health practice and policy.

Methods: The Alcohol Diagnostic Validation for Injury-Related Trauma study will use mixed methods across 3 work packages. Five web-based focus group discussions will be conducted with 6 to 8 key stakeholders, each across 4 areas of expertise (clinical, academic, policy, and operational) to determine the type of alcohol information that will be useful for different stakeholders in the injury prevention and health care sectors. We will then conduct a small pilot study followed by a validation study of alcohol diagnostic tools (clinical assessment, breath analysis, and fingerprick blood) against enzyme immunoassay blood concentration analysis in a tertiary hospital trauma setting with 1000 patients. Finally, selected alcohol diagnostic tools will be tested in a district hospital setting with a further 1000 patients alongside community-based participatory research on the use of the selected tools.

Results: Pilot data are being collected, and the protocol will be modified based on the results.

Conclusions: Through this project, we hope to identify and validate the most appropriate methods of diagnosing alcohol-related injury and violence in a clinical setting. The findings from this study are likely to be highly relevant and could influence our primary beneficiaries—policy makers and senior health clinicians—to adopt new practices and policies around alcohol testing

in injured patients. The findings will be disseminated to relevant national and provincial government departments, policy experts, and clinicians. Additionally, we will engage in media advocacy and with our stakeholders, including community representatives, work through several nonprofit partners to reach civil society organizations and share findings. In addition, we will publish findings in scientific journals.

Introduction

Alcohol indicators obtained from patients seen in emergency departments or admitted to hospitals are one of the key and most cost-effective data sources for estimating the impact of alcohol on communities and health [1] to quantify problem drinking, alcohol-impaired driving, trauma readmissions, and premature death [2]. This assists in identifying high-risk groups that should be targeted for prevention. Effective monitoring of alcohol-related morbidity and mortality requires the collection of alcohol-related indicators, in which regular reports on the key predefined indicators are submitted by hospitals, primary health care units, or emergency services [3,4].

The contribution of alcohol to the global burden of disease is undisputed. In addition to risks such as noncommunicable diseases, infectious diseases, and mental health problems as a result of hazardous and harmful alcohol use [3], the trauma burden of intentional and unintentional risk of injury from alcohol is a major public health concern. Studies from sub-Saharan Africa have highlighted the impact of alcohol on injury and violence [5-8] and concerns over alcohol consumption and alcohol-attributable burden of disease. The lack of attention alcohol-related harm receives from policy makers has been raised [9,10], with calls for stronger and more effective alcohol control measures.

In South Africa, approximately a third (31.2%) of alcohol-attributable deaths in 2012 occurred as a result of injuries, while 15.9% and 12.8% of alcohol-attributable disability-adjusted life years were caused by road traffic injuries and interpersonal violence, respectively [11]. The adult per capita consumption of alcohol in South Africa is extremely high (64.6 g of absolute alcohol per drinker per day). Almost 6 out of 10 South African drinkers older than the age of 15 years are reported to engage in heavy episodic drinking [3], which is strongly associated with increased injury risk.

COVID-19, and the related alcohol bans in South Africa, has brought the impact of alcohol on trauma presenting to health facilities into sharp focus in the country [12]. Moultrie et al [13] and Barron et al [14] demonstrated how a total ban on alcohol during the COVID-19 pandemic resulted in significantly fewer injury deaths. However, the absence of routine and reliable alcohol-related injury surveillance data have been identified as a critical gap, and the government has had to rely on the South African Medical Research Council's (SAMRC) rapid mortality reporting [15] of all injury-related deaths and ad hoc surveillance studies [13,16] to demonstrate the association between the availability of alcohol and alcohol harm. This gap has substantially hindered the ability to provide regular information on changes in the pattern of alcohol-related injuries and limits the ability to measure the impact of policy changes, implementation, and enforcement.

As the country transitions from the COVID-19 crisis response, it is likely that there will be further pressure on the government—from civil society and health and social agencies—to implement more sustained intervention strategies to reduce harmful drinking and to monitor the impact of any interventions on the alcohol-related injury burden. This has highlighted the absence of practical, cost-effective, and accurate alcohol diagnostic tools in the South African trauma setting. Accurate measurement would improve surveillance and influence the clinical management of trauma, inform and improve government policies to address heavy drinking, and assess the impact of alcohol policy reform. The proposed study thus aims to determine the type of information that will be useful for stakeholders in the trauma care and injury prevention sectors, to validate the efficacy of a selection of alcohol diagnostic tools, and to explore their feasibility for wider provincial or national implementation as a routine source of information on the alcohol relatedness of injuries.

Methods

Study Design and Setting

We will use a mixed methods participatory approach across 3 work packages (WPs) to validate alcohol diagnostics for injury-related trauma and assess its use for improving national health practice and policy (Figure 1). Outcomes from this research will inform health practice, policy development, and sustained intervention strategies. A validation study will be conducted in the trauma unit of 2 public health facilities in the Western Cape Province. Further testing will be conducted in 1 hospital setting in the Western Cape Province. These 2 hospitals represent high injury caseloads, particularly for violence and road traffic injuries [17,18].

Research Plan

WP1: Prioritization and Validation of Methods for Assessing Alcohol Use

We will conduct focus group discussions (FGDs) with various stakeholders to ascertain the current alcohol assessment practice in hospitals and the type of information that could assist in the acute management of injured patients and measure alcohol use for public health surveillance. This will be followed by a cross-sectional study to validate the efficacy of three diagnostic tools: (1) clinical assessment, which is based on a clinician's observation of apparent intoxication classifies the alcohol status of a patient into 4 categories as per International Classification of Diseases, Tenth Revision (ICD-10) coding (Y91.0 mild, Y91.1 moderate, Y91.2 severe, and Y91.3 very severe) [19]; (2) breathalyzers provide an estimation of the ethanol content in the breath [20]; and (3) fingerprick test to provide a capillary blood reading in 1-2 minutes and is used to facilitate the clinical process, as well as the use of the ICD-10 Y91 coding [19].

These 3 index tests will be measured against venous blood testing for the presence of ethanol as the reference standard, for which we will use enzyme immunoassay [21] for testing of blood alcohol concentration (BAC). The analysis will be conducted by a private pathology laboratory.

This WP will also describe the epidemiology of alcohol-related injuries among trauma cases presenting at the emergency unit of the selected trauma units through a prospective study. Patients presenting to the trauma units for first-time treatment of their injuries will be interviewed to record patient demographics, the injury intent, and related mechanisms and will be tested for alcohol, using the aforementioned alcohol diagnostic tools. Prior to the validation study, a small pilot study will be conducted over 2 weeks to test the consent procedures, the study questionnaire platform, and the logistics surrounding the blood withdrawal and use of a courier to the contracted laboratory for centrifugation within the 2-hour limit to preserve the alcohol.

WP2: Field Testing Selected Diagnostic Tools

Guided by findings from WP1, the alcohol diagnostic tools will be field tested in a district hospital in a large suburb on the outskirts of Cape Town. This WP aims to test the suitability of validated alcohol diagnostic methods for routine use in a hospital trauma setting on a day-to-day basis.

WP3: Community Engagement and Capacity Development

Engagement with clinicians, operational stakeholders (eg, nongovernmental organizations and emergency services), and individuals working in the policy arena are key to the success of any policy change. These stakeholders will be engaged through the FGDs at the commencement and again at the end to include community and patient representation. Three sets of activities for this phase will thus include:

- Step 1: FGDs on the use of the recommended methods and what would be required for implementation and the role of the measure in health care provision;
- Step 2: workshops or webinars with stakeholders for input on findings and to convey recommendations for uptake and integration; and
- Step 3: community engagement and recommendations for uptake and integration within the health system.

Additionally, capacity development through linking research to policy and practice for increased commitment and support by the government to fund and implement further scale-up of this study in trauma facilities nationally will be threaded through the project.

Study Population and Sampling Procedure

The Applying Research to Policy and Practice for Health (ARCH) stakeholder mapping tool will be used to guide our mapping process [22] to identify stakeholders to participate in FGDs in WP1. FGDs will consist of approximately 6 to 8 participants each, and we anticipate holding 5 FGDs or until theoretical saturation is reached. We will start by making a list of stakeholders in the trauma or injury prevention and alcohol policy fields according to 4 categories: academic, clinical,

operational, and policy stakeholders. Snowballing techniques from the initial core group will be used to identify additional stakeholders. Stakeholders will then be placed in a power-interest matrix based on the information outlined in the mapping [22] in order to categorize South African trauma and injury stakeholders according to their role in the professional landscape, to understand methods of engagement, and to lay out the proposed engagement strategy for the stakeholders throughout the project. FGDs will be exploratory and use a descriptive and contextual design [23]. Participants identified through this process will be invited to take part and required to provide informed consent before participation. FGDs with participants will take place over a 2-month period and will take place digitally to accommodate stakeholders in different locations. These FGDs will be guided by a semistructured interview sheet and run for between 45 and 60 minutes. They will be conducted by a trained facilitator in English.

For inclusion in the WP1 validation study, consenting patients presenting at the trauma units will be 18 years and older and injured <6 to 8 hours prior to arrival at the facility. All new consecutive admissions meeting the inclusion criteria will be tested for alcohol use. Unconscious, ventilated patients, and intoxicated patients with a breathalyzer (BrAC) test result >0.10 mg/L, who will be regarded as too intoxicated for informed consent, will require delayed consent to participate. Patients with severe cognitive impairment will be excluded. If the capacity to consent later is not regained, patients will be excluded. The required sample size to validate and assess the diagnostics' performance is estimated to be 1000 patients. This is based on the eligibility criteria and a targeted sample of cases stratified into a 5-level category variable of intoxication and ICD-10 Y91 severity (Multimedia Appendix 1). From prior studies [24], we expect that 40% will be ineligible for study entry, and a further 60% of the 600 eligible participants will have no alcohol detected or below 0.05 g/100 mL as the legal driving limit. The remaining 4 groups with a positive alcohol detection ("a patient who has a BAC reading of 0.05 g/100 mL" or above) will be closely monitored to ascertain that a minimum of 60 cases per BAC versus ICD-10 Y91/diagnostic measurements code category is captured. Using the expected 60%/40% split in zero versus positive for alcohol, we expect 360 zero alcohol and 240 alcohol-related cases; we do, however, expect that the distribution will vary across BAC categories.

Based on these assumptions, and to test a strict margin that the null hypothesis (k_0=0.7) and the alternative hypothesis (k_1=0.8) will be considered as substantial agreement, further input variables to determining the sample size included the 5 categories with frequencies equal to 0.6 (proportion of 0 alcohol cases) and 0.1 (for each proportion of the 4 remaining alcohol-positive categories). Based on this, we are expecting a sample size of 396 participants at 90% power. This power calculation is based on a significance level of P<.05. Hence, we expect our targeted sample of 600 eligible cases to be enough.

The same sampling strategy will be applied to select patients for the WP2 field testing of validated alcohol diagnostic tools in a district hospital trauma setting and estimated to be approximately 1000 patients. For WP2, the alcohol diagnostic tools will be used in separate data collection periods for ease of use. As the selected district hospital has a monthly average caseload of approximately 561 cases [18], we will plan to collect an approximate sample of 400 eligible cases for 1 alcohol diagnostic tool (breathalyzer), followed by a week's break, then for an additional 400 eligible cases to test a second diagnostic tool (fingerprick test) over the study's planned duration of 90 days.

For WP3, hospital staff from the validation of alcohol diagnostics and field testing will be invited to participate in FGDs (step 1). These will follow the same procedures described previously for the prioritization of methods, and we will include a summary of relevant updated study information. In step 2, national or provincial policy and health management stakeholders and the hospital staff from step 1 will be invited to participate in a feedback workshop to lobby for uptake and implementation nationally and provincially. They will be complemented by approximately 30 key public health, clinician, health management, injury prevention, and policy stakeholders identified using the ARCH stakeholder mapping tool. Step 2 will be held in a hybrid web-based and in-person workshop at the SAMRC in Cape Town after the FGD data have been analyzed. For step 3, we will work with the SAMRC Corporate and Marketing Communications division for policy brief, infographic, and short video design or production. This is for dissemination and engagement with community stakeholders, for research translation and recommendations to national or provincial policy and health management stakeholders, suggesting uptake and integration to other hospital trauma facilities.

Data Collection

The FGDs in WP1 will be conducted to explore stakeholders' knowledge and views on current alcohol indicators collected in trauma settings and gaps in the collection of indicators. We will also obtain opinions from these stakeholders about diagnostic tools, implementation barriers, facilitators, feasibility, acceptability and the appropriateness of collecting routine, and reliable injury surveillance and alcohol-related harm. The findings from this substudy will inform the study on the validation of alcohol diagnostic measures.

For the validation of alcohol diagnostics (WP1), a draft survey questionnaire was adapted from the WHO Collaborative Study on Injuries and Alcohol, a study validated across multicountry sites globally [24]. Information on the injury intent, mechanism, clinical screening according to ICD-10 code Y91, and breathalyzer analysis were retained with additions including the 2 alcohol diagnostic tools (the withdrawal of blood for testing and the fingerprick measure), time of blood withdrawal and fingerprick, the South African Triage Scale, an indication of delayed consent, referring hospital name (if applicable), and hospital folder number.

Fieldworker study nurses will be employed and trained on informed consent and completion of the survey content, and the questionnaire or data capturing on the Kobotools platform [25], using the study's electronic tablet devices. Fieldwork will occur over a 3-month period, with regular monitoring of the caseload

to inform any adjustments to the schedule until the targeted sample of 1000 cases is achieved, of which 600 cases are estimated to be eligible. Study nurses will be required to work midweek during daytime hours as required and during night duty hours of 7 PM to 7 AM over weekends.

Blood samples will be couriered on a regular basis to a Pathcare laboratory near Groote Schuur Hospital. Preservation of the alcohol will be done by centrifuging the samples within 2 hours of blood withdrawal to separate the plasma from the serum and to have it sealed in a separately labeled tube for courier and analysis at a second Pathcare facility identified for blood alcohol testing.

For WP2, the survey questionnaire will be revised for the field testing phase of validated alcohol diagnostics with the addition of questions on the body region injured (head, face, neck, thorax, etc), the nature of injury (fracture, cut, bruise, concussion, etc), the selected alcohol diagnostic tools (Table 1), the patient's drinking history prior to injury, a self-assessment on alcohol intoxication, and information on socioeconomic status.

Table 1. Summary of alcohol diagnostic screening tool measures.

Alcohol diagnostics	Data source
• Clinical assessment: An observational assessment of alcohol intoxication conducted by a trained nurse or medical doctor. The assessment measures the severity of speech impairment, motor coordination, behavioral disturbances, etc through the use of a Likert scale (none to very severe) using ICD-10[a] Y91 codes	• WHO[b] evidence of alcohol involvement is determined by the level of intoxication (ICD-10 Y91 codes) [26]
• Active breathalyzer testing: The blood alcohol concentration measured in breath alcohol (BrAC) mg/L in exhaled breath through a straw. The minimum breath alcohol content detected is 0.03 mg/L BrAC. Alcohol can be detected up to 6-12 hours after the last drink. This method will not be used on ventilated patients • Passive breathalyzer testing: Exhaled breath for all patients to indicate the presence or absence of breath alcohol (yes or no)	• Dräger: SANAS-accredited breathalyzer screener used by blowing through a sterile mouthpiece for a digital reading (active) • Passive: indicate the presence or absence of breath alcohol (yes or no)
• Fingerprick test: Accurate measurement of capillary whole blood samples collected via fingerprick using a lancet. Results displayed in %BAC, mg/L, or µg/dL BrAC. The lowest level of detection is 0.03% BAC	• Fingerprick test: rapid blood alcohol meter
• Blood sample: Detecting the presence or absence of ethanol in the blood [27] using enzyme immunoassay. Venous blood was collected by qualified nurses in a sodium fluoride tube; alcohol levels were reported in g/dL	• Testing with a venous blood sample

[a]ICD-10: International Classification of Diseases, Tenth Revision.

[b]WHO: World Health Organization.

Fieldwork will be based on an idealized week, with a selection of hours across day- and nighttime, during the 3-month period. This is to ensure that the data are representative in terms of the facilities' operating conditions, which are expected to change by time of the month, hour, weekday or weekend, and so forth to assess the suitability of the alcohol diagnostic tools for possible national scale-up.

In WP3, FGDs with participants in step 1 will take place digitally to accommodate stakeholders in different locations. Interview guides will consist of open-ended questions to explore participants' views on the recommended methods, their thoughts on the requirements for implementation (provincially and nationally), and what the role of the measure would be in health care provision more broadly. Specific areas to discuss will include (1) intervention content; (2) intervention delivery; (3) strategies for addressing possible barriers to intervention delivery; (4) research questions around acceptability, feasibility, and sustainability of measuring alcohol-related trauma; and (5) strategies to generate local stakeholder buy-in. These areas of discussion will ensure appropriate information are collected that will inform national stakeholders on the benefits for the adoption of the recommended alcohol diagnostic screening tools for larger implementation [28].

For step 2, the findings from WP1 and WP2, as well as the FGD results from WP3 (step 1) will be shared in a workshop with researchers; clinicians and hospital managers; traffic officials; emergency medical services; police, pathology, and rescue services; and national and provincial policy makers. The output will be a framework to guide the implementation and scale-up of routine diagnostic measuring of alcohol-related trauma. Workshop participants will be asked to evaluate the usefulness of the workshop and their satisfaction with the outcome.

Data Analysis

WP1 and WP3 FGDs will be audio recorded and transcribed verbatim. Thematic analysis will be conducted based on deductive themes focusing on the exploration of current practices, implementation barriers, facilitators, feasibility, acceptability, and appropriateness of conducting alcohol diagnostics in public health facilities (WP1.1) and on acceptability, feasibility, and appropriateness of the recommended measure (WP3). The data will be managed using qualitative data analysis software NVivo (version 12; Lumivero)

and will be presented in line with COREQ (Consolidated Criteria for Reporting Qualitative Research) guidance for reporting qualitative research [29].

For the validation of alcohol diagnostics in WP1 and WP2, data collection will be regularly monitored and managed by the study statistician. The blood alcohol analysis results will be merged into the main database using the unique case ID. The correlation coefficients of the continuous alcohol diagnostic measurements and the blood alcohol tests will be reported and represented graphically. A Kappa statistic [30] will be used to assess the level of agreement between BAC categories and the various alcohol diagnostic tests and the clinical assessment as per ICD-10 (International Classification of Diseases) Y91 codes. Taking into consideration that the alcohol diagnostic measures are ordinal responses, we will use ordinal regression to model the receiver operating characteristic (ROC) curve [31,32]. This diagnostic test plots sensitivity against the specificity of the alcohol diagnostics measures against the gold standard BAC. The area under the ROC curve will also be used to characterize the accuracy of the diagnostic tests, providing all information on its performance, instead of only a single estimate of the test's sensitivity and specificity. The trade-offs between the ROC curve's sensitivity and specificity can then be assessed to inform a decision threshold [33,34] for the alcohol diagnostic methods to be used in phase 2. Any level above 70%, sensitivity and specificity will be acceptable and is usually considered as "fair," followed by 80% as "good" and 90% as "excellent."

If multiple tests meet the same criteria, we will use the area under the curve to determine the best test. We will, however, proceed to test the feasibility of use for both the breathalyzer and the Fingerprick test if they meet the specified sensitivity and specificity criteria. Besides reporting the results of validating the alcohol diagnostic tools, descriptive statistics for analysis will include age and gender, followed by an analysis of the severity of the injury (assessed by the triage scale), the intent of the injury (violence, road traffic, unintentional, and self-harm), the related mechanism of injury (ie, gunshot, stabbing, pedestrian, driver, fall, etc), and BAC categories. Data analysis will be conducted on STATA (version 17; Stata Corp). Data will be presented in line with STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidance for reporting cross-sectional studies [35].

For the field testing (WP2), we will follow the same data management and analysis procedures and packages as for the validation of alcohol diagnostics. Further analysis will include patient demographics, the nature of injury (fracture, sprain, open wound, burn, etc) and body region injured, the intent of the injury (violence, road traffic, unintentional, and self-harm) and the related mechanism of injury (ie, gunshot, stabbing, pedestrian, driver, fall, etc), and triage scale. We will use ordinal regression to analyze the severity of injuries (as indicated by the triage scale) as the outcome, and the level of intoxication (indicated as 0.05 g/100 mL and above) as one of the independent variables. In addition, a multinomial regression will be used to assess the association between the outcome as the type of injury with the level of alcohol intoxication. As information on drinking prior to injury will be recorded to determine the type of alcohol and volume consumed, the dose-response relation between the number of drinks consumed within 6 hours leading up to the injury and the relative risk of being injured will be analyzed and reported. Socioeconomic information on employment status, household income, and suburb of residence will be captured and used to inform alcohol policies.

For the workshop evaluation form in WP3, we will sum each evaluation item to create scores for the evaluation form and will summarize using mean with the SD or median with IQR.

Patient and Public Involvement

Clinicians are an important participant group and were involved in the initial design of the study and as coinvestigators. We will be using a participatory approach through stakeholder engagement initiated in the prioritization of methods to include community and patient representation; then incorporating a synthesis of findings from the validation of alcohol diagnostics and suitability testing to conduct qualitative research on the use of the recommended alcohol diagnostic method. Feedback will be sought on requirements for uptake and integration within the health system, which has a specific focus on community-based participatory research for study synthesis and recommendations. This final uptake activity is iterative and dependent on the outcomes of the formative work. Therefore, the study overall is geared to soliciting participant co-design.

Ethical Considerations

Ethical approval for the study has been granted by the research ethics committee of the South African Medical Research Council (EC005-2/2022) and approval from the Western Cape Health Department. Written informed consent will be obtained from all study participants, and all data will be anonymized. No compensation will be provided for study participation.

Results

Pilot data are being collected, and the protocol will be modified based on the results. The findings will be disseminated to relevant national and provincial government departments, policy experts, and clinicians. We will publish findings in scientific journals, engage in media advocacy, and share findings with our stakeholders, including community representatives, nonprofit partners, and civil society organizations.

Discussion

There is a lack of routine and reliable injury surveillance specifically alcohol-related harm data in South Africa to respond to the related trauma burden. Additionally, research to develop systems or reliable mechanisms to test alcohol-related trauma and to monitor the impact of interventions is lacking. Alcohol is an established risk factor for violence and injuries and accurately monitoring alcohol relatedness in response to interventions, policy changes, and so forth will be necessary to evaluate effectiveness as suggested by the WHO SAFER strategy of "*Monitoring*," 1 of 3 essential strategies aimed at government officials for the purpose of developing evidence-based alcohol policies and action plans to address alcohol harm [36]. The prominent role of alcohol in the trauma

setting has become particularly pronounced during the COVID-19 lockdown, and this study will provide crucial evidence needed for the effective measurement of alcohol-related trauma to improve injury surveillance and clinical management. A few limitations of the study have been identified. First, expert stakeholders included in FGDs will be restricted to known contacts within the field. However, by using the ARCH stakeholder mapping tool to identify appropriate stakeholders, we are confident that we will involve relevant individuals, groups, organizations, and institutions and engage with them in a manner that can contribute to successful research uptake [22]. Second, the validity testing of the alcohol diagnostics will use enzyme immunoassay instead of the gold standard gas chromatography method. The detection of ethanol by gas chromatography, which has the advantage of being able to separate ethanol from other alcohol, is widely considered as the "gold standard" for alcohol measurement [21,27]. Due to the cost implications for this method of testing and the fact that we will not be using the results of this study in medicolegal cases, we will be using enzyme immunoassay [21] for testing of blood alcohol and will consider this as the gold standard for the purpose of this study. Third, validity testing at a tertiary hospital could influence the cut-off period to detect alcohol within the blood due to referrals from primary and secondary health facilities. However, the selected tertiary hospital was specifically selected as the site for validating the alcohol diagnostic tools, as it is a large tertiary hospital situated in Cape Town, South Africa, where the trauma unit is burdened by high injury caseloads, particularly for violence and road traffic injuries [16,17,37]. Through this study, we hope to identify and validate the most appropriate methods of diagnosing alcohol-related injury and violence in clinical settings. The findings from this study are likely to be highly relevant and could influence our primary beneficiaries—policy makers and senior health clinicians—to adopt new practices and policies around alcohol testing in injured patients.

Abstract

Background: Psychological interventions, along with antipsychotic medications, are recommended for adults diagnosed with a psychotic disorder. While initially designed to mitigate positive symptoms, psychological interventions targeting personal recovery were developed and aligned with the recovery framework that many mental health services have adopted. Acceptance and Commitment Therapy (ACT) for psychosis is one such intervention that shows promise when delivered in an individual format. There is preliminary evidence that ACT for psychosis in a group format improves recovery.

Objective: This trial aims to evaluate the effectiveness of the "Recovery ACT" group program on personal recovery among adults living with a psychotic disorder.

Methods: Our unfunded study is a multiagency, prospective, nonrandomized, waitlist control, single-group trial of the Recovery ACT group program. The program involves 7 weekly group sessions of 90 minutes duration and a 90-minute booster session held 1 month later. We intend to recruit 160 adults living with a psychotic disorder who enroll in a group that is offered as a routine clinical service at participating public mental health services in Melbourne, Victoria, Australia. The 4 assessment time points are 4-6 weeks before the start of the group program, at the start of the group program, at the end of the group program, and at the booster session. There is an optional midgroup assessment and follow-up study. The primary outcome is personal recovery. Secondary outcomes include participants' well-being and psychological flexibility processes. Qualitative data are also collected from participants and facilitators.

Results: Recruitment began in September 2019 and is ongoing until 2024, subsequent to a 24-month disruption due to the COVID-19 pandemic. As of the submission of this paper, 93 participants consented to the evaluation, 65 completed T1 measures, and 40 had a complete data set for the proposed analyses.

Conclusions: This is the first trial evaluating the effectiveness of the Recovery ACT group program on personal recovery for adults living with a psychotic disorder. Findings will contribute to knowledge about psychosocial interventions for adults living with psychosis. This trial may also serve as an example of a partnership between clinicians and academics that can facilitate the translation of research into practice.

Introduction

Background and Rationale

Schizophrenia spectrum disorders have a prevalence rate of 3.3 per 1000 individuals worldwide [1], with schizophrenia ranking as the twelfth most disabling disorder [2]. Psychotic disorders are typically first diagnosed in young adulthood and can run a chronic course [3]. About two-thirds of individuals diagnosed with a psychotic disorder continue to experience persistent psychotic symptoms despite adhering to antipsychotic medication regimens; about 20% do not respond at all [4]. In addition, there is a high prevalence of comorbid anxiety and mood disorders—about 40% experience anxiety [5,6] and 30%-80% experience depression [6,7]—and other challenges (eg, stigma and social exclusion) that impact well-being and functioning. Persisting psychotic symptoms, comorbid anxiety and depression, and other challenges not only contribute to an individual's level of distress and functioning but also impact a person's ability to fully engage in life [8], referred to as personal recovery [9].

For over 2 decades, psychological and psychosocial interventions have been internationally recommended as adjuncts to pharmacological interventions [10-13]. The leading evidence-based psychological intervention recommended for psychotic disorders is cognitive behavioral therapy for psychosis (CBTp). This intervention involves teaching skills to modify unhelpful thinking patterns that impact behavior [14] and primarily targets reduction in psychotic symptoms and, arguably, distress and functioning as well. While meta-analyses demonstrate that CBTp reduces psychotic symptoms (most notably positive symptoms) with a small effect size [15-17], CBTp does not appear to mitigate distress or improve quality of life [18]. The latter findings continue to be challenged [19,20]. Modifications of CBTp (eg, low-intensity CBTp [21,22] and group CBTp [23]) are promising, though they have yet to amass robust evidence to be recommended in treatment guidelines.

Another promising psychological therapy for psychotic disorders is Acceptance and Commitment Therapy (ACT). This approach involves developing psychological flexibility, which is the ability to be in conscious contact with the present moment, and the capacity to persist with or change behavior based on whether it aligns with one's personal values [24]. Psychological flexibility processes include willingness to be with mental experiences (thoughts, feelings, sensations, etc) instead of engaging in experiential avoidance; cognitive defusion (distancing or observing with openness and curiosity) with mental experiences; engagement in valued actions; and mindfulness (ie, awareness of the present moment) [24]. ACT adapted for individuals living with a psychotic disorder has been implemented in both inpatient and outpatient settings. There is emerging evidence [25] that this intervention not only reduces rehospitalization [26-28] but can also improve quality of life and personal recovery [29].

The first ACT for psychosis group intervention targeting quality of life and social functioning was a 4-session group (2-hour sessions run weekly) known as the "ACT for Life" program, a manualized protocol developed by researchers in the United Kingdom for adults living with psychosis [30,31]. An initial uncontrolled study evaluating this program at a community psychosis service in the United Kingdom [32] demonstrated small improvements in functioning and mood after group completion. A subsequent controlled study [33] demonstrated the positive effects of group participation on well-being over time and greater independence, as indicated by service use changes. Both studies demonstrated that the group was feasible and acceptable to adults living with psychosis.

Building on promising results from individual and group ACT programs for psychosis, the ACT for Life program was adapted for public outpatient mental health services in Melbourne, Victoria, Australia [34]. A pilot of the adapted program, referred to as "Recovery ACT," was implemented by public mental health service clinicians as part of their routine practice and evaluated using pre- and postgroup outcome measures together with qualitative feedback from facilitators and participating consumers [35]. Results from the uncontrolled pilot study involving 9 groups and 90 consumers demonstrated that the program and its evaluation were feasible, acceptable, and safe [35]. Significant increases in personal recovery, well-being, and psychological flexibility were observed from the start to the end of the program. The extent of consumer and clinician interest in the groups, both from the original agency and additional agencies, strongly indicated the feasibility of conducting a more extensive evaluation. Building on this momentum, our clinician-academic partnership agreed to conduct this more stringent trial by incorporating a waitlist control period and an established measure of personal recovery as the primary outcome.

Objectives

The primary aim is to evaluate the effectiveness of the Recovery ACT group program on personal recovery for adults living with a psychotic disorder in routine clinical practice across public mental health organizations in Australia using a single-group, waitlist control design. A secondary aim is to evaluate the effect of the Recovery ACT group program on well-being and psychological flexibility processes (experiential avoidance, cognitive defusion, engagement in valued actions, and mindfulness). The research questions are as follows: (1) What are the clinical benefits and risks of the Recovery ACT group program for adults diagnosed with psychotic disorders as conducted in routine practice in Australia? (2) Are there changes in psychological flexibility processes due to participation in the Recovery ACT group program? (3) Are changes in psychological flexibility processes associated with changes in personal recovery and well-being?

The primary and secondary hypotheses are that the longitudinal trajectory of personal recovery and the secondary outcomes will not significantly change over the waitlist period, then will improve from the start to the end of the group program, and then improve at a less rapid rate from the end of the group to the booster session. A further hypothesis is that changes in psychological flexibility processes during the first half of the group program will be associated with changes in personal recovery and well-being in the second half of the group program.

Methods

Participants and Study Setting

We plan to recruit a minimum of 160 adults (aged between 18 and 65 years) who enroll in a Recovery ACT group program at 1 of 4 public mental health service study sites in Melbourne (NorthWestern Mental Health, St Vincent's Mental Health Service, Alfred Mental and Addiction Health, and Peninsula Health Mental Health Service). The target minimum number of participants at NorthWestern Mental Health is 95 participants, and 32 participants each at the other study sites. The overall recruitment target was based on the minimum sample size needed to complete the intended analyses and an anticipated 60% participant retention rate based on the pilot study [35].

The inclusion criteria are a primary file diagnosis of either schizophrenia spectrum disorder or other psychotic disorder, a mood disorder with psychotic features, or a substance-induced psychotic disorder; currently receiving outpatient mental health care at 1 of the study sites; and current enrollment in a Recovery ACT group program. The exclusion criteria are lack of capacity to consent to the evaluation; lack of proficiency in speaking and comprehending English; a file diagnosis of intellectual disability or borderline personality disorder.

Study Design

This trial is a multiagency, prospective, longitudinal, nonrandomized, waitlist control, single-group study among Australian adults diagnosed with a psychotic disorder who participate in a routine Recovery ACT group program. The design includes 4 assessment time points: the start of the waitlist period (approximately 4-6 weeks before the start of the group program), the start of the group program (0 weeks), the end of the group program (about 6 weeks after the start of the group program), and the booster session (about 10 weeks after the start of the group program). Some participants may complete outcome measures at the midpoint session (T2, which is 3 weeks after the start of the group program) if the study site is resourced to collect data at an additional time point. Quantitative data from facilitators about participants' clinical severity and clinical improvement will be collected before, during, and after the group program, as well as relevant demographic and clinical information collected at baseline from participants' electronic medical records. At either the end of session 7 or the booster session, participants will be asked to provide written consent for study personnel to contact them for a follow-up study. Facilitators will be invited to complete a semistructured interview with senior investigators after each group program to gather qualitative data about the feasibility of the group program in routine practice and to assist in the interpretation of the quantitative measures completed by participants. The protocol development addressed the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials; Multimedia Appendix 1) guidelines [36] and intends to adhere to the CONSORT (Consolidated Standards of Reporting Trials; Figure 1) criteria [37]. We retrospectively registered the trial with the Australian New Zealand Clinical Trials Registry; Table 1 lists the trial registration data set.

Public title	Acceptance and Commitment Therapy (ACT) Group Program for Recovery from Psychosis: A Multi-Agency Evaluation
Scientific title	A Multi-agency Evaluation of the Routine Practice of an Acceptance and Commitment Therapy Group for Recovery from Psychosis
Countries of recruitment	Australia
Heath conditions or problems studied	Psychosis, Mental Health, Schizophrenia
Interventions	Treatment: “Recovery ACT for Psychosis” Group Program; comparator or control: single group, waitlist control period
Key inclusion and exclusion criteria	
Inclusion criteria	Inclusion criteria: Out-patients aged between 18 and 65 years; have a primary file diagnosis of either a schizophrenia spectrum or other psychotic disorder, a mood disorder with psychotic features, or a substance-induced psychotic disorder; are currently receiving outpatient mental health care at one of the study centers; are self-referred or referred by clinical staff to a Recovery ACT group being conducted by a participating center.
Exclusion criteria	Exclusion criteria: lack of capacity to consent to this evaluation; lack of proficiency in speaking and comprehending English; file diagnosis of an intellectual disability (an intellectual development disorder) or borderline personality disorder.
Study type	Interventional
Allocation	• Nonrandomized trial • Intervention assignment: single-group • Masking: open (masking not used)
Primary purpose	Treatment
Phase	N/A[a]
Date of first enrollment	September 13, 2019
Target sample size	160
Recruitment status	Recruiting
Primary outcomes	Personal recovery
Key secondary outcomes	Well-being

[a]N/A: not applicable.

Procedure

Recruitment

Participants will be recruited from current consumers of the services enrolled in a Recovery ACT group program as part of their normal clinical care. Recovery ACT group programs are conducted at all 4 participating sites, either as part of a program of groups offered to consumers or as periodic opportunities. All sites follow the same recruitment plan. Recruitment will continue until the target is met, as long as the clinical services are willing to continue to support the evaluation. Facilitators will describe the group program and the evaluation study at staff meetings and with fellow clinicians at their study site to ensure they are aware that an evaluation of the program is occurring and that consumers will be invited but not obligated to participate. Facilitators will receive all referrals to the group program and contact potential consumers to schedule an “Information and Engagement” session to brief consumers about the group program and confirm their wish to attend. All consumers who enroll in the group program will be screened for eligibility to participate in the evaluation. Consumers who

meet the eligibility criteria will be provided with an explanation of the study, an information sheet, and an evaluation brochure, and those who choose to participate will be required to provide written informed consent.

After the completion of a group program (after the booster session), senior investigators will invite facilitators to participate in a semistructured group interview for evaluation purposes and seek informed consent.

Due to the time elapsed from the initial consent process, all group members will be asked again at either session 7 or the booster session for permission and written consent to contact them in the future to invite them to participate in a follow-up study on the experience of participating in the group.

Intervention

The Recovery ACT group program includes 7 core sessions scheduled weekly and a booster session scheduled approximately 4 weeks later. The duration of all sessions is 90 minutes, and they are delivered in person. The intervention is an adaptation of the ACT for Life program [30] that centers on a core metaphor (passengers on the bus) [38] to facilitate consumers' engagement in value-based actions when relating to their internal experiences (eg, thoughts, feelings, and memories) once they become aware of the internal experiences and are able to defuse (or cognitive distance) from them. The group focuses on developing awareness of internal experiences through metaphors and mindfulness activities and building defusion skills. In the metaphor, the "bus" represents the consumer's life in the present moment, the "bus driver" is the consumer, and the "passengers" on the bus are the consumer's internal experiences. The topics covered during the core sessions include: introduction to noticing (mindfulness) of present experiences and values; enacting the core passengers on the bus metaphor and "specific, meaningful, adaptive, realistic, and time-framed" (SMART) goals; review of values, noticing, and willingness; identification of passengers and different ways of responding to them and development of noticing skills; passengers on the bus and changing relationships with words; review of values and encouragement of sharing value-guided actions; and review of key group messages. Brief contact with consumers between sessions is encouraged to promote completion of home practice and to encourage attendance.

There are no specified criteria for discontinuing or modifying the intervention, as this is an evaluation of a group program as conducted in routine clinical practice at local mental health services. Participants can choose to withdraw from the evaluation and remain in the group program. Participants may be withdrawn from the study due to a protocol violation or an adverse event.

Facilitators will be clinical mental health staff employed at a participating public mental health service who, where possible, have participated in an introductory ACT workshop and completed training in Recovery ACT. The group is led by 2 facilitators, one of whom is experienced (ie, has previously led a Recovery ACT group program) and adheres to the Recovery ACT group program manual [39]. Facilitators will be invited to attend a minimum of 3 "Support and Supervision" sessions while facilitating a group. The goal of these sessions is to enhance fidelity to the Recovery ACT group program manual [39]. In addition, facilitators will complete a fidelity log after each group session.

There are no restrictions on concomitant care and interventions, as this is an unfunded evaluation of the Recovery ACT group program that is already offered in routine clinical care at the participating public mental health services. To participate in the Recovery ACT program, participants must be receiving care at the respective public mental health service. As such, participants will receive provisions for ancillary and posttrial care at the public mental health service. The potential risks related to the study are deemed minimal. Facilitators are responsible for participants' clinical care during the group program, including distress related to study procedures. Participants have a key support clinician for out-of-group issues that may arise.

Outcomes

Timeline

The schedule of enrollment, interventions, and assessments is displayed in Figure 2. The quantitative self-report outcome measures are intended to be completed independently at the start of the waitlist period (T0, approximately 4-6 weeks before the start of the group program, typically at the "Information and Engagement" session), at the start of the group program (T1), at the end of the group program (T3, which is 6 weeks after the start of the group program), and at the booster session (T4, about 10 weeks after the start of the group program). Some participants may complete outcome measures at the midpoint session (T2, which is 3 weeks after the start of the group program) if the study site is resourced to collect data at an additional time point. Measures are completed after the group session, except for at T1, when participants complete measures before the start of the group to ensure no exposure to the program's content. Participants can request assistance from facilitators to complete the measures. Demographic and clinical information will be obtained from participants' electronic health records at T0 and will include their date of birth, gender, ethnicity, country of birth, highest level of educational attainment, highest level of employment, current employment status, primary mental health file diagnosis, co-occurring mental health file diagnoses, date of first contact with mental health services, number of listed episodes of outpatient mental health care, and number of psychiatric admissions.

[a]Optional for sites.
[b]Optional for participants.
[c]ACT: Acceptance and Commitment Therapy.
[d]CGI-S: Clinical Global Impressions – Severity scale.
[e]CGI-I: Clinical Global Impressions – Improvement scale.

Primary Outcome

The primary outcome is personal recovery, as measured by the 15-item version of the Questionnaire about the Process of Recovery (QPR) [40,41]. The 15-item QPR has good internal consistency (QPR total α=.89), fair to good test-retest reliability (QPR total intracluster correlation coefficient [ICC]=0.74), moderate sensitivity to change, and adequate convergent validity [42]. The QPR is a measure that assesses the 5 core processes of personal recovery that comprise the "Connectedness; Hope and optimism about the future; Identity; Meaning in life; and Empowerment" (CHIME) framework [43], which is currently the strongest conceptualization of personal recovery in serious mental illness. The Recovery ACT group program seeks to support change in these dimensions for participants.

Secondary Outcomes

The secondary outcomes are well-being (Clinical Outcomes in Routine Evaluation 10 [CORE-10]) [44] and 4 psychological flexibility process variables, namely committed action (the Valuing Questionnaire's Progress scale comprised of items 3, 4, 5, 7, and 9) [45], mindfulness (Southampton Mindfulness Questionnaire) [46], cognitive defusion (Cognitive Fusion Questionnaire) [47], and experiential avoidance (Brief Experiential Avoidance Questionnaire) [48].

Other Clinical Outcomes

A facilitator will rate illness severity at enrollment and before the start of the group using the "Clinical Global Impression–Severity" scale and will rate illness improvement at the end of the group and at the booster session using the "Clinical Global Impression–Improvement" scale [49,50].

Consumer and Facilitator Feedback

Permission will be sought from participants to use their responses to routine qualitative feedback questions for evaluation purposes. These questions ask about their hopes and expectations for the group (at T0), helpful and unhelpful aspects of the group (at T2 and T3), requests for remaining sessions (at T2), and reflection on any perceived changes attributed to the group (at T3 and T4). The method of collecting these routine feedback responses is dependent on the site. The baseline feedback questions (at T0) are typically asked and recorded by a facilitator during the "Information and Engagement" session; the feedback questions at other time points are typically written responses by participants. Qualitative data about the group will be sought from facilitators who consent to participate in a semistructured interview after completing a group. The qualitative interview will assess the feasibility of the group, its evaluation in routine practice, and perceptions of the group program's effectiveness.

In addition, during the initial consent process, participants will be asked for written consent to contact them in the future to invite them to participate in a follow-up study involving a qualitative interview exploring their experience of participating in the group.

Statistical Methods and Sample Size

We intend to use an intention-to-treat sample to test a univariate latent growth curve model of the primary outcome from before the start of the waitlist period to the start of the group to the booster session in order to compare the trajectory over the waitlist period to the trajectory over the active treatment period. We selected this method of analysis to strengthen our estimations of associations due to the limitations of the nonrandomized study design chosen as the most realistic option for an evaluation of a program already in routine practice [51]. A minimum sample size of 90 is required to conduct the proposed growth curve structural equation model (5 observed variables and 2 latent variables) with an anticipated medium effect size (0.3), α set at .05, and power (1–β) at .80. Univariate latent growth curve models for each of the 5 secondary outcomes will also be tested. If there are sufficient data, we will test whether the trajectory of the 4 psychological flexibility process variables from the start of the group to the midpoint session (T1 to T2) is significantly associated with the trajectory of personal recovery (T2 to T4) using multivariate growth models. We do not predict a priori any differences associated with the study site. We intend to calculate the ICC after the data are collected to determine the relatedness of the data collected at different study sites.

Randomization and Blinding

This study is a nonrandomized (unblinded) trial that uses a single group, waitlist control, and a quasiexperimental design. All participants serve as their own control. The data for all participants on change in outcomes over the waitlist period (no active intervention) will be used to compare with the data on change in outcomes during the active intervention. The planned statistical methods will strengthen our conclusions. The risk of researcher bias is lessened by the self-report format of the primary and secondary outcomes and the opportunity for participants to submit questionnaires in a sealed envelope.

Data Collection and Management

The data will be collected using deidentified hardcopies of all evaluation documents (quantitative questionnaires completed by participants and facilitators, copies of qualitative feedback forms, and demographic and clinical information forms), and other trial documents (attendance records, fidelity logs, and recruitment logs). Facilitators will assist participants with questionnaire completion if needed. As facilitators will serve a dual role as clinical service providers and study personnel, participants will be provided a sealable envelope to return deidentified self-report questionnaires that will be reviewed by study personnel other than their facilitators if sealed (either at the site or by the study coordinator). If a participant does not attend a group session when data are collected, facilitators will attempt to schedule an appointment to complete study measures.

Deidentified data from hard copy evaluation documents will be entered into a password-protected electronic file maintained on secure computers by the study coordinator. A coding sheet with identifiable participant information will be saved as a password-protected electronic file on the sponsor site's server. Hard copies of consent forms and study documents will be kept in a locked filing cabinet at the Academic Psychology Unit located at the sponsor's site.

Data Monitoring and Adverse Event Reporting

Anticipated risks to participant safety due to participation in the evaluation and the group are deemed minimal based on pilot study data [35]. Therefore, there is no data monitoring committee, and there are no planned interim analyses to identify risks. Adverse events will be monitored by facilitators, site principal investigators, the coordinating principal investigator, and the Interagency Investigator Committee. An adverse event form and guideline are used.

An Interagency Investigator Committee led by the coordinating principal investigator meets quarterly to oversee the trial's progress, monitor any adverse events or serious adverse events related to the procedures or the group program, and discuss any necessary protocol modifications. A study coordinator is responsible for liaising with the site principal investigators, who

are responsible for the evaluation at each site. In addition to the published Recovery ACT group program manual, evaluation procedure manuals were created to ensure that the protocol is adhered to by study personnel at all sites and over the course of the multiyear study.

Ethical Considerations

Melbourne Health's Human Research Ethics Committee (HREC/51498/MH-2019) provided ethics approval for this study. All methods will be performed in accordance with the relevant guidelines and regulations, and written, informed consent will be obtained from participants. The results of the main aim of the study will be published in a peer-reviewed scientific journal and submitted for presentation at clinical and scientific meetings and conferences. The coordinating principal investigator will oversee the publication and presentation of study results, including decisions about authorship. Participants are asked whether they would like to be informed of the main results of the study. Those who express interest and provide contact details will be provided with this information when it is available. Participants who complete quantitative outcome measures will be compensated with a US $6.54 department store voucher at each time point.

Results

Trial enrollment began in September 2019 and was originally planned to continue until at least March 2022. In March 2020, the Victorian Government in Australia introduced public health directions in response to the COVID-19 pandemic that derailed study progress as in-person groups were not permitted for over 20 months at some sites. While study recruitment and follow-up study procedures were broadened to allow for the use of telehealth, the group program format (in-person) was not changed as it would introduce significant variability to the study outcomes. As there remains notable interest from all stakeholders (investigators, facilitators, managers, and consumers), the study will continue to accept enrollments until at least 2024. As of the submission of the manuscript, 93 participants consented to the evaluation, 65 completed T1 measures, and 40 had a complete dataset for the proposed analyses. No data analysis has been conducted. Due to the uncertainty of the trial's viability due to the public health directions during the COVID-19 pandemic, the protocol's publication was delayed. The current protocol version is 8.0 (issue date: July 14, 2021).

Discussion

To our knowledge, this is the first trial in Australia evaluating the effectiveness of an ACT for psychosis group program on personal recovery outcomes. Although limited by the single-group design, its strength lies in the opportunity to evaluate effectiveness in routine practice. External validity is strengthened by the practice settings being spread across 4 public mental health networks in a large city, serving communities with a range of sociodemographic characteristics.

A randomized design was not feasible as the program is offered in routine practice [51], thus limiting causal conclusions. However, the quasiexperimental design includes a waitlist period that provides a baseline comparison to evaluate the effectiveness of the group program and can also allow for process analyses if sufficient data are collected. A further enhancement is a proposed qualitative follow-up study of the experience of the group program, intended to inform program development and assist in the interpretation of quantitative results.

A feature of note is the clinician-initiated origin of the evaluation and the forging of a partnership between clinicians and academics during a previous pilot evaluation that then led to the co-design and collaborative implementation of the trial [34]. This clinician-researcher partnership is likely to not only ensure the practical applicability of program modifications and the feasibility of study procedures, but may also lay the foundations for more rapid implementation into practice should the results warrant it. Nonetheless, as an unfunded study, the project is subject to significant risk of noncompletion as it relies on the participating mental health services supporting facilitators to undertake some evaluation tasks, services continuing to provide the group program over the proposed study period, and the support of the sponsor site to provide a study coordinator.

This study exemplifies an effectiveness-implementation hybrid trial [52]. If successful, the trial will further support psychosocial interventions to improve personal recovery among consumers who experience persisting psychotic symptoms.

Acknowledgments

The authors would like to thank all facilitators, colleagues, and peer reviewers for their contributions to the development of the protocol, including Ms Sheran Kay. The authors also thank all facilitators who offer their service in kind to collect data, as well as local area managers and department heads at each site. The authors are also grateful to all consumers who participated in the trial.

This is an unfunded study. This study received in-kind support from NorthWestern Mental Health-Royal Melbourne Hospital, St Vincent's Hospital-Melbourne, Alfred Mental and Addiction Health, Peninsula Health Mental Health Service, and La Trobe University. Participant gift vouchers are courtesy of La Trobe University.

Data Availability

The data sets generated during or analyzed during this study are not publicly available as the authors do not have research participants' permission to share data.

Authors' Contributions

JF was the initial coordinating principal investigator; EMJM is the current coordinating principal investigator. JF, EMJM, and MLC led the evaluation development, and all authors contributed. All authors contributed to either the conception, design, or acquisition of ethics and governance approval of the evaluation. MLC and JF were major contributors to writing the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Most new HIV diagnoses among cisgender women in the United States occur in the South. HIV pre-exposure prophylaxis (PrEP), a cornerstone of the federal Ending the HIV Epidemic (EHE) initiative, remains underused by cisgender women who may benefit. Awareness and access to PrEP remain low among cisgender women. Moreover, improving PrEP reach among cisgender women requires effectively engaging communities in the development of appropriate and acceptable patient-centered PrEP care approaches to support uptake. In a community-clinic-academic collaboration, this protocol applies an evidence-based community organizing approach (COA) to increase PrEP awareness and reach among cisgender women in Atlanta.

Objective: The aim of this study is to use and evaluate a COA for engaging community members across 4 Atlanta counties with high-priority EHE designation, to increase PrEP awareness, interest, and connection to PrEP care among cisgender women.

Methods: The COA, consisting of 6 stages, will systematically develop the skills of community members to become leaders and advocates for HIV prevention inclusive of PrEP for cisgender women in their communities. We will use the evidence-based COA to develop and implement a PrEP-specific action plan to create broader community change by raising awareness and interest in PrEP, reducing stigma associated with HIV or PrEP, and connecting women to sexual health clinics providing PrEP services. In the first 4 stages, to prepare for and develop action plans, we will gather data from one-on-one interviews with up to 100 individuals across Atlanta to capture attitudes, motivations, and influences related to women's sexual health with a focus on HIV prevention and PrEP. Informed by the community interviews, we will revise a sexual health curriculum inclusive of PrEP and community-centered engagement. We will then recruit and train community action team members to develop action plans to implement the curriculum during community-located events. In the last 2 stages, we will implement and evaluate COA's effect on PrEP awareness, interest, HIV or PrEP stigma, and connection to PrEP care among cisgender women community members.

Results: This project was funded by the National Institutes of Health and approved by the Emory University institutional review board in July 2021. Data collection began in December 2021 and is ongoing. COA stage 1 of the study is complete with 70 participants enrolled. Community events commenced in November 2023, and data collection will be completed by November 2025. Stage 1 qualitative data analysis is complete with results to be published in 2024. Full study results are anticipated to be reported in 2026.

Conclusions: Through a community-clinic-academic collaboration, this protocol proposes to mount a coordinated approach across diverse Atlanta counties to strengthen HIV prevention for cisgender women and to create a sustainable systems approach to move new sexual health innovations more quickly to cisgender women.

Introduction

Initiatives for ending the HIV epidemic in the United States must include cisgender women. Among ~37,000 people diagnosed with HIV annually in the United States, 19% are cisgender women, with the majority (~60%) of new HIV diagnoses among cisgender women occurring in the South [1,2]. Georgia has the highest rate of new HIV diagnoses (21% occur among cisgender women), and also has one of the highest rates of perinatal HIV infection [1,3]. HIV diagnoses among cisgender women in Georgia and nationally are more evenly distributed across age groups than in men, with magnified disparities by race or ethnicity [2,3]. This highlights the importance of women-tailored HIV prevention care, including pre-exposure prophylaxis (PrEP) to effectively reach all who may benefit. Within Georgia, the Atlanta metropolitan area accounts for over half of all annual HIV diagnoses [3], with 4 counties (Cobb, DeKalb, Fulton, and Gwinnett) identified as a high priority in the federal Ending the HIV Epidemic (EHE) initiative [4]. Reducing HIV in Atlanta is a public health priority, and cisgender women–tailored strategies will be necessary to achieve an end to HIV.

PrEP is dramatically underused by cisgender women. There has been wide-scale endorsement to bring PrEP use to scale through dissemination and implementation efforts in the United States since its approval in 2012 [5-8]. PrEP use has since steadily increased among men but remains flat in women [9]. PrEP is underused in women relative to need, especially in the Southern United States [10]. Women are <5% of US PrEP users, and account for only 2% of the estimated 176,670 cisgender women for whom PrEP is indicated [11,12]. The first steps for increasing PrEP uptake are ensuring that those who can benefit from PrEP are aware of it, and ensuring that PrEP is accessible in settings where they seek health care [13]. Unfortunately, PrEP knowledge is low among cisgender women in the United States, including in the Southern United States) [14-20] and among women's health care providers [21]. Encouragingly, cisgender women report interest in taking PrEP once informed [22,23], and women's providers are willing to prescribe PrEP once trained [21]. Our group previously investigated PrEP awareness and provider PrEP knowledge in 4 Atlanta family planning clinics that were not previously providing PrEP. Clients resided in 103 (91%) of 113 metropolitan Atlanta zip codes (the majority of clients resided in zip codes with HIV prevalence >1%) [14,24]. Only 95 (19%) of 500 cisgender women clients surveyed knew about PrEP, but after a brief provider training, 72 (66%) of 110 cisgender women with PrEP indicators received PrEP counseling during their visits. After receiving PrEP counseling, clients expressed interest in PrEP if it were offered on-site rather than through off-site referral. This study demonstrated the potential reach of sexual health clinics in high HIV burden areas as PrEP delivery sites.

However, PrEP delivery in publicly funded family planning clinics in the South remains low, despite clinical guidelines incorporating PrEP [25]. We previously surveyed nearly 600 providers or staff working in 286 Title X clinics across the South in 2018; only 22% of clinics provided any PrEP services (including through referral), and the Southeastern region (including Atlanta) had the fewest clinics offering PrEP [14,26].

Once clinic capacity for PrEP is built, it does not address low PrEP awareness among cisgender women. Lessons learned from the rollout of other prevention technologies, such as human papillomavirus vaccination [27] and new contraception methods [28], highlight the need to simultaneously address demand barriers that impede use [29]. We are learning that the same applies to scaling PrEP, particularly for cisgender women in Atlanta [14,15,24,26]. To date, efforts to scale PrEP in the United States have largely focused on PrEP awareness for men who have sex with men [8], despite continued low PrEP knowledge among women [15-20]. Our 2018 research found that once informed about PrEP, cisgender women in Atlanta wanted more information and widespread awareness-building specifically for women [30]. Thus, ending the HIV epidemic among women will require addressing uptake barriers through building interest in PrEP and promoting and connecting cisgender women to women-friendly PrEP clinics.

A comprehensive systems-level approach is needed to increase PrEP reach among cisgender women. To create a proactive solution for bridging the chasm from science to practice for PrEP use among cisgender women and building on our existing clinic-academic-community partnerships, we will innovatively use the Interactive Systems Framework (ISF) [31]. The ISF is a multisystem model to guide the dissemination and implementation of prevention programming through the work of 3 interactive systems, "prevention delivery" (implements the innovation in the real world), "prevention support" (provides training and technical assistance to users in the field), and "prevention synthesis and translation" (conducts research and distills information about innovations in user-friendly formats). The ISF has been used successfully by the Centers for Disease Control and Prevention (CDC) in their multisite

capacity-building effort to reduce teen pregnancies in the United States [32], showing its feasibility for building prevention infrastructure to guide large-scale prevention efforts in the area of sexual health for women [32,33]. All 3 systems, and the different stakeholders who populate each system, interact to support each other toward a common goal, which is necessary to mount successful, sustainable, large-scale adoption of new prevention innovations (eg, PrEP, including long-acting PrEP).

The ISF provides a strong model to strengthen access to PrEP care, but it lacks equally robust attention to addressing PrEP awareness and interest. Thus, in this protocol, we innovatively supplemented the ISF with an evidence-based community organizing approach (COA), previously demonstrated effective for addressing underage alcohol use [34,35]. This evidence-based approach can create broader change across the community for any community challenge [36,37]. The COA consists of 6 stages of activities. The first stage is assessing the community through one-on-one conversations with citizens, typically done by a lead community organizer (LCO). The second stage is building the base, in which an action team of approximately 15 citizens is assembled. The action team members are not typically affiliated with formal prevention programs or HIV coalitions and do not need to hold formal positions of power. Rather they are everyday citizens—a retired teacher, minister, stay-at-home parent, coach, and so forth—who care deeply about preventing HIV. The action team is then trained by the LCO on strategies for reducing HIV, including PrEP, and how to take actions to advance those evidence-based strategies (eg, where individuals can go to get these services near them). In the third stage, expanding the base, the action team builds additional rings of supporters connected to the effort. In the fourth stage, the LCO and action team members develop an action plan, wherein they schedule strategic actions designed to accomplish specific organizing outcomes (eg, sharing at community events). Stage 5 involves implementing the plan and carrying out their planned actions. Stage 6 involves assessing results, celebrating accomplishments, and refining the next steps that were planned. Thus, this COA systematically develops the leadership skills of trusted community members to become leaders and advocates for HIV prevention inclusive of PrEP for women in their communities.

We propose to innovatively use this COA to systematically develop the leadership skills and HIV prevention knowledge of individuals to become community advocates for HIV prevention in metro Atlanta to reduce HIV or PrEP-related stigma, build demand for PrEP, and facilitate linkages to women-friendly PrEP clinics. We hypothesize that the COA is feasible to implement and that the PrEP action plan implemented as part of the COA will be associated with increased PrEP awareness and interest, decreased HIV or PrEP stigma, and increased awareness about where women or individuals can get PrEP among cisgender women community members.

Methods

Study Setting

We will implement the COA (Textbox 1) within the 4 Atlanta high-priority EHE counties, in partnership with SisterLove, an Atlanta-based women's HIV and reproductive justice community based organization (CBO) that is internationally recognized for raising sexual health and HIV awareness among women and has deep connections in the community, and additional CBOs identified through our formative work.

Textbox 1. Description of the 6-stage community organizing approach.

Stage 1: assess community

Conduct one-on-one interviews to assess pre-exposure prophylaxis (PrEP) attitudes, motivations, and influences among key community members; use these findings to adapt a sexual health curriculum to address feedback.

Stage 2: build the base

Assemble "action teams" composed of approximately 15 individuals who work or reside across 4 metro Atlanta counties with the help of community-based organization partners and train them on an adapted sexual health curriculum.

Stage 3: expand the base

Identify individuals to engage during implementation (influencers to connect with to recruit women to attend workshops) and resources to contribute (eg, space to conduct the workshops).

Stage 4: develop an action plan

Schedule community education meetings across all 4 counties (5-10 per year per action team member) to reach diverse communities of cisgender women.

Stage 5: implement the action plan

Action team members conduct community events (~150 annually) using the adapted sexual health curriculum.

Stage 6: evaluate the action plan

Monitor the number of events, participant demographics, and fidelity to the sexual health curriculum; collect survey data to evaluate changes in PrEP awareness, interest, stigma, and reach.

Implementation of the COA

Preparing for Action (COA Stages 1-4)

We will first hire and train an LCO. In collaboration with the Emory team, the LCO will assess the community (COA stage 1) through one-on-one conversations with up to 100 individuals across Atlanta; ~25 per EHE county (collaborating CBOs will assist in identifying individuals such as opinion leaders, influential partners in their work, and diverse women in the community). Interviews will capture attitudes, motivations, and influences related to women's health and well-being, as well as their sexual health, with a focus on HIV prevention and PrEP. Interviews will be recorded and transcribed. Using an inductive coding approach, the LCO and Emory team members will code interviews and identify themes salient to address during COA implementation. We will then use findings to adapt SisterLove's existing sexual health curriculum (Healthy Love Workshop [38]) to address community feedback salient to PrEP use among women. Healthy Love is an evidence-based single-session, a small-group intervention for women with core content designed to increase participants' HIV and sexual health knowledge (including prevention strategies), risk perception, and self-efficacy to engage in HIV or sexually transmitted infection (STI) testing and preventative practices. The fundamental information within Healthy Love, specifically related to knowledge, risk perception, and self-efficacy for testing, will be retained, and updates will be made to incorporate information about PrEP.

Next, we will build the base (COA stage 2) by assembling action teams comprised of approximately 15 individuals who work or reside across all 4 counties with the help of CBO partners. Action teams will be essential for reaching diverse groups of women in their community and raising awareness, interest, and connection to PrEP via facilitating educational outreach. Action team members will be asked to commit to at least 1 year of engagement. They will be provided with an annual honorarium for serving in this role, and a certificate of appreciation from SisterLove and Emory teams acknowledging their significant role in reducing HIV in their communities. Action team members will work in coordination under the LCO, but each team will focus their implementation activities on their respective EHE counties. The LCO and SisterLove team will prepare the action teams with training on the adapted sexual health curriculum, supplemented with information on women-friendly places to access PrEP.

To expand the base (COA stage 3) action team members will identify individuals to engage during implementation and resources they might be able to contribute during implementation (eg, space for community education meetings to conduct adapted Healthy Love Workshop, audiences for meetings, and access to influencers to connect with to recruit women to attend meetings). As part of COA stage 4 (developing an action plan), the goal for each action team member is to arrange 5-10 community education events to be held per year in their EHE county. The LCO and action team members (supported by SisterLove and Emory teams) will schedule community education meetings reaching diverse communities of cisgender women, built on the unique reach of each action team member, across the 4 EHE counties.

Implementing and Evaluating the PrEP Action Plan (COA Stages 5-6)

Over 2 years, action team members will collectively conduct ~300 community events (~10 events per action team member per year) with an average of 10 community members attending each event. The action team members will facilitate their planned events (~2 hours each), following the adapted Healthy Love Workshop manual, with the assistance of the LCO, SisterLove, and the Emory team for data collection.

To monitor the implementation of the PrEP action plan, we will use electronic monitoring logs to capture (1) the number of community events scheduled or conducted by each action team member with dates and locations recorded, (2) the number and demographics of participants at each event (gathered through attendance logs at events), and (3) the number of requests for scheduling other community meetings. A study team member will collect monitoring data at each event to ensure the accuracy and completeness of logs and use a fidelity checklist to record fidelity to the adapted sexual health curriculum for each event.

We will collect data via surveys from the ~3000 community event participants to evaluate changes in PrEP awareness, interest, stigma, and reach after participating in a community education event conducted as part of the PrEP action plan. Specifically, all cisgender women participants at community events will be asked to complete brief pre- and posttest surveys that include measures on demographics, knowledge and attitudes about PrEP [15], concerns or barriers to PrEP use [39], and PrEP or HIV stigma [40,41]. Upon arriving at the event, each participant will sign in (name, email, phone number, and social media usernames) on a study laptop. Two additional questions will be asked: (1) "Is it ok to contact you in a few months to ask a few follow-up questions about the workshop—you will receive a US $5 gift card for your time?" and (2) "What is your preferred way to be contacted—text, phone, or email?" Participants will then be assigned a unique identifier to be used in the pre- and posttest surveys which will be administered electronically using a QR code link. The study team member will verify the unique identifier used with the participant ID log which will be stored separately from the participant's contact information. Participants' pretest surveys will be collected at the onset of the event, and posttest surveys will be collected upon completion. Study staff will review surveys upon collection and encourage participants to complete any missing items. Approximately 3 months after participation, ~50% of participants (among those agreeing to be contacted) will be randomly selected per event to participate in a brief survey (via text, email, or phone). Survey questions will be yes or no items assessing PrEP reach since participation in the community event to determine whether the participants has (1) received HIV or STI testing, (2) gone to a clinic for sexual health services, (3) talked to a health care provider about PrEP, (4) started PrEP, and (5) shared information about PrEP with other women (if so, how many). See Table 1 for a full list of evaluation measures.

Table 1. Comprehensive evaluation of pre-exposure prophylaxis (PrEP) action plan implementation on PrEP awareness, interest, and connection to PrEP care.

Method	Data source	Timing	Evaluation measures
Action plan implementation monitoring	Electronic monitoring log to capture the number of events, number of participants, types of PrEP resources shared, and number of requests additional events	Completed for each community event	Number of community events conducted by each action team member; number and demographics of participants at each event; and number of requests for scheduling other community meetings
Fidelity to sexual health curriculum	Fidelity checklist to record fidelity to the adapted sexual health curriculum in real time	Completed for each community event	Overall and individual checklist item
Pre- and posttest assessment of events	Brief paper-pencil pre- and posttest survey completed by ~3000 cisgender women attending community events	All cisgender women who participate in community events before and after the event	Demographics, knowledge, and interest in PrEP, PrEP stigma and attitudes about PrEP, history of PrEP use, and knowledge of PrEP clinics
Follow-up survey after events	Random sample of 50% of community event participants who agree to be contacted will be sent a brief email or text survey	Three months after participating in a community event	Yes or no questions since event: (1) received HIV testing, (2) went to Title X clinic that provides PrEP, (3) talked to a doctor about PrEP, (4) started PrEP, and (5) shared information about PrEP with other women (if so, how many)
PrEP reach among cisgender women seen in area clinics	Number of PrEP prescriptions to cisgender women seen in PrEP-providing clinics shared in community event resource list	Quarterly before, during, and after community events	Changes in number of PrEP prescriptions to women per quarter among PrEP-providing clinics

Statistical Analysis Plan

Descriptive statistics will be conducted on monitoring and fidelity data by year for each of the 2 implementation years. Feasibility of the COA will be determined by (1) successful implementation of ~10 community events per year by each action team member (~15 members), (2) at least 100 community members reached by each action team member per year (as indicated by # of participants attending their events), and (3) high fidelity to the adapted Healthy Love by action team members per year (>80% fidelity: determined by fidelity checklist indicating >80% content completed per event).

For pre-post assessments, scores on scales will be computed according to published guidance [39-42]. Descriptive analyses and paired *t* tests or chi-square tests will be conducted to ascertain pre-post changes in PrEP awareness, interest, stigma, and knowledge of where to access PrEP. For follow-up surveys, descriptive statistics will summarize the connection between PrEP care, connection to HIV testing, and PrEP reach (ie, self-reported initiation of PrEP) among the subset of community event participants who complete a follow-up survey.

We will conduct exploratory logistic regression analyses examining the association between pre-post survey scores (PrEP knowledge, attitudes, barriers, stigma, and prior use of PrEP) on PrEP reach, including demographic factors as covariates. Finally, exploratory descriptive analysis will summarize changes in PrEP reach among cisgender women receiving care at publicly funded family planning clinics in the 4 Atlanta EHE counties (number of PrEP prescriptions to women per quarter among PrEP-providing clinics discussed or shared during community events) for each year before, during, and after PrEP action plan implementation. Given our design, it is not appropriate to conduct comparison tests for this analysis.

Ethical Considerations

This study was approved by the Emory University institutional review board (#00002950). For the community interviews which were all completed via video conferencing, a waiver of documentation of consent was obtained, and the interview was completed after verbal consent. Community interview participants received a US $50 gift card upon completion of an interview. Community event participants who complete pre-post assessments and follow-up surveys will provide written informed consent. Community event participants will receive a US $5 gift card for completion of the 5-item 3-month follow-up text or email survey.

Interviews are conducted by trained research staff and recorded with audio recording devices; we instruct individuals to avoid using their names during the interview. In the event an identifier is used in the recording, all personally identifiable information is redacted from the transcripts during data quality assurance procedures performed by the study team. All audio recordings are professionally transcribed by a trusted vendor with secure web-based file transmission procedures. After transcription, the study team reviews each transcription against the audio recording to ensure verbatim accuracy and to remove identifiable information from the transcripts during this quality assurance procedure. After all transcripts are quality-checked and saved, the audio recordings will be destroyed. A study log kept by the study team will document this process. Transcripts and audio recordings are only stored on secure, password-protected platforms. No personal identifiers will be stored for other data

collection components, except to contact community event participants for follow-up surveys and distribute participant incentives. Personal identifiers will not be linked to any other data and will be destroyed as soon as survey invitations and participant incentives have been distributed.

Results

Study activities were funded by the National Institutes of Health (NIH) and was approved by the institutional review board in July 2021 and data collection began in December 2021 and is ongoing. From December 2021 to October 2022, we hired and trained the LCO and completed 70 community interviews with key stakeholders. Eligible participants worked or resided in Dekalb, Gwinnett, Fulton, or Cobb County in the state of Georgia and were able to provide verbal consent to participate. Participants were primarily female-identifying (n=64, 91%); of 70 total participants, 20 (29%) endorsed being a lay community member, while others reported community involvement through organizations or businesses (n=19, 27% members of a nonprofit organization; n=12, 17% staff at a clinic; n=4, 6% self-employed; n=4, 6% college students; and n=1, 1% affiliated with a faith-based organization). About 10% (n=7) of participants reported involvement in HIV support groups (n=5, 7%) or advocacy groups (n=2, 3%) as their community involvement. Of those who reported race and ethnicity (n=46, 66%), 35 (76%) identified as Black, 7 (15%) identified as White, and 4 (9%) identified as more than 1 race. A total of 4 (9%) participants reported Hispanic or Latino ethnicity which parallels HIV diagnoses by race or ethnicity in Georgia [3].

From October 2022 to December 2022, we analyzed interview data and identified important preliminary themes in these conversations including the need for broad-based, inclusive approaches to discussions about women's sexual health and HIV prevention with accurate, straightforward, and reliable content delivered by trusted, relatable members of the community in safe and easy to access spaces. From December 2022 to June 2023, we collaborated with SisterLove on the adaptation of the Healthy Love sexual health curriculum based on these preliminary community interview findings while taking care to retain fundamental information within Healthy Love, specifically related to HIV knowledge, risk perception, and self-efficacy for testing (COA stage 1). From February 2023 to July 2023, we recruited and trained a diverse group of 15 action team members and gathered feedback on the curriculum adaptation. Additional changes to the curriculum were made based on community feedback from July to August 2023. Community events commenced in November 2023 and data collection will be completed by November 2025. Full trial results are anticipated to be reported by July 2026.

Discussion

Principal Findings

Using a COA that engages and supports community members in educating other community members about their sexual health can broaden and enrich the awareness, and potentially the reach of, HIV prevention, testing, and PrEP into diverse networks of cisgender women. Our findings in assessing the communities in metro Atlanta thus far have affirmed the need for greater emphasis on women-inclusive initiatives delivered by individuals considered relatable within the community who are comfortable and knowledgeable about discussing sexual health with the overarching goal of creating safe spaces for authentic conversations. Taking this into consideration when forming action teams, the LCO, with the assistance of SisterLove and Emory partners, dedicated extra time and attention during stage 1 of the COA to identify, recruit, and train team members to ensure that teams remain representative of women of varying ages, races, ethnicities, and social networks living in EHE high priority counties in metro Atlanta.

Adjustments in the protocol for the adaptation of the evidence-based Healthy Love curriculum by SisterLove, Inc were also made to include the opinions and feedback of the action team members on the revised curriculum content. Initial curriculum revisions were drafted to include content salient to data outcomes from the in-depth community interviews capturing attitudes, motivations, and influences related to women's sexual health, with a focus on HIV prevention and PrEP. The revised draft was then presented to action team members as a community event and their feedback was gathered and later incorporated into the final curriculum to guide action teams in facilitating health education community events.

Moving forward, we anticipate that the evidenced-based COA will be feasible, and participation in its community events will be associated with increases in PrEP awareness and interest, decreases in PrEP or HIV stigma, and greater knowledge about where women can go for PrEP care (eg, PrEP-providing Title X clinics). We also expect that participation in events will be associated with improved PrEP reach among women who participate. These findings will provide critical data related to the COA use to create a potentially sustainable community-engaged approach for disseminating information about new HIV prevention products from trusted members in the community inclusive of cisgender women.

Limitations

Action team members may discontinue participation over time. If this occurs, we will work with our collaborating CBOs and other action team members to recruit new individuals into this role. If a member withdraws before completing community events, other action team members, the LCO, and CBO staff will conduct the remaining scheduled events. We may encounter challenges related to the completion of the follow-up survey. If randomly selected individuals do not complete the survey, we will select another. We expect 90% will indicate willingness to be contacted, and we are only attempting to sample 50% of participants, so we are confident we can achieve our goal sample size.

Conclusions

Through a community-clinic-academic collaboration and innovative application of COA, this protocol proposes to mount a coordinated approach across diverse Atlanta counties to strengthen HIV prevention for cisgender women, and importantly, to create a sustainable systems approach to move

new and sexual health innovations more quickly to cisgender women.

Acknowledgments

The authors would like to thank the study staff, community and clinical partners, and study participants who supported this work. They would like to acknowledge their community action team members for their key role in this study, Athena Carpenter, Ashley Cobb, Aku Dogbe, Muriel “Alea” Grant, Zykeria Holmes, Bailey Ledbetter, Mayra Martinez, Simitri Nassar, Rosie Palmer, Alexis Perkins, and Masonia Traylor. This study is funded by the National Institutes of Health (NIH; R01MH121962).

Abstract

Background: Neonatal unit (NU) admissions for premature babies can last for months, which can significantly impact parental mental health (MH) with symptoms of depression, stress, and anxiety. Literature suggests fathers experience comparable MH symptoms to mothers. Family integrated care (FICare) is a culture where parents are collaborators and partners in caring for their hospitalized newborns. FICare improves infant outcomes and maternal MH. Similar reports on fathers are limited.

Objective: The primary aim of this study is to investigate the impact of supporting father or partner engagement in FICare of preterm infants on their MH up to 6 weeks postdischarge. The secondary aim is to investigate the impact on maternal MH.

Methods: This is a 2-phase study: phase 1 to gather baseline information and phase 2 to assess the impact of enhanced father or partner engagement in FICare on their MH, involving 2 NUs (tertiary and level 2). Enhanced FICare will be developed and introduced (eg, information booklet, workbook, classes, and a father peer-support group) alongside standard FICare practices. Father or partner MH will be assessed with semistructured qualitative interviews and validated questionnaires: Generalized Anxiety Disorder Assessment, Patient Health Questionnaire, and Parental Stressor Scale: Neonatal Intensive Care Unit from NU admission to 6 weeks postdischarge. Mothers will be assessed by focus groups and the same questionnaires. Descriptive statistics and appropriate comparative tests, such as the 2-tailed *t* test, will be used to analyze and compare phase 1 and 2 data. Qualitative data will be coded line by line with the use of NVivo (Lumivero) and thematically analyzed. Simultaneously, systematic reviews (SRs) of fathers' experiences of FICare and their MH outcomes will be conducted. The study was approved by the National Research Ethics Committee (22/EM/0140) in August 2022. A parent advisory group was formed to advise on the study methodology, materials, involvement of participant parents, and dissemination of study findings.

Results: A recent SR demonstrated that data saturation is likely to be achieved by interviewing 9 to 17 participants. We will study a maximum of 20 parents of infants born at less than 33 weeks' gestation in each phase. As of October 2023, the study was

ongoing. The SR studies are registered with the PROSPERO database (324275 and 306760). The projected end date for data collection is July 2024; data analysis will be conducted in November 2024 and publication will occur in 2025.

Conclusions: The study aims to demonstrate the feasibility of using a father or partner-sensitive FICare model for parents of premature babies with a positive impact on their MH. It will demonstrate the feasibility of providing FICare to extremely premature babies receiving intensive care. This study may support the development of inclusive FICare guidelines for nonbirthing parents and their extremely premature infants.

Introduction

In 2019, in England and Wales, 49,489 premature births were recorded, and the majority would have required a neonatal unit (NU) admission [1]. Scientific and technological advancements have led to significant reductions in mortality and morbidity for preterm infants [2], and now the importance of decreasing psychosocial morbidity for the family unit is being addressed. Admission of a critically ill baby to the NU is a deeply traumatic time for parents and may result in parental mental health (MH) difficulties during and after discharge [3,4]. Studies exploring paternal experiences in the NU highlight fathers feeling neglected and in a unique position of stress, trying to balance work and home life to allow the mother to focus on their sick baby [5]. As paternal and maternal MH are closely linked, supporting the fathers could also positively impact maternal MH [6,7]. A recent study has shown reduced paternal stress in relation to the provision of family integrated care (FICare) in single-family rooms, but it only included parents of babies who did not require intensive care [8].

FICare in the NU means that parents are partners and collaborators in the care of their hospitalized baby, rather than observers or visitors. They are included in decision-making and supported to feed, clean, and hold their baby as well as learning how to provide neurodevelopmental care [9,10]. FICare studies that have focused on mothers and infants demonstrate improved neurodevelopmental outcomes [11], improved breastfeeding rates [12], reduced infection rates, and improved maternal MH [13,14]. There is a paucity of similar research regarding fathers [15]. The impact of parental MH on children is a focus of the UK government's "First 1000 days of life" paper [16]. Implementation and improvements to FICare as a method of enhancing "parenting opportunity" are also highlighted in the National Neonatal Critical Care Review in England [17]. Synthesizing the evidence base surrounding the impact of paternal engagement addresses recommendations from National Health Service (NHS) England, the Cross Government 1001 Critical Days Campaign [7], the Neonatal Critical Care Transformation Review, and Care Quality Commission standards to increase the evidence base to support women and their families experiencing perinatal MH problems. This area currently costs the NHS an estimated £1.2 billion (equivalent to US $1.5 billion) per year [16,17]. The UK government has recently recognized the importance of maternal and paternal presence for babies in the NU via the Neonatal Care (Leave and Pay) Act, which achieved royal assent in May 2023 granting parents up to an additional 12 weeks of leave [18]. Hence, we developed a study protocol to investigate and enhance fathers' or partners' involvement in FICare and its impact on their MH.

This study will be the first to report on fathers' experiences of FICare in the NU with extremely premature babies. It will broaden the field of FICare research with respect to fathers from diverse social and cultural backgrounds and will highlight the needs of fathers in the NU. Therefore, it will demonstrate the value of designing a father- or partner-sensitive FICare program. This study will also generate evidence for the feasibility of the introduction of FICare from day 1 while preterm babies are receiving intensive care.

From here on, although the study refers to "fathers," all second parents of any gender or relationship status are included under this term throughout the remaining text.

Methods

Aims

This study aims to undertake an in-depth longitudinal study of the engagement of fathers or partners in FiCare and their experience and MH from NU admission to 6 weeks postdischarge of their premature baby born at 22 to 33 weeks' gestation.

Objectives

Our objectives are to (1) assess baseline fathers' experiences in the NU, their involvement in FICare, and MH status during babies NU admission up to 6 weeks postdischarge, (2) conduct systematic reviews (SRs) of published papers on "Fathers and FiCare in NU" and "Fathers' MH in the NU," (3) develop a program to enhance the involvement of fathers in FiCare, and (4) introduce the program developed to enhance fathers' involvement in FiCare and explore their experiences and effects on their MH.

Outcomes

The primary outcome is paternal MH (stress) assessed by semistructured interviews.

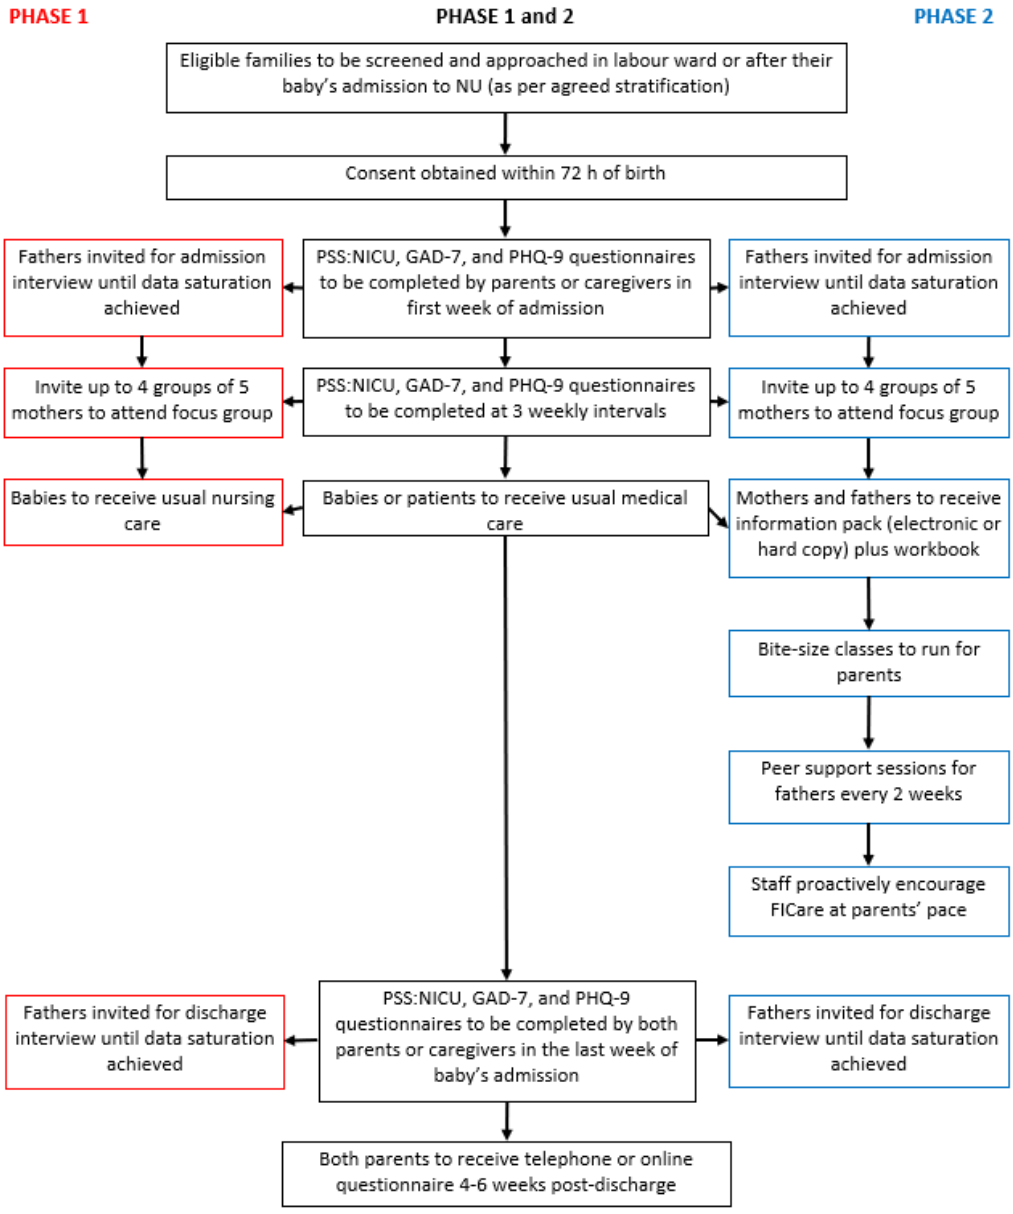
The secondary outcomes are (1) maternal stress, assessed by the Parental Stressor Scale: Neonatal Intensive Care Unit (PSS:NICU) questionnaire; (2) paternal stress, assessed by the PSS:NICU questionnaire; (3) parental anxiety, assessed by the Generalized Anxiety Disorder Assessment-7 (GAD-7); (4) parental depression, assessed by the Personal Health Questionnaire-9 (PHQ-9); and (5); paternal engagement with FICare, assessed via interviews.

Study Design

This is a prospective, multicenter, and multiphase study. Phase 1 will assess baseline fathers' experiences in the NU, their involvement in FICare, and MH status during babies' NU admission up to 6 weeks postdischarge. Simultaneously, an SR of fathers' involvement in FICare and their MH outcomes will be conducted. A program to enhance the involvement of fathers in FICare will be developed using information from the phase 1 study, SR, existing DadPad or Imperial Family Delivered Neonatal Care app, and advice from the parent advisory group (PAG). In the phase 2 study, an enhanced father involvement program in FICare will be implemented and similar assessments as in phase 1 will be conducted (Figure 1). We will provide regular debrief sessions, and research updates or newsletters to keep staff engaged and supportive of the project. This support will be continued throughout the study.

This study has been registered with clinicaltrials.gov (NCT06022991) [19].

Figure 1. Participant flow chart. FICare: family integrated care; GAD-7: Generalized Anxiety Disorder-7; NU: neonatal unit; PHQ-9: Patient Health Questionnaire-9; PSS:NICU: Parental Stressor Scale: Neonatal Intensive Care Unit.



Systematic Reviews

The SR studies have been registered on the PROSPERO database (324275 [20], 306760 [21]) and will follow a similar methodology. A literature search of health care databases including EMBASE, EMCARE, CINAHL, Medline, BNI, PYCHInfo, and Psychology and Behaviour, and a gray literature search will be conducted. Two independent researchers will screen the results at the title and abstract level against the eligibility criteria (Table 1), with mediation by a third researcher available for any disagreements to reevaluate the paper and come to a team agreement. The matrix method will be used for data extraction [22].

Table 1. Eligibility criteria for the systematic reviews.

[a]NU: neonatal unit.

[b]FICare: family integrated care.

Study Centers

The study will be conducted at a tertiary NU (level 3) and a local NU (level 2), as defined by the Department of Health [23], in East London, United Kingdom. Average annual admissions are approximately 900 and 600 respectively, with parents from diverse ethnic and socioeconomic backgrounds. Both level 3 and 2 NUs are selected to show the feasibility of delivering enhanced father involvement in FICare in all NUs and the study findings are applicable to all levels of NUs. Although FICare culture is practiced at both sites, a formal program and expectations of FICare are not implemented.

Clinical Staff Involvement

The wider multidisciplinary team was consulted in the study design and consideration of phase 2 study materials. They included physiotherapists, clinical psychologists, occupational therapists, dieticians, and speech and language therapists along with neonatal nursing input. The London neonatal network care coordinator was also consulted regarding the study design and implementation.

Patient and Public Involvement

Patients and the public were involved in the design, conduct, reporting, and dissemination plans of the study. A PAG consisting of parents of preterm infants was developed. They consisted of a diverse socioeconomic and cultural mix of 4 fathers and a mother who had experienced the admission of their premature baby in the NU within the last 4 years. The PAG was involved in developing the study design. The PAG has reviewed and provided feedback on study materials, for example, participant information leaflet. A lay member is included as a coinvestigator (JB, Director of Inspire Cornwall CIC's Neonatal DadPad) of the study.

The PAG was consulted to advise on the burden of intervention and the time required to participate in the research. This has influenced the frequency of questionnaire administration and locations of interviews and focus groups. They will support the development of appropriate phase 2 materials for the information booklet, workbook, and education sessions. The PAG will also support the dissemination of the study findings to research participants, related charity bodies (eg, Bliss), and the wider neonatal community.

Study Participants and Recruitment

Parents of preterm infants will be recruited to the study.

Inclusion Criteria

The inclusion criteria are as follows: (1) parents of 22^{+0} to 32^{+6} weeks preterm infants; (2) infants aged 1 to 7 days; (3) infants with 2 primary caregivers (the father's or partner's participation in the study is a must, and participation from both parents is ideal), and (4) the parents should have conversational English.

Exclusion Criteria

The inclusion criteria are as follows: (1) infant with life-limiting conditions or no realistic chance of survival, (2) infant is likely to be transferred to nonparticipating center within 4 weeks of age, and (3) parents are younger than 16 years.

All parents with babies born between 22^{+0} and 32^{+6} weeks' gestation admitted to the participating centers at less than 7 days of age will be assessed for eligibility. A sequential recruitment strategy will be followed with all eligible parents from the date of recruitment opening until 20 parents have been recruited in each phase. Within each eligible parent, consent and recruitment of the father or partner is essential. Maternal recruitment in addition to the partner, is encouraged but not mandatory.

Sample Size

The sample size of the study is estimated based on qualitative study outcomes. A recent SR of qualitative study demonstrated that to achieve data saturation we need to interview 9 to 17 participants [24]. A focus group of 5 to 7 participants would be

enough for in-depth conversations and 2 or more groups would increase the chances of successful data output [25].

In the first and second phases, up to 20 parents will be recruited (until the fathers' interviews reach data saturation). With a father and mother each, there could be 40 participants per phase. In total, there could be 80 participants in the study.

Phase 1 Study: Baseline Data Collection (9 Months)

Overview

Phase 1 will be conducted as follows: (1) Prior to the introduction of the study to wider NU clinical staff members, staff knowledge, experiences, and opinions about the role of fathers and FICare will be assessed by a questionnaire. (2) Once a parent is recruited, the PSS:NICU [26] and MH questionnaires (GAD-7 [27] and PHQ-9 [28]) will be given to complete within 7 days. (3) Fathers or partners will be invited to participate in 2 semistructured interviews, within 2 weeks of recruitment and immediately prior to discharge. The interviews will explore their MH, experiences of bonding with baby, understanding the neonatal environment, and reflecting on their service expectations. Based on the father's or partner's preference, interviews will be undertaken either in a private room on the NU or digitally via MS Teams at a mutually convenient time. Interviews will be digitally recorded and are anticipated to last up to 1 hour. Data saturation is expected at around 12-15 fathers. (4) The parents will be asked to complete the PSS:NICU, GAD-7, and PHQ-9 questionnaires at 3 weekly intervals, finishing on the week of discharge, to monitor their MH through their NU stay. (5) Up to 4 groups of 5 mothers will be invited to participate in a focus group to assess their wellbeing, experience of the NU, and their perspective on support for and from their partners. This will occur in a room in the NU at a time convenient to the mothers. Groups will be organized until data saturation is reached. (6) Telephone interviews and emailed questionnaires will be completed by parents at 4-6 weeks postdischarge to assess family confidence and bonding after NU discharge.

Description of Questionnaires Used

PSS:NICU Questionnaire

The PSS:NICU was originally developed in 1993 [26]. It assesses neonatal intensive care unit–specific stressors on a Likert scale. Each item can be scored from 0 to 5, with a maximum total score of 230 over the 46 items. Modified versions exist, but the original full-length questionnaire will be used for this study as all subsections are of interest with changes to be implemented.

GAD-7 Questionnaire

The GAD-7 is a 7-item self-administered questionnaire that assesses the presence and severity of symptoms of anxiety over the preceding fortnight. Scores range from 0 to 3 on each item, with a total score ranging from 0 to 21. There are established set points for mild, moderate, and severe anxiety [27].

PHQ-9 Questionnaire

The PHQ-9 is a 9-item self-administered questionnaire that assesses the presence and severity of symptoms of depression over the previous two weeks. It is scored in the same manner as the GAD-7 with total scores ranging from 0 to 27 and with established set points for mild, moderate, and severe symptoms [28].

Washout Period, Phase 2 Preparation (4 Months)

A program to enhance father participation with the FICare model will be developed using the existing Neonatal DadPad or Imperial Family Delivered Neonatal Care app. Both of these apps are currently used in several NHS Trusts to guide fathers through their NU journey. The phase 1 and systematic review findings, along with guidance from the PAG will inform our decision for what is best suited for our local population.

Teaching sessions will be undertaken to educate and upskill all clinical NU staff on the study aims, recruitment, phase 1 study findings, and upcoming phase 2 study, highlighting the importance of fathers' role in the FICare (eg, teaching parents how to safely give nasogastric feeds and nappy changes in a ventilated baby). In addition, there will be regular FICare teaching for staff, including encouragement of parents to attend ward rounds, and with guidance to parents in the workbook (Table 2).

Table 2. Program to enhance father involvement in family integrated care.

Strategies	When	Who
Educational booklet or app, including • Introduction to the neonatal unit • Meeting the multidisciplinary team—tailored to the individual unit • Family integrated care • Taking care of yourselves • Routine care and "observations" • Breastfeeding • Developmental care • Medications • Nutrition and growth • Ventilation and breathing support • Cardiac (heart) conditions • Gastrointestinal and liver (gut) conditions • Brain development • Planning for discharge • Eyes	At parents' disposal	Both parents
Suggested tasks or workbook, including • Kangaroo care • Nappy changes in incubator • Mouth care and cleaning of baby • Reading of observations (heart rate, temperature, respiratory rate) • Helping to weigh baby • Bathing baby • Ward round participation	To work through at parents' pace	Both parents
Peer support sessions—led by specialist clinical psychologists or therapists	Every two weeks	Fathers[a,b]
Ward round participation	Daily	Both parents[a]
Bite-size education classes	2-3 per week at varying times including weekend	Both parents[a,b]

[a]Any parent in the unit is welcome to participate or attend.

[b]Sessions to occur at times to suit fathers with cultural, religious, family, and work obligations, as determined through phase 1 data collection.

Phase 2 Study: Enhanced Father Involvement in FICare (9 Months)

Once a family is recruited, the program developed to enhance the father's involvement in FICare will be implemented to take place at the parents' pace (Table 2). Materials will be freely available to the study participants in a format suited to their needs (electronic or paper copy). All interested parents are encouraged to attend the peer support sessions, ward round participation, and bite-size education classes.

The NU experience and MH status of both parents will be assessed as in the phase 1 study (Figure 1) including assessing their experience of the FICare program. At the end of the phase 2 study, staff knowledge, experiences, and opinions about fathers and FICare will be reassessed and compared with the start of the study.

Statistical Analysis

Qualitative data will be imported into dedicated software packages to facilitate analysis including NVivo (Lumivere) and SPSS (SPSS Inc). Interviews will be transcribed, following which the original recordings will be destroyed.

Interviews and Focus Groups

Data will be uploaded into NVivo to facilitate qualitative data management and thematic analysis. We will use several methods to minimize researcher bias during the study. All interviews will be conducted by 1 person (RR), who will maintain a reflexive diary through the study process. The transcripts will be independently coded by 2 researchers (RR and KG) to find repeated patterns of meaning which provide a detailed understanding of the perspective of the participants [29]. Both researchers will systematically code the data in detail and group them together into broader themes, with themes revisited to ensure that data saturation has been reached. These will then be grouped into broader themes generating a thematic map that will allow us to understand the parents' experiences in NU. The chief investigator (NA) will have control of the data and will be able to access the audio recordings of the interviews at all times to audit the quality of the interview process. Decision trails and coding trees will be used to ensure that coding and decision-making in data analysis are clear and transparent. Any discrepancies will be discussed with a third person (NA). Verbatim (anonymous) quotes will be shared with the results to allow the reader to determine whether the final themes reflect the data. Finally, the research team and participants will be invited to comment on the emerging or final themes during the data analysis.

Questionnaires

For descriptive statistics, the median and mode scores of the PSS:NICU, GAD-7, and PHQ-9 will be used to describe the outcome of the questionnaires. For inference analysis, the difference in median for the PSS:NICU, GAD-7, and PHQ-9 at admission, discharge, and 6 weeks postdischarge will be compared between phase 1 and phase 2 using the Mann-Whitney test and the paired 2-tailed *t* test. The data will be checked for outliers and these will be corrected or removed. However, where these outliers are accurate, a nonparametric statistical analysis will be performed. Depending on the data type, missing data will be replaced with mean, median, or mode. In addition, regression and multiple imputations analysis will also be used to impute or generate missing values.

Staff survey questionnaire responses to individual questions will be presented as a percentage of individuals responding yes or no. The percentage of "yes" responses to each question by the staff at the start and end of the study will be compared by paired *t* test.

Data Storage and Availability

All patient-identifiable data will be stored in a locked office of the principal investigator (PI) of participating sites. Access to identifiable data will be restricted to the PI and research team. The paper questionnaires will be stored securely in a file kept in the locked research office and electronic versions will be stored in a password-protected NHS computer. The electronic version of questionnaires will be emailed by parents to a secure NHS email account. This will also be used if transcription or audio files need to be transferred with third-party transcription services. Third-party services will be vetted as per NHS standards to ensure data protection and confidentiality. The sponsor will have access to the pseudoanonymized data if requested. Anonymized data will be made available on request. Study data will be kept for up to 18 months after the study completion.

Potential Risk to Participants and Mitigation

Considering the nature of the study, it is unlikely to have any adverse events. However, fathers may feel the additional burden of fulfilling their expected NU obligations alongside their breadwinner role and feelings of guilt for being unable to fulfill the expectations set for them [30,31]. To mitigate this difficulty, there is flexibility in when and to what extent fathers would like to be involved in FICare set at their own pace. The questionnaires and interviews may be emotionally challenging. This is being mitigated by the option to attend peer support sessions run by an appropriately trained professional and all parents will have access to the local neonatal psychologist. Interview frameworks were reviewed by the PAG and neonatal psychologist. A protocol is in place for any participants exhibiting severe MH symptoms through questionnaire responses or other forms of communication. Adverse events will be reported to the chief investigator and local research and development office and follow research and development, protocols with consideration of modification of study procedures if required.

Adverse events in the hospital setting will follow local hospital protocols as well as escalation to study PI with consideration of modification of study procedures if required. The risk of psychological distress resulting from study participation has been minimized with the support of a specialist psychotherapist who reviewed the study design and materials. A protocol is in place for any parents exhibiting severe MH symptoms through questionnaire responses or other forms of communication. We do not anticipate any risks to parents as they are simply being encouraged to participate in standard FICare activities that already occur in the participating centers. There is an emphasis that this should occur at the parents' pace.

Dissemination

The study findings will be presented at neonatal and FICare conferences and published in medical and nursing journals. The study findings will also be shared with relevant charities (eg, Bliss), and the study participants if they wish. It will form the basis of a PhD thesis. The PAG will be involved in the dissemination of the study findings.

Ethical Considerations

Participants will be able to withdraw from the study at any point. Anonymized data gathered until this point will be retained for data analysis. Following each interview or focus group, parents will be given 2 weeks to withdraw their data from the study. The study was approved by Leicester, South Research Ethics Committee (22/EM/0140)in August 2022, and written consent will be obtained from participants (see participant information leaflets and consent forms in Multimedia Appendices 1 and 2).

Results

The study is currently ongoing. As of October 2023, 22 families, comprising 22 fathers and 17 mothers had been recruited. The SR studies have been registered with the PROSPERO database (324275 and 306760). The projected end date for data collection is around July 2024, data analysis will occur in November 2024, and publication of the study findings will occur in early 2025.

Discussion

This study will test the hypothesis that if fathers are facilitated to engage more with their baby on the NU and are better supported during the neonatal stay, both parents will experience fewer MH symptoms during their baby's hospitalization and up to 6 weeks postdischarge. Improving parents' MH is shown to allow greater parent-child bonding [32] and more sensitive responsiveness of mothers to their infants' cues [33]. Mothers engaged in the FICare model have greater confidence in caregiving at the point of discharge and seek less medical support after discharge [32]. It is anticipated that these results will translate to fathers or partners.

Unlike many other studies [12,33], this study includes parents of a wide gestational age range of premature infants, including extremely premature infants and those who are invasively ventilated and at the highest risk of adverse outcomes. This is vital as research has found that fathers find the fragile appearance of their premature infants causes significant stress

[34]. A focus of the study methods will be to upskill NU staff to increase awareness and understand the importance of father engagement in FICare and their MH as well as the impact on mother and child, which is in line with the NHS Long Term Plan [17].

Limitations of the study include the need for conversational English. This is required to be able to complete the standardized questionnaires, participate in the interviews and focus groups, and to be able to engage with the phase 2 provisions. The language for the phase 2 materials will be kept as simple to ensure readability and understanding. Exclusion from recruitment based on language will be monitored. The perceived research burden may disproportionately impact parents who have older children, have a greater distance to travel, limited parental leave, or who do not have English as their first language. There may also be cultural barriers to overcome when discussing MH.

A prospective cohort study was the most practical and ethical study design. The sample size and the primary outcome of the study is based on the qualitative data. A bigger sample size will be required for the study to be based on the quantitative or questionnaire data. The quantitative or questionnaire data collected in this study is to support the qualitative data and to test the feasibility of collecting such data longitudinally.

The PSS:NICU questionnaire has been translated into many languages across the world [35,36], and is a well-used tool in neonatal research. It has been validated in mothers and fathers of NICU babies in the United Kingdom [37]. There are limited validated tools to assess paternal and maternal anxiety and depression in the postpartum or NU period. Therefore, simple screening tools that are validated in primary care and the general population for patients with a variety of backgrounds and stages of life were chosen [27,38,39].

Acknowledgments

The authors would like to acknowledge Felix Asamoah for his statistical advice and support. The authors would like to thank the neonatal doctors, nurses, and allied health professionals for their support, and the parents and babies who are participating and will be recruited. The authors are grateful to parent advisory group for their help in reviewing the study methodology and all the participant-facing study materials. The authors received no specific funding for this work. The Homerton Healthcare NHS Foundation Trust sponsors the study and will review and audit the progress and final outcomes of the study.

Data Availability

The deidentified data sets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

NA, RR, and KG conceptualized the study. RR and NA prepared the first draft of the paper. All authors contributed to the study design, sample size calculation, and writing of the protocol for this study. All authors contributed to revisions of the manuscript and to the final version of the manuscript. All authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Cutaneous T-cell lymphoma (CTCL) is a rare group of lymphomas that primarily affects the skin. Mycosis fungoides (MF) is the most common form of CTCL and Sézary syndrome (SS) is more infrequent. Early stages (IA-IIA) have a favorable prognosis, while advanced stages (IIB-IVB) have a worse prognosis. Around 25% of patients with early stages of the disease will progress to advanced stages. Malignant skin-infiltrating T-cells in CTCL are accompanied by infiltrates of nonmalignant T-cells and other immune cells that produce cytokines that modulate the inflammation. Skin infection, often with *Staphylococcus aureus*, is frequent in advanced stages and can lead to sepsis and death. *S. aureus* has also been reported to contribute to the progression of the disease. Previous reports indicate a shift from Th1 to Th2 cytokine production and dysfunction of the skin barrier in CTCL. Treatment response is highly variable and often unpredictable, and there is a need for new predictive and prognostic biomarkers.

Objective: This prospective translational study aims to identify prognostic biomarkers in the blood and skin of patients with MF and SS.

Methods: The Predictive and Prognostic Biomarkers in Patients With MF and SS (BIO-MUSE) study aims to recruit 120 adult patients with MF or SS and a control group of 20 healthy volunteers. The treatments will be given according to clinical routine. The sampling of each patient will be performed every 3 months for 3 years. The blood samples will be analyzed for lactate dehydrogenase, immunoglobulin E, interleukins, thymus and activation-regulated chemokine, and lymphocyte subpopulations. The lymphoma microenvironment will be investigated through digital spatial profiling and single-cell RNA sequencing. Microbiological sampling and analysis of skin barrier function will be performed. The life quality parameters will be evaluated. The results will be evaluated by the stage of the disease.

Results: Patient inclusion started in 2021 and is still ongoing in 2023, with 18 patients and 20 healthy controls enrolled. The publication of selected translational findings before the publication of the main results of the trial is accepted.

Conclusions: This study aims to investigate blood and skin with a focus on immune cells and the microbiological environment to identify potential new prognostic biomarkers in MF and SS.

Introduction

Mycosis Fungoides and Sézary Syndrome

Cutaneous T-cell lymphoma (CTCL) is a rare group of lymphomas that primarily affects the skin [1-3]. The pathogenesis of CTCL is not yet fully understood [3]. The annual incidence of CTCL is 0.7 per 100,000. Mycosis fungoides (MF) is the most prevalent form and comprises 60% of CTCL, with a higher male incidence (1.6:1.0) and a peak age incidence between 50 and 74 years [4]. Since MF often has a chronic course, its prevalence is considerably higher. The skin lesions in MF can be patches, plaques, tumors, or erythroderma. Sézary syndrome (SS) is an aggressive leukemic variant of the disease and constitutes only 5% of CTCL; it is defined as a triad of erythroderma, lymphadenopathy, and the presence of neoplastic T-cells in peripheral blood [5]. The extent of the disease in the skin is measured according to the Modified Severity-Weighted Assessment Tool [6,7]. Both MF and SS are staged according to the same tumor-node-metastasis-blood (TNMB) classification, assessing the involvement of skin, peripheral lymph nodes, peripheral blood, and visceral organs [8].

Prognosis of MF and SS

The TNMB stage at diagnosis remains the most important prognostic factor [9,10]. Many patients with early stages of MF have an indolent disease with a 5-year disease-specific survival of 89% to 98% [8,11]. However, approximately 25% of patients with early stages of disease will later progress to advanced stages [4]. Patients with advanced stages of MF have a 5-year disease-specific survival of 18% to 56% associated with treatment failure [8,10]. The 5-year disease-specific survival of SS is 36% [3,8,10].

Multivariate analyses of cohorts of patients with MF and SS have identified potential adverse prognostic factors in the early stages of disease consisting of male gender, aged >60 years, plaques, folliculotropic disease, and stage N1/NX and negative prognostic factors for advanced disease consisting of male gender, aged >60 years, stages B1/B2 and N2/N3, and visceral involvement [12,13]. The presence of plaque lesions in the early stage of the disease, large cell transformation in the skin, and elevated lactate dehydrogenase are also identified as adverse prognostic factors [11,14,15]. Still, there is an unmet clinical need to identify which patients will progress to an advanced stage of disease, and there is a great need for new reliable prognostic markers.

Treatments for MF and SS

The therapeutic options for MF and SS range from skin-directed therapy (SDT) to systemic treatment, and the selection of appropriate treatment is primarily based on the stage of the disease. There are only a few randomized controlled trials for the treatment of MF and SS, and current recommendations for treatment are mainly based on consensus meetings and international guidelines [4,5,10]. The treatment of the early stages of MF aims at modulating the immune response in the skin through SDT, such as topical corticosteroids and UV light therapy. Local radiation therapy usually has a good effect in all stages. In early stages that are refractory to SDT or in advanced stages, systemic treatment is used, including retinoid derivatives, low-dose methotrexate, and interferon alfa. In patients with lymphoma cells expressing CD30, targeted chemotherapy with brentuximab vedotin can be used. Further, standard chemotherapy such as gemcitabine or doxorubicin can be used; however, this often results in only short remission periods. Extracorporeal photopheresis can be used in erythrodermic stages of MF and SS and mogamulizumab and alemtuzumab can be used in advanced stages of disease. Highly selected patients with advanced stages of disease can be considered for allogeneic stem cell transplantation. Histone deacetylase (HDAC) inhibitors such as vorinostat and romidepsin are approved by the US Food and Drug Administration but are not commonly used in Europe [16,17]. Total skin electron beam therapy can be used in widespread disease in the skin or before allogeneic stem cell transplantation. Treatment response is unpredictable, and there is an unmet clinical need to find reliable predictive markers.

Immunological Changes of the Microenvironment of CTCL in Skin and Blood

Early stages of CTCL derive from mature CD4+ T-cells, or rarely CD8+ T-cells, in the skin. The restriction to the skin suggests that the affected cells are dependent on the specific cutaneous microenvironment, including cytokines and adhesion molecules. Malignant skin-infiltrating cells are accompanied by infiltrates of nonmalignant T-cells and other immune cells. The infiltrating benign immune cells produce a variety of cytokines that modulate cutaneous inflammation and are important constituents of the local environment of the tumor, fostering proliferation, survival, and migration [3]. Attempts to associate a unique cytokine profile of the disease based on skin or blood samples have indicated that a shift from Th1 to Th2 cytokine production accompanies disease progression [18,19], but the mechanisms behind this shift are not completely known [20]. In the advanced stages of the disease, a reduction of

skin-infiltrating CD8+ T-cells has been observed, as well as a shift toward M2 polarized macrophages and increased frequencies of NK cells and B-cells [21,22]. Other major immunological changes also facilitate the environment of the lymphoma cells and impair the host immunological defense [22]. The hypothesis of this study is to further explore these immunological changes through analysis of lymphocyte subpopulations in blood and skin together with cytokine expression in plasma through protein array analysis. We also hypothesize that we will detect other cells, molecules, and factors in the microenvironment of the tumor that could influence the clinical course of CTCL.

Epigenetic Modifications in CTCL

Regulation of DNA transcription is complex, and the mechanisms of regulation of DNA transcription in CTCL are partially unknown. HDACs can regulate the expression of genes and activities of transcription factors involved in malignant transformation and immune defense. HDACs act mainly through alteration of the structural components of chromatin by histone deacetylation, thus affecting the 3D conformation of DNA without changing or interrupting its sequence. Epigenetic drugs such as HDAC inhibitors have shown promising results in patients with advanced disease, emphasizing the impact of epigenetic regulators on the disease. Based on phase II data demonstrating long-term remission in 35% of heavily pretreated patients, HDAC inhibitors have been approved by the US Food and Drug Administration for second-line treatment of CTCL [16,17]. Although the dysregulated function of HDAC inhibitors may have an important role in malignant transformation and in the response to cancer treatment, the in vivo mechanisms behind the effects of HDAC inhibitors in CTCL are largely unknown. However, next-generation sequencing data have shown amino-acid or copy number alterations of 13 chromatin modifiers in 1% to 7% of CTCL cases, respectively, suggesting a mutation-driven epigenetic imbalance in CTCL [23]. Interestingly, HDAC inhibitors have been shown to reprogram the epigenome of host nonmalignant T-cells toward normal patterns, emphasizing the role of the host T-cells for therapy response [24,25].

Microbiological Changes and Skin Barrier Function in MF and SS

Skin infections, often with *Staphylococcus aureus*, are frequently seen in advanced stages of MF and SS. In patients who are immunocompromised, skin infections can lead to sepsis and death. Some studies indicate that a shift from Th1 to Th2 cytokine production and dysfunction of the skin barrier contribute to skin infections [26,27]. The underlying basis for the microbiological changes and the skin barrier function in CTCL need to be further elucidated for their potential role in the pathogenesis and progression.

Goals of This Study

The primary objective of this study is to identify serum-protein markers for 6-month progression-free survival (PFS) and to identify the immune cell profile in blood for 6-month PFS.

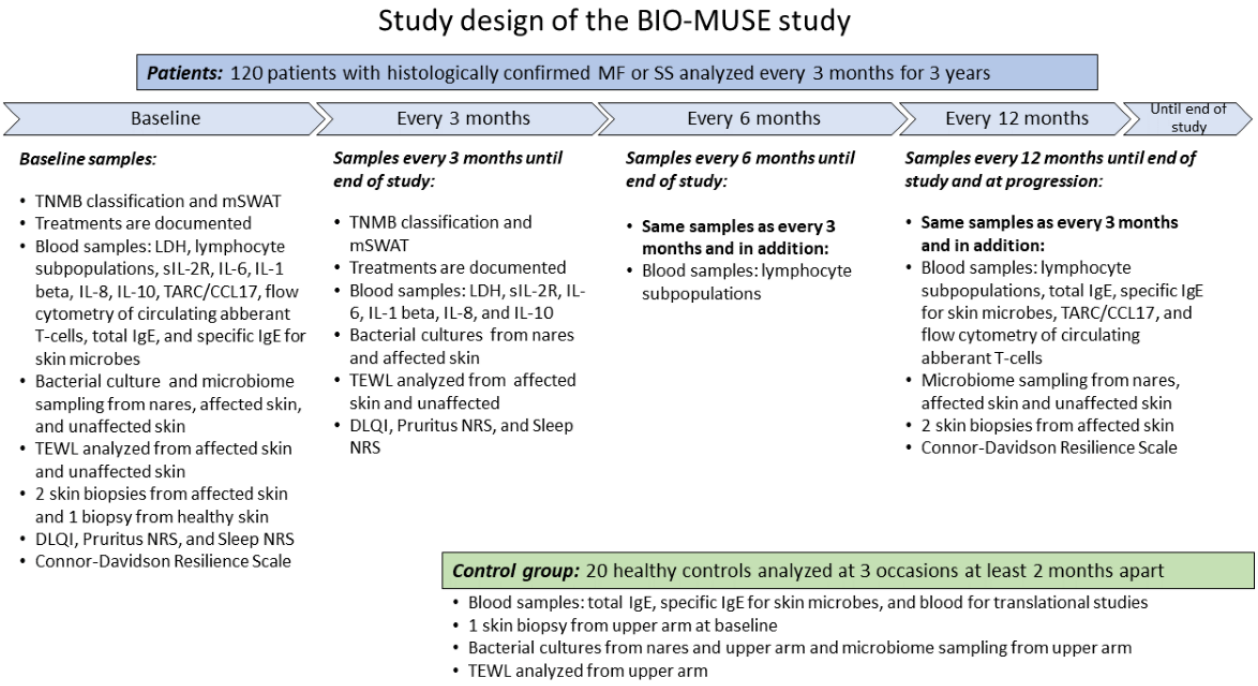
Secondary objectives are to identify the immune cell profile in the skin for 6-month PFS, analyze the lymphoma microenvironment in the skin for 6-month PFS, identify the skin barrier and skin microbiology profiles for 6-months PFS, and identify the epigenetic changes in lymphoma T-cells and host T-cells for 3 months PFS.

Methods

Study Design

The Predictive and Prognostic Biomarkers in Patients With MF and SS (BIO-MUSE) study is a translational prospective study, aiming to include 120 adult patients with MF and SS and a control group of 20 healthy volunteers (Figure 1). Sampling of each patient will be performed every 3 months for 3 years. The control group will be examined on 3 different occasions at least 2 months apart. This study is presently open at Skåne University Hospital and aims to open at Karolinska University Hospital. The multicenter study design enables other Swedish sites to be included, after further ethical approval.

Figure 1. Study design of the BIO-MUSE study. BIO-MUSE: Predictive and Prognostic Biomarkers in Patients With Mycosis Fungoides and Sézary Syndrome; CT: computed tomography; DLQI: Dermatology Life Quality Index; IgE: immunoglobulin E; IL-6: interleukin-6; IL-8: interleukin-8; IL-10: interleukin-10; IL-1beta: interleukin-1beta; LDH: lactate dehydrogenase; MF: mycosis fungoides; mSWAT: Modified Severity-Weighted Assessment Tool; NRS: Numerical Rating Scale; sIL-2R: soluble interleukin-2 receptor; SS: Sézary syndrome; TARC: thymus and activation-regulated chemokine; TEWL: transepidermal water loss; TNMB: tumor-node-metastasis-blood.



Ethical Considerations

This study's protocol is written per the Declaration of Helsinki and the International Council for Harmonisation's good clinical practice guidelines. This study was registered with ClinicalTrials.gov (NCT04904146) and approved by the Swedish Ethics Committee (2019-05130). Written informed consent will be obtained from participants according to the Declaration of Helsinki and International Council for Harmonisation's good clinical practice guidelines.

Eligibility Criteria

Inclusion criteria will be patients aged 18-100 years with histologically confirmed MF and SS (stage IA-IVB) and World Health Organization performance status 0-3. The inclusion criteria for the healthy control group will be healthy adults aged 18-100 years with World Health Organization performance status 0-2 and the absence of any malignant, autoimmune, or infectious disease. The exclusion criteria for both groups are psychiatric illnesses or conditions that could interfere with the ability to understand the requirements of this study.

Stage of Disease and Modified Severity-Weighted Assessment Tool

Patients will be staged according to the TNMB classification [8]. The extent of disease in the skin will be measured according to the Modified Severity-Weighted Assessment Tool [6,7]. Progression or regression will be defined as a shift from one stage to another.

Treatment of MF and SS

The treatments will be given according to clinical routine and national and international guidelines for MF and SS and participation in this study will not affect the choice of treatments. Ongoing treatments will be documented.

Blood Samples for Soluble Interleukin-2 Receptor, Interleukins, and Thymus and Activation-Regulated Chemokine/CCL17

Blood samples in patients will be analyzed for complete blood count, liver and kidney function, lactate dehydrogenase, soluble interleukin-2 receptor, interleukin-6, interleukin-8, interleukin-10, and thymus and activation-regulated chemokine/CCL17 (Multimedia Appendix 1).

Blood Samples for Analysis of Immunoglobulin E Against Specific Antigen

Total immunoglobulin E and specific immunoglobulin E for *S. aureus* enterotoxin A (m80), enterotoxin B (m81), toxic shock syndrome toxin-1 (Rm226), *Malassezia* (m227), and *Candida albicans* (m5) will be analyzed in patients and in the control group (Multimedia Appendices 1 and 2, respectively).

Blood Samples for Analysis of Lymphocyte Subpopulations

Flow cytometry of peripheral blood will be performed in patients to analyze the T-cell subpopulations including naive, effector, and memory T-cells (including Th1, Th2, and Th17 cells) and activated and regulatory T-cells. Monoclonal antibodies recognizing CD4, CD8, CD197, CD45RA, CD25, CD194, CD127, CD45RO, CD183, and CD196 will be used [28]. In

addition, to evaluate the presence of clonal T-cells in peripheral blood and biopsies the following panel: T-cell receptor fluorescein isothiocyanate, TRBC1 phycoerythrin, CD16 electron coupled dye, CD2 PC7, CD3 BV421, CD4PC5.5, CD7 A700, CD8 KrO, CD26 allophycocyanine, and CD45 allophycocyanine-H7 will be used [29] (Multimedia Appendices 1 and 3, respectively).

Serum-Based Profiling of Immune-Related Soluble Proteins

Broad sets of serum-based protein profiling focused on immune-related proteins will be performed in patients. Global protein profiling will be performed using commercially available methods, allowing high-plex analyses of immune-related soluble molecules. State-of-the-art bioinformatic tools will be applied for preprocessing and analysis of data (Multimedia Appendix 1).

Assessment of Tumor Microenvironment by Digital Spatial Profiling and Single-Cell RNA Sequencing

To allow the study of the cellular tumor immune microenvironment, 2 biopsies from affected skin and 1 biopsy from unaffected skin, at least 5 cm away from affected skin, will be taken. In the control group, 1 skin biopsy is taken from the upper arm. The skin biopsies will be formalin-fixed and paraffin-embedded. In addition, blood will be drawn from patients and healthy controls and peripheral blood mononuclear cells will be cryopreserved.

Multiplex analyses of samples taken before and after progression have the potential to contribute to novel biological knowledge as previously discussed in a recent review by the group Kalliara et al [30] and will be performed in samples collected over time. In brief, in skin biopsies, Digital Spatial Profiling will be performed to study immune infiltration in CTCL and how it evolves during the progression of the disease [31]. Single-cell RNA and T-cell receptor sequencing will be applied to sorted CD3+ cells to follow the evolution of the malignant clone over time. Moreover, additional assessments of genetic and epigenetic changes in the tumor and tumor microenvironment will be performed in skin biopsies (Multimedia Appendix 1).

Assessment of Epigenetic Factors in Circulating Tumor Cells Compared to Normal and Host T-Cells

Cell sorting of CD3+ cells from peripheral blood in patients with blood involvement will be performed using FACSAria (BD, Bioscience). When possible, 2-3 million cells will be sorted from each patient to allow the preparation of DNA for epigenetic analysis and RNA for gene expression analysis. Analysis of histone modifications and chromatin accessibility will be performed by ChIP-seq (chromatin immunoprecipitation with sequencing) and ATAC-seq (assay of transposase-accessible chromatin with sequencing), respectively. Moreover, molecular profiling using nCounter analysis (NanoString Technologies, Inc) will be performed to profile cells through expression panels focused on immune profiling and proliferative signaling pathways (Multimedia Appendix 1).

Microbiological Sampling

Microbiological samples will be analyzed from affected skin and from unaffected skin 5 cm away from affected skin, preferably from the upper body, and from nares in patients. In the control group, the microbiological samples will be analyzed from the upper arm and from the nares (Multimedia Appendices 1 and 2, respectively).

Analysis of Skin Barrier Function

Skin barrier function will be measured as transepidermal water loss (TEWL) with a closed chamber TEWL meter, VapoMeter 300 (Delfin Technologies Ltd), according to guidelines [32]. TEWL will be measured on affected skin and on unaffected skin 5 cm away from affected skin, preferably from the upper body. TEWL will be measured on the upper arm in the control group (Multimedia Appendices 1 and 2).

Hematopathology of Skin, Lymph Node, Bone Marrow, and Tumor Biopsies

Hematopathology of skin biopsy will be performed in affected skin from patients and is optional from lymph nodes, bone marrow, and tumors (Multimedia Appendices 1 and 3).

Patient-Oriented Life Quality Measures

Patient-oriented life quality measures will be performed. The Dermatology Life Quality Index [33], Peak Pruritus Numerical Rating Scale [34], Sleep Numerical Rating Scale, and Connor-Davidson Resilience Scale [35] will be used (Multimedia Appendix 1).

Statistical Analysis

The sample profiles from patients with an early stage of disease (stage IA-IIA) will be compared to samples from patients with an advanced stage of disease (stage IIB-IVB) using multivariate analysis with principal component analysis. Individual samples will be compared between the groups using the Mann-Whitney *U* test. Other translational samples will be presented by descriptive statistics. Progression-free and overall survival will be presented using Kaplan-Meier plots.

Results

Patient inclusion started in 2021 and is still ongoing in December 2023, with 18 patients and 20 healthy controls enrolled. Until December 2023, a total of 2 included patients have declined further participation due to the extra visits in this study. Further, 2 patients have died from MF during this study. The publication of selected translational findings before the publication of the main results of the trial is accepted, and data analysis is in progress.

The evaluation of the stage of the disease will be observed every 3 months according to the TNMB classification, where the shift from one stage to another implies progression or treatment response. After the study, patients will be grouped as either early stage of the disease (IA-IIA) or advanced stage of the disease (IIB-IVB). The patients crossing over from the early stage of the disease to the advanced stage of the disease group will be analyzed both individually and as a group. Approximately 30% (36/120) of patients are estimated to be in

the advanced stage of the disease group. The translational samples in the early stage of the disease group will be compared to samples from the advanced stage of the disease group. The treatments directed against MF are documented throughout this study. Excluded patients will be presented along with the final results. Depending on patient numbers, treatment data will be presented descriptively, or if possible, to support data on treatment predictive biomarkers.

Discussion

Principal Findings

This study aims to find potential predictive and prognostic biomarkers in patients with MF and SS. This study will investigate translational samples from skin and blood concerning the stage of the disease over time, which has the advantage of monitoring patients with consecutive samplings to be able to capture changes before and during a possible progression. This study will be able to compare differences in patients with early (IA-IIA) and advanced (IIB-IVB) stages of the disease. It will also be possible to analyze the data separately for patients with MF and SS, respectively. The translational samplings in this study are chosen to be able to detect changes in the immune system and in tumor cells, as well as changes in the skin barrier function and the skin microbiota. There is a clinically unmet need to find new predictive and prognostic biomarkers in MF and SS, and studies further exploring these areas are therefore a high priority. The research team, techniques, and management presented in this protocol have capacities to investigate new aspects and bring new knowledge to the field of CTCL. This study combines a multidisciplinary outpatient clinic with extensive translational research sampling, which has considerable potential to lead to true patient benefit.

Limitations

MF and SS are rare diseases, and the inclusion of the proposed number of patients in this study protocol may take considerable time. To reach the estimated number of patients in this study, inclusion will also start at Karolinska University Hospital, and to expand this study further, cooperations with other centers is ongoing. Another possible limitation is that the control group will be followed for a shorter period compared to the patients.

Comparison With Prior Work

The Prospective Cutaneous Lymphoma International Prognostic Index study is an ongoing international study of a confirmed early-stage MF cohort, which is being followed up to identify prognostic factors in the hope of providing better management and improving survival by identifying patients at risk of disease progression [36].

Conclusions

The BIO-MUSE study is a prospective translational study aiming to identify new prognostic and predictive biomarkers in blood and skin in patients with MF and SS.

Acknowledgments

We thank Anna Porwit, professor emerita, Department of Pathology, Lund University, Skåne University Hospital, Lund, Sweden, for help with planning the hematopathology analysis. We are grateful to Andreas Lennartsson, Department of Biosciences and Nutrition, Karolinska Institutet, Sweden for help with planning the epigenetic analysis. Abstract

Background: While ecological momentary assessment (EMA) is commonly used to study social contexts and social influence in the real world, EMA almost exclusively relies on participant self-report of present circumstances, including the proximity to influential peers. There is the potential for developing a proximity sensing approach that uses small Bluetooth beacons and smartphone-based detection and data collection to collect information about interactions between individuals passively in real time.

Objective: This paper aims to describe the methods for evaluating the functionality and validity of a Bluetooth-based beacon and a smartphone app to identify when ≥2 individuals are physically proximal.

Methods: We will recruit 20 participants aged 18 to 29 years with Android smartphones to complete a 3-week study during which beacon detection and self-report data will be collected using a smartphone app (MEI Research). Using an interviewer-administered social network interview, participants will identify up to 3 peers of the same age who are influential on health behavior (alcohol use in this study). These peers will be asked to carry a Bluetooth beacon (Kontakt asset tag) for the duration of the study; each beacon has a unique ID that, when detected, will be recorded by the app on the participant's phone. Participants will be prompted to respond to EMA surveys (signal-contingent reports) when a peer beacon encounter meets our criteria and randomly 3 times daily (random reports) and every morning (morning reports) to collect information about the presence of peers. In all reports, the individualized list of peers will be presented to participants, followed by questions about peer and participant behavior, including alcohol use. Data from multiple app data sets, including beacon encounter specifications, notification, and app logs, participant EMA self-reports and postparticipation interviews, and peer surveys, will be used to evaluate project goals. We will examine the functionality of the technology, including the stability of the app (eg, app crashes and issues opening the app), beacon-to-app detection (ie, does the app detect proximal beacons?), and beacon encounter notification when encounter criteria are met. The validity of the technology will be defined as the concordance between passive detection of peers via beacon-to-app communication and the participant's EMA report of peer presence. Disagreement between the beacon and self-report data (ie, false negatives and false positives) will be investigated in multiple ways (ie, to determine if the reason was technology-related or participant compliance-related) using encounter data and information collected from participants and peers.

Results: Participant recruitment began in February 2023, and enrollment was completed in December 2023. Results will be reported in 2025.

Conclusions: This Bluetooth-based technology has important applications and clinical implications for various health behaviors, including the potential for just-in-time adaptive interventions that target high-risk behavior in real time.

Introduction

Behavioral Influence in Social Contexts

Social context, which refers to immediate temporal, situational, and intrapersonal factors, is important for many health behaviors [1]. Understanding how context influences behavior is an essential first step toward the development of preventive interventions to reduce risk, as it provides essential information on why, with whom, where, and when a person engages in a particular behavior. For alcohol use, the health behavior we will focus on, the presence of peers is a highly influential contextual factor for all ages [2-6]. Recent studies have examined real-time information gathered about individuals and their environment [7-9] via purposeful, self-initiated reports or prompted reports [eg, ecological momentary assessment (EMA)]. Compared with retrospective recall, which can lead to error, EMA methods probe for participant reports in real time, leading to more accurate perceptions of behavior and allowing for the assessment of changes in the social context across a day [10]. However, while EMA as a method can help advance our understanding of the social context, it requires individuals to be both aware of and able to report peer presence or influence. Thus, there is value in research that relies less on self-report and more on passive assessment of the social context.

Use of Technology to Examine Social Contexts

There has been a rapid rise in the passive ambulatory assessment of behavior [11,12] using various technologies, including wearables for physical activity or heart rate [13,14] and alcohol biosensors [15,16]. In addition to wearable sensors, smartphones passively collect data from their built-in sensors in real time [17], including information on location and movement [18-20] and social interactions [20,21]. A smartphone-based technology with potential applications for understanding social contexts is Bluetooth, which is a ubiquitous connectivity protocol embedded in mobile phones and other wearable devices. Designed to underlie communication between digital devices, the unique characteristics of Bluetooth have enabled the development of software that can identify nearby Bluetooth beacons (eg, Apple AirTags or other transmitters, including smartphones themselves), allowing smartphone apps to assess the duration and frequency of interpersonal interactions [22-24].

Despite its promise, little research has applied Bluetooth technology to proximity sensing to study the social contexts of health behavior change. An epidemiological study used smartphone-based Bluetooth sensors to predict behavior change associated with disease spread [25], and another used Bluetooth-based proximity sensing to assess the relationships among sociability, sleep, and mood [26]. A recent study on alcohol use incorporated Bluetooth sensing to examine the social context of young adult drinking, in which the Bluetooth technology captured features such as the number of proximal devices and signal strengths [27]. Recently, researchers have evaluated the performance of Bluetooth-integrated methods to understand disease spread during the COVID-19 pandemic [28-30]. Our goal is to develop and evaluate the stability of a smartphone app that leverages a Bluetooth-based wearable sensing protocol to study the real-world social context of alcohol use but could be applicable to other behaviors in which social contexts act as key determinants.

Study Objective

The objective of this research is to develop technology that will allow for the passive detection of contact between individuals, and specifically between participants and their close friends. In this paper, we describe a smartphone app, Bluetooth-based beacons, and our planned procedures for evaluating the *functionality and validity* of the developed technology. In a companion paper [31], we describe our approach to evaluating participant responses to using the technology in a study on the social context of alcohol (ie, feasibility and acceptability). *Functionality* will be determined by evaluating the stability of the app (ie, low app crashes or other issues) and the success of the beacon detection protocol and app notifications across different devices and in different situations. We will collect data on functionality throughout the study, primarily using app-based data and secondarily using qualitative data from interviews with participants and peers at the completion of data collection. *Validity* will be determined by evaluating the concordance between beacon detection and participant EMA reports of peer presence data sources. Details of the project goals and methods for evaluating the goals are described in Table 1.

Table 1. Project primary goals and methods for evaluating goals.

Goal	Definition	How determined	Data source
Functionality			
Beacon detection	Whether the peer beacons are detected by the participant app consistent with app settings	Tested in participant orientation to confirm that beacons are detected by participant phone	• Beacon Encounter data set • App Log data set
Beacon encounter notifications	Whether the app functions as expected, defined as delivering report notifications with the expected latency when beacon encounter criteria are met	An indication of notification sent by the server when actual encounters are identified	• Beacon Encounter data set • Participant Event data set
App overall stability	Whether the app functions as expected with minimal errors	App error reports (crash and reinstall) and participant error reports	• App Log data set • Participant EMA[a] report data set • Postparticipation interview
Phone and operating system differences	Whether differences across Android phone and operating system versions are noted	Information about participant phones and operating systems	• App Log data set • Baseline survey • Participant postparticipation survey and interview
Validity	Concordance between beacon detection and participant report of peer presence	Cross-classification of beacon encounter and participant self-report data	• Beacon Encounter data set • Participant EMA report data set • Participant postparticipation interview • Peer weekly surveys

[a]EMA: ecological momentary assessment.

Methods

Design

Young adults will participate in a 3-week protocol during which they will complete reports about interactions with peers, including (1) signal-contingent reports triggered by the presence of a Bluetooth beacon being carried by a participant-nominated peer, (2) random reports triggered in time blocks 3 times per day, and (3) a morning report. A baseline assessment will precede field data collection and will aid in identifying peers, and an interview at the end of the study will collect qualitative information and feedback about participant experiences.

Participants

We will recruit up to 5 participants for our pilot study, and we will recruit 20 participants in the main study, with a conservative estimate of 15 completing the full protocol. The inclusion criteria are as follows: (1) be able to read English, (2) own an Android smartphone with OS11 or newer and have it with them throughout the day (typical for the age group between 18 and 29 years), (3) have a data plan (limited or unlimited), (4) be willing to approach peers to participate, and (5) anticipate not deviating from their typical routine during the study period, including leaving the region (as this would likely reduce exposure to selected peers). Additional inclusion criteria related to our substantive research aims are as follows: (1) aged 18 to 29 years; (2) drinking alcohol with others at least once a week, including drinking >4 (women) and >5 drinks (men) per occasion at least once a week in the past month; and (3) not in or seeking treatment for substance use.

We restricted our project to Android phones because there were several barriers that emerged with iOS. First, iOS places significantly more restrictions on apps that can be put on users' phones and the methods by which those apps can be loaded onto devices. Relatedly, when provisional software is distributed via the developer side of the App Store, a very limited number of developer testing accounts are provided, limiting the ability to test the app. Second, iOS takes more control than Android over processes that run in the background of the phone, including notifications, which are critical to the functionality of the app. Third, with the availability of the Apple AirTag we were concerned that implementing an alternative Bluetooth Low Energy (BLE) signal detection network with a different beacon would appear in competition with first-party applications and thus our app would be precluded or significantly delayed in distribution via the App Store. Further, as app development for this project started during the COVID-19 pandemic, there was significant focus placed on using BLE for proximity detection by both Apple and Google, with Apple in particular restricting the use of some features. For these reasons, and given the available resources and time frame of the project, we decided early in the course of the project to exclusively develop for Android phones. We note, however, that while owning an Android phone is a requirement for participants, it is not a requirement for peers.

Procedures

Eligibility and Recruitment

Young adults will be recruited from the community through flyers, email listserves, and social media advertisements. A brief web-based screener will establish their initial eligibility. Eligible participants will provide contact information, and a research assistant (RA) will schedule the in-person baseline session.

Participant Orientation and Baseline Assessment

A 90-minute in-person session will collect informed consent, demographic characteristics, and alcohol use data and identify possible peer participants. The RA will orient the participant to the project procedures, starting with installing the app on the participant's phone and recording device characteristics (device manufacturer, model, and Android operating system version). The RA will assist participants in changing settings on their phones to ensure the app will work optimally, including setting Bluetooth, location, nearby devices, and notifications to *on* or *allow*, and checking that settings that pause activity (eg, pause app activity if unused) or remove permissions are *off*. The RA will demonstrate the app interface, including showing the participants how to initiate reports and respond to notifications. The participants will navigate through each report, view examples of response types (radio buttons and text fields), and practice making entries. They will be instructed to respond as soon as possible after a prompt. We will explain that they are expected to keep their phone on, charged, and nearby. We will verify that the participants are not planning on traveling.

Peer Eligibility and Recruitment

The inclusion criteria for peers are as follows: (1) at least once a week in a typical week, having meaningful in-person social interaction with the participant. The alcohol-related inclusion criteria for peers are as follows: (2) between the ages of 18 and 29 years, and (3) drink with the participant at least twice a month in a typical month. While not all influential people with regard to alcohol use will be same-age peers, research indicates that same-age peers will most likely be present during drinking events (and in social interactions when drinking might occur) [32-34]. To identify possible peers, the RA will conduct a social network interview (SNI) that involves the participant nominating up to 10 people who they are close to, including friends, family members, or anyone they regularly spend time with in person who is close to their age [35,36]. The participants will report on the characteristics of these individuals, including their age, gender identity, whether they live together, relationship (friend, partner or significant other, casual acquaintance or coworker, sibling or cousin, other family member, and other), and frequency of meaningful social interaction ("How often in a typical month do you spend at least 15 consecutive minutes with this person?"). In line with the substantive study goals, we will also assess the frequency of the network member's drinking ("How many times in the past month do you think this person drank alcohol?") and the frequency of drinking with the person ("In the past month, how often did you drink with this person [while both of you were drinking]?"). For this protocol, we will ascertain the participant's perception of the willingness of the peer to participate in this study.

Working with the RA, the participants will identify 3 peers to be invited to participate in the study based on eligibility. During the baseline session, the participant will attempt to contact each of the 3 selected peers to invite them to participate. If the participant contacts the peer with the RA present and the peer agrees to hear more about the study, the participant will, with the peer's agreement, share the peer's contact information with the RA, who will then provide the peer with a web link to the study description and informed consent procedures and will communicate with the peer about their participation from that point forward. If the peer does not respond to the participant in the presence of the RA, the participant will send the peer a brief study description with the web link. If any peer who has received the project description does not respond after 3 days, we will move to the next person on the SNI list and ask the participant to make initial contact with the (new) peer. The participants will be given 5 days to recruit up to 3 peer participants.

Once a peer participant has consented to participate, the RA will arrange a time to give them the beacon and answer any questions. The beacon is 4.4 cm square and 1 cm thick (Figure 1). We will provide a small adhesive patch to allow the peer to attach the beacon to their phone and a ring to facilitate attachment to their keys if they choose. Peers will carry their beacon for 3 weeks of the project. Each beacon is assigned a unique ID that associates the beacon with the participant and peer. The smartphone app reports will begin for the participants once the beacons are distributed to their peers. The peer participants will complete web-based surveys at the end of each of the 3 weeks of data collection, in which they will indicate the days and time of day in the prior week they did not have their Bluetooth beacon with them and times in the prior week they were with the participant. This information will be useful for determining why a beacon was not detected.

Figure 1. The beacons used in this research were asset tags from Kontakt.io.

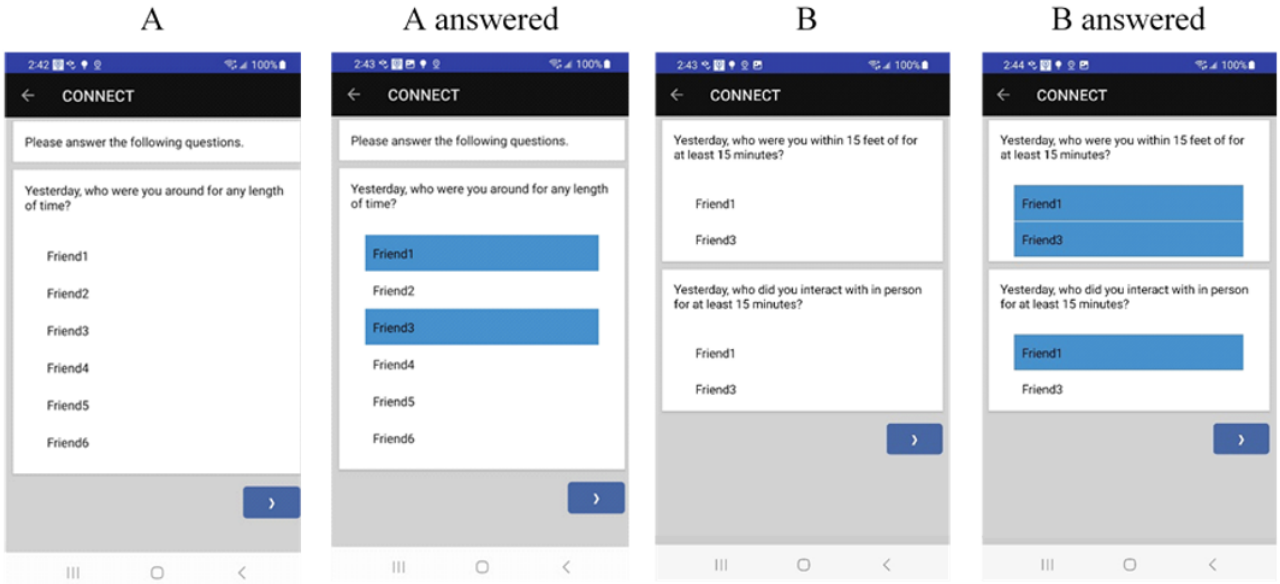
EMA Reports

Overview

Our project will use a custom smartphone app for data collection, developed in conjunction with our developer, MEI Research [37]. The app, which is only available for Android phones, comprises 2 primary components: the participant-facing EMA report delivery component and a background process that continuously scans for the Bluetooth beacons. Researchers create EMA reports and adjust the settings using a web interface. Notification of random and beacon signal-contingent EMA reports is handled locally on-device, so internet connectivity is not needed for either report triggering or beacon detection to function. Content is delivered dynamically from the MEI Research server, which requires cellular or Wi-Fi connectivity. Data are synchronized with the server when the participant opens the app or activates the sync function.

Before the 21-day EMA phase, the names of the SNI-identified peers and information about their associated beacons are uploaded using the researcher-facing web interface into the app so that the customized list of peers is presented to each participant on EMA reports (refer to the examples in Figure 2). This list of peers will have a maximum of 6 names from the SNI. All peers carrying the beacon will be on the list; others on the list may have declined to carry the beacon or may not have been asked. First, names, nicknames, or initials are presented to maximize confidentiality during data collection. Updating this list can occur in real time without involving the participant, thereby avoiding protocol disruptions. EMA reports begin with an item measuring *peer proximity*: “Yesterday/In the past hour, who were you around for any length of time?” The friend list is presented to the participant for them to choose from, with branching logic used to determine the presentation of subsequent questions. The names or nicknames of peers are not included in the researcher data set; numeric peer IDs (also associated with beacon data) ensure deidentification.

Figure 2. Screenshots of 2 items in the morning survey, first presented without answers (A) followed by the item with friends selected (B). Note that image B presents only friends that were selected in question A.



The participants will provide 3 types of EMA reports, completed in 1 to 3 minutes each.

Signal-Contingent

Signal-contingent reports are triggered by the app according to its detection of beacons carried by peer participants (refer to the subsequent section for details on beacon and trigger settings). We will not have constraints on times when these reports are prompted, and reports will expire (ie, will disappear from the app display) after 1 hour.

Random

Random reports are intended to sample experiences outside of drinking events and those prompted by signal-contingent reports, including peer contact and influence. The participants will receive 3 random EMA reports per day between 12 PM and 12 AM (12 to 6 PM, 6 to 9 PM, and 9 PM to 12 AM). We chose these intervals to optimize the measurement of alcohol use and exposure to peers. The participants will be informed of these intervals; missing data because of going to sleep is of low concern. Notifications will be followed by reminders at 15 and 30 minutes and will expire after 1 hour. The notification and in-app display for signal-contingent and random reports appear identical on the EMA app interface to minimize unintentional awareness of peer presence. Although there is no basis on which to project a compliance rate with beacon-triggered surveys, we expect a 70% or higher compliance rate with random surveys [31,38].

Morning

Morning reports will be completed by participants every day. The morning report is always available on the app, with a notification at 10 AM and reminders at 15 and 30 minutes thereafter. The EMA app prioritizes signal-contingent and random reports such that participants are not able to complete morning reports until any pending triggered reports are completed. The morning report items are identical to the signal-contingent and random reports but refer to *yesterday*, whereas the random and signal-contingent reports refer to *in the past hour*. In the morning reports, we also ask about prior-day app functionality related to participant experience (ie, *participant-related functionality*; "Were there times yesterday when you think our system was not working as you expected?"); those who indicate *yes* or *maybe* are asked to describe the issue in a text box. Items also identify possible missing data (eg, "Did you do any of the following yesterday?" with answers "You silenced your phone," "You turned your phone off," "You turned off notifications on your phone or for the EMA app," and "You turned off Bluetooth detection"). During the 3-week EMA period, the study staff will contact the participants once a week to check in, encourage compliance, and address technical issues as needed. The participants can also email, call, or text study staff at any time they have issues or questions.

Postparticipation Assessments

After the 3-week data collection period, the participants will complete a modified 15-item System Usability Scale (SUS [39]) with items adapted to our protocol that assess functionality (eg, "The app drained my battery" and "The app worked as expected") with response options on a 5-point Likert scale from 1=strongly disagree to 5=strongly agree. We will also conduct a semistructured interview to clarify any reported functionality or validity issues. Before the interview, we will examine the participant's beacon encounter data and reports of peer presence, and during the interview, we will clarify discrepant information, including reconciling signal-contingent reports (ie, indicating beacon detection) at times when the participant did not indicate that the peer was present. We will also probe the reasons for noncompliance and whether triggered report noncompletion appears to be systematically related to peer presence. In this final session, participants will be told how to delete the app from their phone.

Ethical Considerations

Human Subject Protections

The procedures were approved by the Brown University Institutional Review Board (protocol number 2022003448).

Informed Consent

The participants and the peer participants will complete informed consent, which includes reviewing detailed consent forms, discussion with the researcher, and documentation of consent.

Privacy and Confidentiality

All information obtained during the assessments will be confidential and will be used solely for research purposes. To protect the data and prevent unauthorized access, all EMA data will be encrypted and will remain so until it is accessed by the project staff using a username and password specific to this project. All files with participant-identifying information will be password-protected and stored separately from the data on a server accessed only by the project staff. To preserve confidentiality, we will deidentify data for both peers and participants using a numeric code. The participants will have the researcher provide credentials for the smartphone app that will not include their names, and we will encourage the participants to use phone passwords.

Compensation

Participants will be paid US $50 for attending the first session, US $5 per day for answering the EMA reports (at least 2 of 4 of the morning and random reports per day), and US $40 for attending the second session. The participants will also receive a weekly bonus of US $20 if they complete at least 80% of the random and morning reports. The most they can receive for participation is US $255. Peer participants will be compensated US $30 for each week they carry the beacon and answer the weekly survey questions, and US $10 for returning the beacon to the research team, so the most they can receive is US $100. All compensation will be provided in the form of an Amazon e-gift card.

Beacons and Parameters for Signal-Contingent Triggers

Beacon Selection and Features

We prioritized 4 criteria in the selection of the beacon used in this study: signal strength, robustness of the application programming interface, size and convenience of carrying, and battery life. The expected functionality of the beacon is primarily advertising (ie, one-way communication comprising transmission of small packets of data over fixed time intervals for detection and localization by a receiver—here, the EMA app used by the participants) [40]. Given these requirements, we selected BLE, an extension of the traditional Bluetooth protocol. Using BLE facilitated the optimization of our first criterion, signal strength. The Bluetooth protocol includes a feature called Received Signal Strength Indication, an indicator of the signal power received by a device detecting BLE signals. This feature, together with the specifications of the transmission source hardware, enables the computation of approximate positioning in the natural environment, including the estimation of distance [41,42]. Many hardware vendors provide these features; a subset of these vendors provides open, nonproprietary documentation of these values [43] and the ability to interface directly with the beacons through a robust application programming interface, our second criterion. After reviewing options, conducting testing, and consulting with the app developer, we selected Kontakt.io, a company with beacons that met the first 2 criteria and have form factors that can be attached to a phone or keyring to ensure that it is carried consistently. We extensively tested the options available from Kontakt.io and determined that the asset tag was most reliably detected by our app and by generic BLE scanner apps. Its battery life is 6 to 12 months and can be monitored on the internet; therefore, even with reuse, there should be no missing data attributable to a depleted battery.

We initially investigated whether we could build the system such that the Bluetooth on the peers' phones would be detected by the app on the participant's phone. For this, an app was needed that could use the BLE functionality within the participant phone to detect and identify the peer phone and prompt the participant to respond within the EMA app. One problem with using the peer phone as the BLE transmitter is that different Bluetooth hardware installed in different phones will report differing RSSI values for the same physical distance since this metric is contingent on the strength of the signal being sent out by the original device. This increases the complexity of the programming logic and would add error into what is a simple threshold check for beacons. Another issue is that we were unable to identify any phone-to-app software with an SDK available to use with our EMA app, whereas beacon detection SDKs were available. There were other considerations, including that in early developmental work concerns were raised by peers about installing an app on their phone, but the most critical were that the resources needed for phone-to-app detection were higher than the beacon-to-app model due to the initial development process, variability of operating systems and hardware, and required ongoing maintenance when relying on operating systems that evolve over time. The key benefits of beacon-to-app detection are the consistency of the technology and lower development costs when using an existing SDK.

EMA Report Triggering by Beacon Proximity

The protocol for peer proximity detection and subsequent triggering of reports involves the detection of *transient encounters* (ie, incidental, brief social interactions between the participant and a peer identified through signal detection), their conversion into *actual encounters* (ie, meaningful social interactions differentiated from incidental encounters using a time criterion), and their termination as *end encounters* (ie, discontinuation of meaningful social interaction; refer to Figure 3 for a representation of the process). The EMA app continuously scans the participants' environments for peer beacons. A transient encounter is recorded when the BLE proximity detection service integrated into our EMA app detects a beacon, defined as detecting a signal from a peer beacon that is at least as strong as the Received Signal Strength Indication criteria that correspond to our proximity criterion (ie, 15 ft, 4.6 m). The peer beacon advertising interval, which is the frequency at which beacons send out signals, was set to 1000 milliseconds (1 second) to ensure that the detection corresponds closely to real-world interactions. However, given that the detection of every signal from the peer beacon by the participants' device during the initial encounter period is not guaranteed, a window

of time for the detection of this signal is needed to ensure that detection occurs (ie, that it is not missed, resulting in a false negative); this window was set at 2 minutes for the transient encounter.

A *transient encounter* is converted into an *actual encounter* when the beacon has been detected for at least 15 minutes (our definition of meaningful interaction) without being undetected (ie, gone) for >2 minutes. A signal-contingent report will be triggered upon the conversion of a transient encounter to an actual encounter. Critically, the algorithm that determines triggering by beacon proximity runs separately for each peer participant, such that a transient and actual encounter with a peer beacon can be initiated even when the participant is in an actual encounter with another peer. Given that there will be 3 peers carrying beacons, it is possible that up to 3 reports could be triggered at a time, although we do not anticipate that this will happen frequently. In addition, given our encounter parameters that require 60 minutes of nondetection before another encounter with the same beacon would occur (refer to the subsequent section for explanation), we do not expect the number of signal-contingent reports to be overwhelming but will evaluate this closely.

A separate criterion to end an actual encounter after 60 minutes of nondetection (vs 2 minutes for a transient encounter end) was selected. We selected 60 minutes to reduce spurious nondetection and accommodate behaviors such as going to the restroom or being in different rooms at a party (which may still be part of an ongoing meaningful interaction despite not meeting the proximity criterion). Although the duration of the time criteria (ie, 15 minutes for the actual encounter and 60 minutes for the end encounter) were somewhat arbitrary, the evaluation of the sensitivity and specificity of the criteria via concordance with self-report is a goal of the study. Subsequent work can trial different definitions based on study findings, as well as what contact is truly influential and whether the length of influential contact varies by relationship type. Table 2 presents our initial criteria (far-right column) based on the best judgment, but the criteria are modifiable within the researcher-accessed interface.

Figure 3. State flow diagram that incorporates the beacon detection, encounter definition, and notifications. PlotProjects is a service and application programming interface used by the app software for the Bluetooth beacon detection.

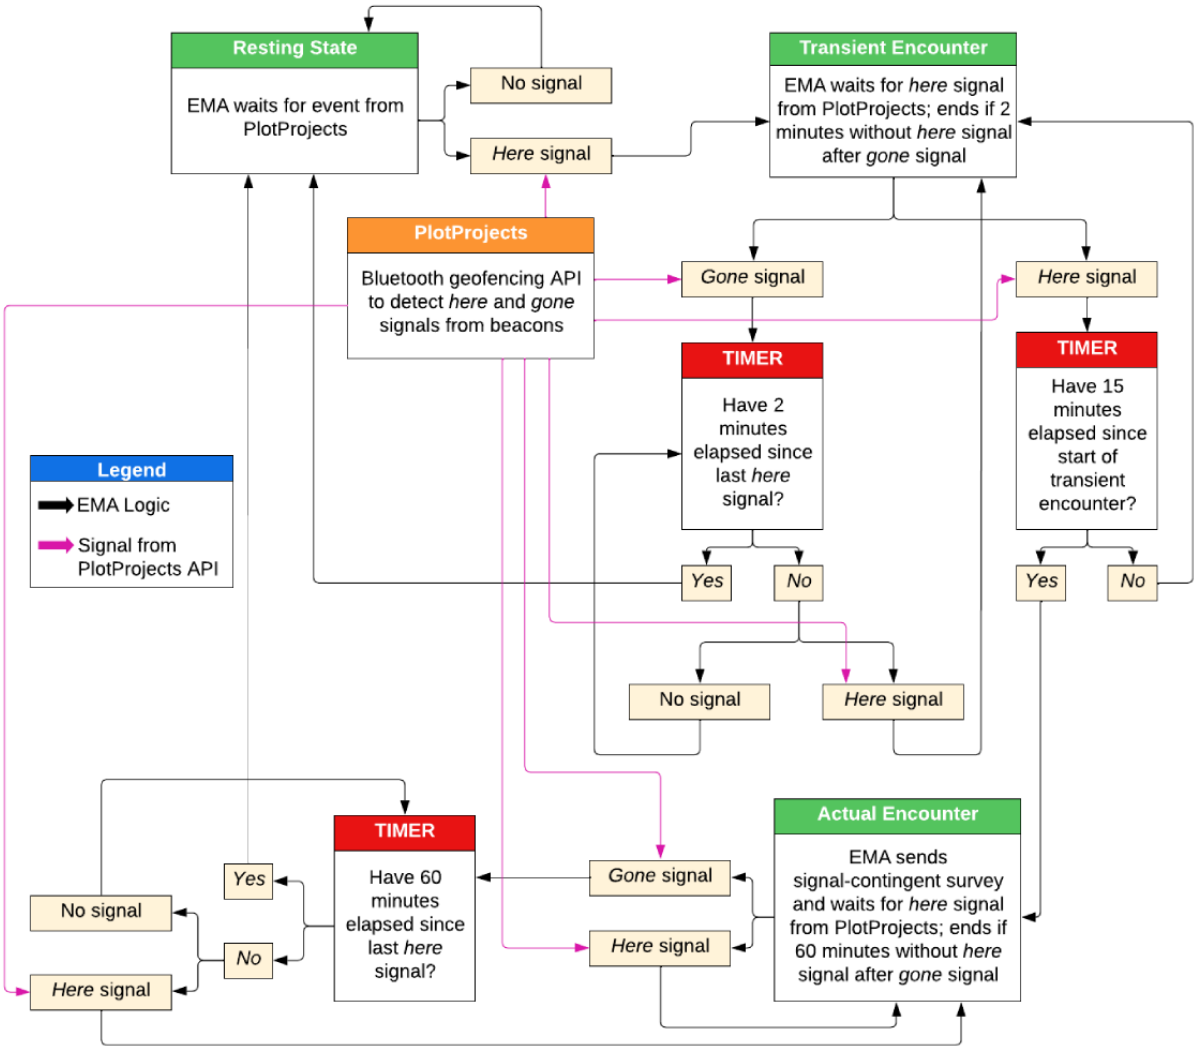


Table 2. Transient and actual beacon encounter terms, definitions, and criteria.

Term	Definition	Criteria
Encounter	Incidental or purposeful social interaction between the participant and a peer is identified through BLE[a] signal detection with a predefined proximity criterion.	15 ft (4.6 m)
Start of a transient encounter	Brief social interaction. A transient encounter begins but does not constitute meaningful interaction until it converts to an actual encounter.	1000 milliseconds
End of the transient encounter	End of a brief social interaction is defined by a given time criterion. Intended to ensure that very brief encounters do not prompt a notification.	2 minutes without beacon contact
Start of an actual encounter	Meaningful social interaction defined by a given criteria of time. A transient encounter is converted to an actual encounter. An actual encounter triggers a signal-contingent report.	15 minutes of beacon contact with no periods >2 minutes without beacon contact
End of the actual encounter	Discontinuation of meaningful social interaction.	60 minutes without beacon contact

[a]BLE: Bluetooth Low Energy.

There are several technology-related considerations for the detection of meaningful interactions. First, an a priori definition of a meaningful social interaction had to balance sensitivity for detecting such events (addressing the *feasibility* of detecting social interactions) with specificity in excluding incidental, nonmeaningful interactions (and reducing the burden of responding to multiple signal-contingent reports). However, our a priori criterion of requiring 15 minutes for a transient encounter to be converted into an actual encounter will miss brief but meaningful interactions (eg, consuming a shot of hard alcohol together, offering alcohol). Importantly, we designed our protocol to minimize missing data associated with such events by including the assessment of past-hour peer presence in our random reports and past-day peer presence in our morning reports. This design will allow us to cross-tabulate the occurrence of self-reported interactions of even short duration (as recorded in the EMA report data set) with the occurrence of all beacon detections, including transient encounters (as recorded in the Beacon Encounter data set).

Data Sets and Calculated Variables

Overview

Data produced by the app, including information about encounter events, participant self-reported data, and metadata, are stored in several data sets. These data sets are supplemented by postparticipation self-report data from (non-EMA) surveys and semistructured interviews. Table 3 contains a description of the data sources; Table 1 links the data sources with the study goals and methods to the evaluate goals.

Table 3. Metadata and calculated variables and associated source data sets that will be used to evaluate research goals.

Metadata or calculated variable	Source data set					
	App log	Beacon Encounter	Participant events	Notification log[a]	EMA[b] report	Postparticipation
Participant ID	✓	✓	✓	✓	✓	✓
Peer ID (corresponds to beacon ID)		✓			✓	✓
Event or Report timestamp	✓	✓	✓	✓	✓	✓
Event type (eg, action delivered, participant report started, report response, and app synced)[c]	✓	✓	✓		✓	
Session ID (helps link together events from different data sets)		✓	✓	✓	✓	
Source of event (eg, morning or random report)			✓	✓	✓	
Corroborative self-report					✓	✓

[a]Contains only notifications for morning and random reports.

[b]EMA: ecological momentary assessment.

[c]Metadata recorded by the app and stored.

Further information about the source data sets are presented in the Multimedia Appendices 1-5.

App Log

This data set contains information about the app version used and (morning, random, beacon-triggered) report items that are programmed into the app. It also contains event types (eg, app opened and app synced) and errors (eg, when the operating system denies permission to the app). We will use information from this data set to determine that the app was installed correctly and that it was functioning as expected during the study.

Beacon Encounters

Variables include participant ID, beacon ID, start and end timestamps of transient and actual encounters, the timestamp when the transient encounter was converted into an actual encounter, and the timestamp for when the report notification was sent. A unique session ID links the elements (start and end) of given (transient and actual) encounters.

Participant Events

Variables include participant ID and types of events (eg, report start, report submit, and report notification) with timestamps. The report start and submit timestamps are present for all reports, including random, morning, and signal-contingent reports. Report notification timestamps (1) duplicate the timestamp of the transient-to-actual conversion reported in the Beacon Encounter data set (which triggers a notification) and (2) indicate whether other notifications are for random or morning reports.

Notification Log

Variables include session ID, report type (ie, random and morning), and timestamps when timed notifications and reminders were scheduled to be sent.

EMA Reports

Data include participant responses to items in the signal-contingent, random, and morning reports, including indicators of who among their peers is or was present and self-reports about app functionality. For example, in each report, we ask, “Who did you interact with in person for at least 15 minutes?” The report type and timestamp will be used to ensure that data responses are aligned with information from other data sets and reports.

Postparticipation Data

Data from the postparticipation interviews and the SUS will be used to evaluate the app’s functionality. Participant interviews will also be used to investigate identified discrepancies between the beacon-derived data and participant reports (ie, validity) and will be supplemented with weekly survey day-level reports from peers about their proximity to participants.

Data Analysis Plan

Functionality of Beacon Detection by the Participant’s Smartphone

We will confirm the detection of the 3 beacons by the participant’s phone during the orientation. We expect to observe smartphone notifications for each beacon when the transient encounter is converted into an actual encounter (after 15 minutes). If notifications are not observed, we will examine the Beacon Encounter data set to determine whether transient encounters are being recorded (ie, whether the beacon is detected by the app) without being converted into an actual encounter. Functionality will be evaluated with 3 metrics: (1) the proportion of participants whose phones detect all beacons during the orientation, (2) the proportion of beacons detected by participant phones, and (3) the latency between exposing the participant phones to the beacons and the start of a transient and actual encounter. These observations will be systematically recorded and aggregated across beacons and participants.

Functionality of the Beacon Encounter Notifications

Data from the Beacon Encounter data set will be used to evaluate functionality in two ways: (1) the proportion of actual encounters for which a signal-contingent notification was shown as sent by the server in the Beacon Encounter data set, and (2) the mean latency in minutes between the conversion to an actual encounter and the sending of the signal-contingent notification. The functionality of notifications for random and morning reports will not be evaluated, as these are commonly used in EMA and are fully functional in the app.

Functionality Related to App Stability

The app log, the EMA data, and the end-of-study interview and survey will be used to assess the participant-experienced functionality. The app log contains details about the events that have occurred within the app, including information about app crashes and app reinstalls. Using data provided by participants in the morning report, participant-related functionality will be determined as follows: (1) the total count (ie, person-days) of participant-reported suspected functionality problems, (2) the person-level proportion of days of suspected functionality problems, and (3) aggregated item-level and overall mean scores on the adapted SUS. Open-ended feedback will also be obtained in the morning report as well as in the end-of-study interviews.

Functionality Related to the Phone and Operating System

The manufacturer, model, and Android operating system of the participant devices will be examined as moderators of the above metrics of functionality. The variables will be evaluated using a series of Mann-Whitney *U* tests (for means and counts) and chi-square tests (for comparing proportions) for each metric. Considering the small sample size, the groups will be driven by the sample of the device itself. For instance, the manufacturer could be binned to *Samsung* (or potentially *Google*) versus *all other manufacturers*; the model could be binned to *currently supported* (ie, receiving ongoing feature and compatibility updates) versus *legacy*; and the operating system could be binned to *Android 13* (the newest) versus *Android 11 or 12* (operating systems that were used during app development). Independent of group comparisons, descriptive findings on functionality will be aggregated for each manufacturer and operating system version.

Validity

We define validity as the concordance between encounters recorded in the Beacon Encounter data set and participant reports of peer presence recorded in the EMA reports (Table 4).

Table 4. Beacon validity: cross-classification of beacon encounter and participant self-report data[a].

	Participant self-report data	
	Positive (participant reports peer within 15 ft, 4.6 m for 15 minutes)	Negative (participant does not report peer nearby)
Beacon detection		
Positive (signal-contingent trigger)	True positive: beacon detected and triggers signal-contingent report and participant reports peer presence in signal-contingent report (*sensitivity*)	False positive[b]: beacon detected and triggers signal-contingent report but participant does not report peer presence in signal-contingent report (*specificity; protocol criterion validation*). This could happen if: • delay or error in notification (*technology failure*) • peer is not actually present (*technology failure*) • peer is present with beacon but the index participant is not aware (*inaccurate index participant self-report*) • peer is present with beacon but not when the participant answers report (*limitation of detection settings*)
Negative (no signal-contingent trigger)	False negative[c]: 1. beacon never detected but participant reports peer presence on next EMA[d] random report (*sensitivity*). This could happen if: • peer is present with beacon but beacon is not detected (*technology failure*) • peer is present without beacon (*peer noncompliance*) • inaccurate index participant self-report 2. peer beacon is detected in transient encounter but criteria for actual encounter are not met so does not trigger signal-contingent report but participant reports peer presence on EMA random report (*specificity; protocol criterion validation*)	True negative: 1. beacon never detected and no report of peer presence on EMA random report (*sensitivity*) 2. peer beacon is detected in transient encounter but does not trigger signal-contingent report (criteria for actual encounter are not met) and no report of peer presence on EMA random report or morning report (*specificity; protocol criterion validation*)

[a]Concordance will be evaluated only when self-report EMA data are available. Therefore, beacon data collected when index participants are not compliant with random or signal-contingent reports will not be usable in the evaluation of concordance, as no self-report of peer proximity will be available.

[b]Reasons for false-positive signal-contingent triggers may not be known to the study team.

[c]Reasons for false-negative signal-contingent triggers may not be known to the study team.

[d]EMA: ecological momentary assessment.

False negative beacon detections will be evaluated in a series of steps: First, we will compute the proportion of (1) days and (2) random reports in which a participant reported peer presence (from the EMA data set), but a corresponding transient or actual encounter does not exist (from the Beacon Encounter data set). If a transient encounter, but not an actual encounter, is recorded, we will compute (3) the proportion of these false negative events that occurred because of the a priori selection of 15 minutes as the threshold delineating a transient versus an actual encounter (based on timestamps of encounter events in the Beacon Encounter data set). For the false negative events that are not associated with a transient encounter, we will further attempt to delineate the reason underlying this false negative as either technology-related (the peer was carrying the beacon but the beacon was not detected) or compliance-related (the peer was not carrying the beacon) by integrating self-report data on compliance from the peer weekly surveys. If sample size and base rates allow, we will also fit a series of generalized linear mixed models [44] regressing concordance at the person level (eg, sex and age) and proximal prior event level (eg, context and alcohol use) predictors to identify systematic factors associated with detection failure. *False positive* beacon detections, as indicated by the triggering of a signal-contingent report when the peer beacon is not present, have never occurred in preliminary testing. Given the factors needed to incur a false positive detection, which should only occur if beacon information was entered incorrectly by the research team, we believe that such events are highly unlikely. However, it is possible that a notification could be delayed by the operating system or other action (eg, if the index participant phone is off), which would result in the participant report being delayed, and thus the participant report would not confirm the peer presence. Beacon detection also could occur when a peer was present but the participant was not aware (eg, at a large party) or if the peer left the area before the participant answered the report. We will compute the proportion of signal-contingent reports in which participants deny a past-hour peer presence. We expect that the participant interviews and the peer surveys will be informative about the conditions under which false positives occur and will improve our understanding and measurement of peer proximity and influence. Ultimately, the detection of an encounter by the protocol when such an interaction did not occur from the participant's perspective provides critical information necessary for the computation of the specificity and positive predictive value of our detection protocol.

Anticipated Sources of Missing Data

With various momentary assessment reports and passive data collection from multiple peers, the source of missing data is important to identify. We expect to have missing data owing to technical issues for the following reasons: (1) the beacons could stop sending a signal because of low battery or hardware failure; (2) the app could crash or be unable to send or receive data; (3) the phone operating system could update, resulting in the app or phone features not working as expected; or (4) the software detection algorithm may stop identifying encounter start and end signals. Missing data may also be because of participant or peer noncompliance, including the following: (1) participant nonresponse to EMA reports, (2) participant changing phone settings or status such that the detection of beacon signals or notifications is interrupted, or (3) peer failure to carry the beacon. Items in the morning report, postparticipation surveys and interviews, and the peer weekly survey will capture times when the participant or peer is aware of these issues occurring. While imperfect, this information should allow us to characterize situations in which the reason for missingness is known and thus maintain the missing-at-random assumption. Situations in which we are not confident about the reason for missing data will be investigated for systematicity using proximal prior predictors in the EMA data set to further maintain the missing-at-random assumption.

Results

Participant enrollment began in February, 2023. As of submission of the manuscript (June 2023), nine participants and 21 peers were enrolled, with data collection anticipated to finish in December, 2023. Data analysis will begin immediately upon completion of data collection.

Discussion

Principal Findings

The research described in this paper will advance the literature by developing and validating a passive detection system for situations in which social influence is important. While this Bluetooth-based technology could be applicable to many research, clinical, or community settings in which social contact is relevant, our substantive goal is to facilitate research characterizing the real-time social context of alcohol use and, in turn, to inform the timing and context of mobile-delivered interventions to reduce hazardous drinking [45,46]. In this paper, we describe our planned procedures for evaluating the functionality and validity of the system, which incorporates multiple components of functionality and uses data from the app and reports from participants and up to 3 of their close peers. Our approach to collecting user-reported information along with passively recorded data is consistent with recommendations for identifying high-risk events and the timing of real-time intervention [47].

Just-in-time adaptive interventions target behavior in the natural environment at a time when behavior is opportune for modification [48]. These tailored mobile-delivered interventions provide the right type and timing of intervention in response to real-time behavior, cognition, or context to prevent negative health outcomes [48-50]. Ideally, interventions could incorporate this BLE-based peer proximity approach to help people who are interested in changing behaviors by identifying contexts that confer greater risk (or alternatively, that protect against risk), alerting these people or others about the risk inherent in their present situation, and including encouragement and information about how to avoid the situation. This approach could be combined with other sensor technology, including location detection or geofencing using GPS to detect proximity to risky locations (eg, alcohol outlets), and other smartphone features (eg, the smartphone accelerometer to measure movement or engagement with messaging and texting apps) [27]. This study will provide much-needed information about the appropriate timing and context for just-in-time adaptive interventions in a scenario that is highly characteristic of young adult drinkers: consuming alcohol with close peers.

Limitations

Limitations related to technology include the need to build the system with a contracted app developer; to the best of our knowledge, there are no systems that researchers could use out of the box for person-proximity detection and EMA report triggering. The system only works with phones that use the Android operating system; iOS imposes barriers to the development of technologies and the distribution of test builds, whereas Android allows for the installation of third-party software outside of the context of Google Services (ie, sideloading). However, Android had multiple operating system updates while our project was under development; each update required a revision of the app and additional testing. This is an unavoidable element of app development that adds considerable time and resources to a project. We considered providing Android phones to participants who did not have them but had concerns that intermittent or limited use of a secondary phone would reduce both compliance and app functionality (eg, fewer notifications being sent to phones frequently in sleep mode). Another technology limitation is our inability to implement a minimum time interval between random and signal-contingent reports or to set a limit on the number of signal-contingent reports a participant receives. We will evaluate the average number of reports and intervals between reports and hope to include adjustments in future iterations.

Our design will not detect influential peers who are not carrying a beacon; therefore, its success will rely largely on how well our SNI identifies influential peers and whether they participate. Our procedures will also poorly detect friends who are influential through interactions other than in-person contact (eg, via social media or text). Influence could also occur more quickly than the time duration estimate that we defined in the protocol; this influential interaction would be missed. During all EMA reports, we collect information about peers who are present but not carrying a beacon (identified a priori) and peers who are present but not on the participant's selected peer list, which will help us to determine how successful our SNI selection process was and address some of the above limitations; we also expect that information collected in the postparticipation interviews will assist us in adjusting procedures for identifying influential peers.

We are relying on self-report to a considerable extent in that we are using it as the ground truth for whether a beacon detection is accurate or not. Self-report can be inaccurate or missing, but it is the standard in the field for describing context and alcohol use, and there are no alternatives that we could use to compare to beacon detection. While we are confident that our informed consent procedure, the provision of a clear rationale to participants and peers, and confidentiality protections will minimize inaccurate reporting, it is possible that social desirability or other person-level or contextual effects in some situations will result in missing or inaccurate reports of peer presence or alcohol use [51,52]. We expect that we will not be able to identify the reason for some disagreements between beacon detection and self-report, but the very robust data sets will allow for sensitivity analyses that will help us identify and understand discrepancies. For example, with morning reports and sensor data, we can compare the concordance between beacon detection and self-report on drinking versus nondrinking evenings. The weekly web-based surveying of peers was designed to minimize burden (and thus increase the likelihood of peer inclusion), but may produce unreliable data about the time spent with the participant.

The success of this research relies on participant and peer compliance, as their reports are needed to evaluate every project goal. Although some degree of noncompliance with EMA is common [38], poor compliance would limit our ability to evaluate functionality (refer to Table 4 for details) independent of systematic bias owing to missingness in the data collected. Although our participant burden is consistent with the current practice in EMA research, our peers must consistently carry a small beacon. Our requirement that peers continuously carry a beacon will likely result in more missing data than if there were an app for peers to install on their phone (which would also be easier to do remotely). Finally, this type of work requires considerable staff time for participant and peer recruitment (up to 3 peers per participant), monitoring incoming EMA and beacon data, and data management and analysis.

Future Work

In addition to the evaluation described herein of functionality and validity, we are collecting participant feedback about our procedures, which will allow us to evaluate feasibility and acceptability. Together, this information will inform a large-scale study with a representative sample, a wider age span, and a broad representation of social context, permitting the study of dynamic intersections of multiple determinants of drinking behavior, including social context, location context, and individual factors (eg, craving, affect, and motivation) that underlie contextual influences [53].

Acknowledgments

This research was supported in part by grants (R21AA027329 [multiple principal investigators NPB and KMJ], K08DA048137 [principal investigator AWS], and K01AA025994 [principal investigator MKM]) from the National Institute on Alcohol Abuse and Alcoholism. The National Institutes of Health had no role in the study design, collection, analysis, or interpretation of the data, writing the manuscript, or the decision to submit the paper for publication.

Data Availability

Data sharing is not applicable to this paper as no data sets were generated or analyzed in this protocol. Once data are generated, data sets will be available from the corresponding author on reasonable request.

Abstract

Background: Physical activity and exercise are important aspects of maintaining health. People with mobility impairments, including survivors of stroke, are less likely to exercise and at greater risk of developing or worsening chronic health conditions. Increasing accessible, desired options for exercise may address the gap in available physical activity programs, provide an opportunity for continued services after rehabilitation, and cultivate social connections for people after stroke and others with mobility impairments. Existing evidence-based community programs for people after stroke target cardiovascular endurance, mobility, walking ability, balance, and education. While much is known about the effectiveness of these programs, it is important to understand the local environment as implementation and sustainment strategies are context-specific.

Objective: This study protocol aims to evaluate community needs and resources for exercise for adults living with mobility impairments with initial emphasis on survivors of stroke in Richland County, South Carolina. Results will inform a hybrid type I effectiveness and implementation pilot of an evidence-based group exercise program for survivors of stroke.

Methods: The exploration and preparation phases of the EPIS (Exploration, Preparation, Implementation, and Sustainment) implementation model guide the study. A community needs assessment will evaluate the needs and desires of survivors of stroke through qualitative semistructured interviews with survivors of stroke, rehabilitation professionals, and fitness trainers serving people with mobility impairments. Additional data will be collected from survivors of stroke through a survey. Fitness center sites will be assessed through interviews and the Accessibility Instrument Measuring Fitness and Recreation Environments inventory. Qualitative data will be evaluated using content analysis and supported by mean survey results. Data will be categorized by the community (outer context), potential participants (outer context), and fitness center (inner context) and evaluate needs, resources, barriers, and facilitators. Results will inform evidence-based exercise program selection, adaptations, and specific local implementation strategies to influence success. Pilot outcome measures for participants (clinical effectiveness), process, and program delivery levels will be identified. An implementation logic model for interventions will be created to reflect the design elements for the pilot and their complex interactions.

Results: The study was reviewed by the institutional review board and exempt approved on December 19, 2023. The study data collection began in January 2024 and is projected to be completed in June 2024. A total of 17 participants have been interviewed as of manuscript submission. Results are expected to be published in early 2025.

Conclusions: Performing a needs assessment before implementing it in the community allows for early identification of complex relationships and preplanning to address problems that cannot be anticipated in controlled effectiveness research. Evaluation and

preparation prior to implementation of a community exercise program enhance the potential to be successful, valued, and sustained in the community.

Introduction

Physical activity (PA) and exercise are important aspects of maintaining health and reducing the development and severity of chronic conditions [1]. PA can lower the risk of mortality and reduce the incidence of hypertension, diabetes, heart disease, and some cancers [1]. Older adults have additional benefits of improved quality of life and lower risk of falls [1]. People living with disability are at a greater risk for chronic health conditions and are less likely to exercise than their age-matched peers [2,3]. People with disabilities have limited access to exercise in order to mitigate their health conditions and improve their aerobic capacity [2,4].

For survivors of stroke, reduced PA additionally increases their risk for a recurrent stroke [3]. Up to 80% of the risk of recurrent stroke can be mediated by lifestyle factors including medication management, diet, and exercise [3]. Individuals after stroke with mobility impairments have poor movement economy and higher cardiovascular demands that increases their need to build aerobic capacity over their peers [5]. However, even after receiving inpatient rehabilitation services, deficits remain. After completing inpatient rehabilitation, 80% of stroke survivors can ambulate indoors, but only 27% can perform the essential skills of community ambulation [6]. Despite the remaining deficits, many do not receive additional care in the community [7]. A lack of services after rehabilitation to promote independent community living results in unmet needs for continued physical recovery [4,6,8].

In addition to the physical benefits of PA, structured exercise programs can provide social connection [9,10]. People living with disability, including survivors of stroke, are socially isolated and desire a sense of belonging and social participation [7,10,11]. Increasing accessible, desired options for exercise may address the gap in available PA programs, provide an opportunity for continued services after rehabilitation, and cultivate social connections for people after stroke and others with mobility impairments. Group exercise programs that focus on functional fitness for clinical populations are a worldwide fitness trend and are a suggestion of focus for fitness professionals by the American College of Sports Medicine [12].

Existing evidence-based community programs for people after stroke include Fitness and Mobility Exercise [13], Together in Movement and Exercise [14], and Fit for Function [15]. These programs target fitness with a varied focus on cardiovascular endurance, mobility, walking ability, balance, and education [13-15]. While much is known about the effectiveness of these programs, it is important to understand the local environment as implementation and sustainment strategies are context-specific.

The aim of this study protocol is to evaluate community needs and resources for general and group exercise for adults living with mobility impairments with initial emphasis on survivors of stroke in Richland County, South Carolina. Results will inform an action plan for a hybrid type I implementation study testing the effectiveness and implementation process of a modified evidence-based exercise intervention [16]. Involving the community in the needs assessment and performing the needs assessment with a systematic approach facilitates the success and sustainability of the program [17,18].

Methods

Overview

This project will address the study objective using the EPIS (Exploration, Preparation, Implementation, and Sustainment) framework, concepts of community-based participatory research, and the implementation research logic model [17-19]. The exploration and preparation stages of EPIS seek to determine health needs, identify barriers and facilitators, select an evidence-based program, determine program modifications, and create implementation strategies [17]. These stages are the focus of this protocol. The EPIS implementation and sustainment stages test the evidence-based program and the ability of the program to be maintained in the community after the research process ends [17]. The EPIS framework considers participants inside and outside the organization (inner and outer context) that will offer the community program, the academic and community partners that bridge these contexts, and the characteristics of the program itself [17]. Each stage is dependent on and related to the others [17].

The EPIS exploration and preparation stages (Figures 1 and 2) will be completed as part of this study and include three steps: (1) performing a needs assessment; (2) identifying determinants, selecting an evidence-based exercise program to address, and creating implementation strategies; and (3) determining mechanisms of action for the implementation strategies and their corresponding outcome measures, and creating a logic model [17,19]. Results will inform the implementation protocol and program pilot-testing as a separate study (EPIS implementation and sustainment stages; Figure 1 [17,20]).

Figure 1. Applied EPIS (Exploration, Preparation, Implementation, and Sustainment) framework for implementation studies (adapted from Moullin et al [17], which is published under Creative Commons Attribution 4.0 International License [20]). The exploration and preparation stages will be completed as part of the current needs assessment for community group exercise for people after stroke. The exploration stage performs a needs assessment whose resulting determinants and strategies feed into the preparation stage that results in an implementation logic model and detailed protocol for the pilot study. The implementation and sustainment stages will be completed as a separate study and perform the pilot, evaluate the outcomes, and produce changes and further research for sustainment in the community.

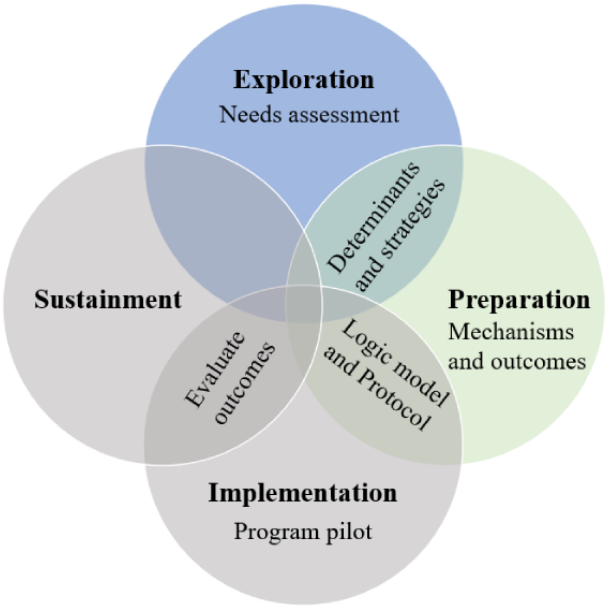

Figure 2. Steps to complete EPIS (Exploration, Preparation, Implementation, and Sustainment) framework: evaluation (blue-textured) and preparation stages (green-solid). This framework will be used as part of the needs assessment for a group exercise program for people after a stroke. Step 1 identifies the actions and data analysis of this study community needs assessment. Step 2 evaluates the results and selects the evidenced-based exercise program. Step 3 details the plans for pilot implementation including the mechanisms of action and the outcome measures.

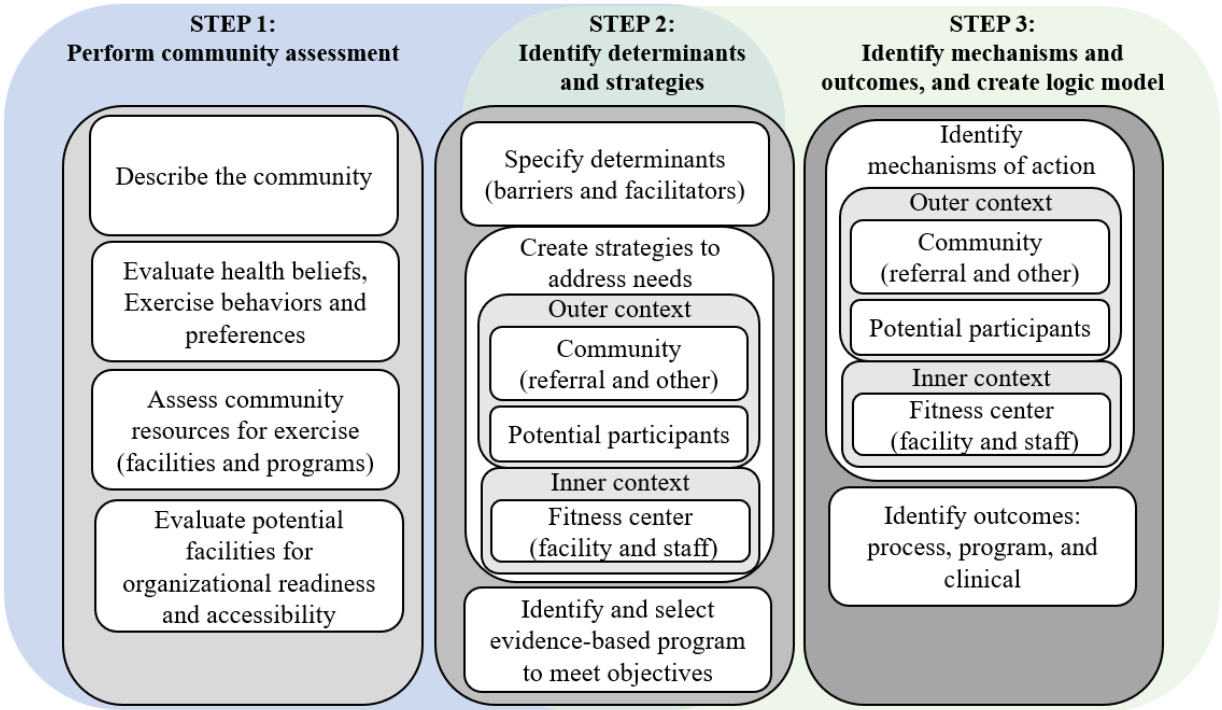


Step 1: Perform Community Assessment

Describe the Community

A literature review will provide perspective on the communities of Richland and Lexington Counties in South Carolina. Several resources will help provide demographics including United States Census data, Center for Disease Control American Community Survey and Center for Health Statistics, the Behavioral Risk Factor Surveillance System, and County Health Rankings. Prisma Health, the largest nonprofit health system serving Richland County SC, completed a community needs assessment in 2022. This assessment will provide data to

describe the community health concerns and overall health priorities. General demographics, demographics of people living with disabilities, and demographics of survivors of stroke will be described.

Evaluate Health Beliefs, Exercise Behaviors, and Preferences

This step will use semistructured interviews with key stakeholders to assess the culture of the community around health beliefs and exercise behaviors and preferences both for people with mobility impairments and specifically for survivors of stroke. Individual or small group interviews will be conducted with targeted key organizational stakeholders which will include health care providers (physicians, rehabilitation providers, and cardiac rehabilitation providers), other nonprofit or public organizations serving people with disabilities (independent living support services, diabetes educators, vocational rehabilitation, and veterans' organizations) and fitness providers who currently serve people with mobility issues. After initial contact with stakeholders in each category, snowball sampling [21] will identify additional people or organizations to include.

Interview questions will relate to health needs, specific exercise needs, beliefs, contextual factors, exercise services, and gaps. Survivors of stroke will be interviewed in a focus group format at a community stroke survivor support group and additionally in small groups. Care partners will be invited to participate. Interview questions will be the same regardless of format or stakeholder (Textbox 1). Questions will be piloted in the first 2 interviews and revised as needed.

Sample goals are to collect data from a diverse set of viewpoints in order to adequately answer study aims [22]. A pragmatic approach targets 10-15 stakeholders and 10-15 survivors of stroke for the initial sample to achieve.

In addition to the questions in Textbox 1, the stroke survivors focus group will receive additional questions related to specific desires around group exercise (Textbox 2).

Once the focus groups and individual interviews are complete, a survey will be created based on the results. The survey will be distributed to a wider audience in the community and will evaluate desires for general and group exercises and the barriers and facilitators to participation. The survey will be distributed through stakeholder organizations and research contact lists for people with mobility impairments using REDCap (Research Electronic Data Capture) electronic data capture tools hosted at the University of South Carolina.

Textbox 1. Semistructured interview questions for stakeholders to evaluate community health services and exercise beliefs and behaviors as part of the community needs assessment for a group exercise program for people after stroke. Health care providers, organizations serving people with disabilities, fitness professionals, survivors of stroke, and care partners will be interviewed in individual, small group, or focus group formats.

Questions:

1. What is important to this community from a health and quality of life perspective?
2. What are the beliefs about access and treatment for ongoing health care needs?
3. What existing organizations and services address health care and quality of life needs?
    - What are they doing well?
    - What are the gaps in services?
4. What are the beliefs about and interest in exercise for this community?
5. What are the barriers and facilitators to exercise?
6. What are existing community resources for people to exercise and to engage in other ways to improve health?
    - Who is using these resources? Describe the people who engage.
    - What are they doing well?
    - What are the gaps in services?
7. What are your thoughts on funding to support exercise programming on-going? (organizational stakeholders)?

Textbox 2. Semistructured interview questions to evaluate specific exercise interests and preferences for survivors of stroke only as part of the needs assessment for planning a community group exercise program for people after stroke. Interviews will occur in a focus group or small group format.

Semistructured interview questions on exercise interest and preferences (stroke survivors only):

1. What types of exercise activities would you be interested in (endurance, strength, balance/coordination, stretching, and relaxation) Examples given of each type of exercise.
2. In what formats (small group, larger group/Type of group based on mobility: seated vs standing, requiring assistance vs nonrequiring assistance, based on diagnosis or not based on diagnosis)
3. What type of facility (community fitness facility, private gym, community center, senior center, church center) and in what part of the county is desired?
4. How often and what time of day is preferred?
5. What do you think the benefits of an exercise program would be for you individually and others with stroke?
6. What do you think you will like about exercising in a group? What do you think you will dislike about group exercise?
7. What are factors currently and potentially impacting access and engagement in exercise?
    - Are you currently exercising, and if so, what are you doing, and if not, why not?
    - What do you like about exercise or movement?
    - What is your confidence in your ability to exercise independently? With instruction? With assistance?
        - If low confidence, what do you think would increase confidence?
    - How would you be able to get to a group exercise program (transportation)?
    - How much would you be willing to pay for an exercise program?

Assess Community Resources for Exercise

Using results from the community assessment and internet searches, the facilities and program resources available for group and individual exercise for people with mobility impairments in Richland County will be identified. Information gathered will include whether the facility or organization self-identifies as accessible and the goals and mission of the organization.

Evaluate Potential Facilities for Accessibility and Organizational Readiness

A subset of the listing of community resources will be evaluated in more detail to assess accessibility and general organizational readiness for new or modified exercise programs for people with mobility impairments (Textbox 3). Facility management, staff, and fitness providers will be interviewed to determine readiness for change. Interview questions were developed based on the components of the theory of organizational readiness for change [23]. The evaluation will include an accessibility evaluation using the Accessibility Instrument Measuring Fitness and Recreation Environments (AIMFREE) inventory [24].

Textbox 3. Potential location for pilot group exercise program for people after stroke facility evaluation will include facility stakeholder (exercise instructors and management) semistructured interviews in individual or small group format and a comprehensive accessibility inventory.

Methods: (1) Stakeholder interview and (2) Accessibility Instrument Measuring Fitness and Recreation Environments (AIMFREE) accessibility inventory (Rimmer et al [24])

Facility stakeholder interview questions:

1. Describe the interest and priority in the organization to serve those with mobility impairments.
2. What is your openness to adding additional or modified programs for people with mobility impairments?
3. Describe your perception of your organization's ability to support an exercise program for people with mobility impairments both initially and ongoing.
4. What are the resources available to support new programming?
    - Describe your staff who could potentially support these new programs.
    - Would new staff need to be hired?
    - What are your anticipated barriers or facilitators?
    - What types of equipment and space would be available? At what time of day?

AIMFREE accessibility inventory:

The inventory includes both physical space accessibility and behavior and policy evaluations. The AIMFREE inventory can be obtained from the National Center on Health, Physical Activity and Disability (NCHPAD), nchpad.org. The following sections will be completed with the assistance of facility staff and a consultant with mobility impairments. Section E, which evaluates hot tubs, whirlpools, and saunas will be omitted.

- SECTION A: Access Routes and Entrance
- SECTION B: Equipment
- SECTION C: Information
- SECTION D: Locker Rooms and Showers
- SECTION F: Elevators
- SECTION G: Bathrooms
- SECTION H: Professional Behavior
- SECTION I: Professional Support and Training
- SECTION J: Policies
- SECTION K: Programs

Step 1: Data Analysis

Outer Context Description

A narrative summary of the neighborhood characteristics and priorities in the community based on the formal community statistics and health priorities review will be created to provide descriptive background for the remaining data. Community participants will be described with demographic descriptive statistics for each group (referral sources, health care providers, fitness providers, community organizations, and potential participants).

Inner Context Description

General descriptions of fitness facilities including location, program availability, inclusion as part of the mission, and goals of the organizations in Richland County will be summarized. For the subset of facilities that receive detailed reviews, a summary of each facility will be provided. The summary will include the AIMFREE findings.

Qualitative Thematic Analysis and Survey Analysis

Focus group and interview data will be analyzed using deductive-dominant qualitative content analysis using NVivo software (version 12; Luminvero Inc) [25-27]. Captured data will be open-coded and categorized for thematic analysis in the following levels: community (outer context), individual (outer context), and fitness center (inner context). At each level, needs/desires, resources, barriers, and facilitators will be defined by the responses to the categories in Table 1 by 2 researchers and combined by group review and discussion to resolve discrepancies. Any themes newly arising from the data outside of these categories will be included. Survey results will also be mapped to the same categories from Table 1 and combined in an evaluation matrix with the themes from the content analysis.

Table 1. Categories of determinants and implementation strategies for results in the outer context and the inner context of the needs assessment for group exercise for people after stroke. Determinants categories will serve as the organizational structure for qualitative thematic data analysis and implementation strategies categories will serve as the planning structure for the implementation protocol.

Categories and levels	Determinants categories	Implementation strategies categories
Outer context		
Community	• Health care and other potential referral resources and the facilitators and barriers to referral • Other assistance needed from health care or community organizations to support potential new programs.	• Identify referral sources • Create strategies to address barriers to referral • Build strategies to address needs for health care or other community supports vital to the success of the program including champions
Potential participant	• General health and quality of life priorities, services, and organizations to meet related needs and gaps in services. • General exercise resources, use, beliefs, and priorities • General exercise desires and needs • Barriers and facilitators to exercise	• Strategies to address barriers and promote uptake and retention of potential participants
Inner context		
Intervention characteristics	• Group exercise desired format, types of exercise, and frequency	• Identify and select evidence-based exercise program
Organizational (fitness facility)	• Available facilities and programs already meeting the identified individual needs and desires • Accessibility of targeted facilities/organization (physical, behavioral, policy) including gaps and potential future needs • Organizational readiness for change	• Select an organization to pilot the program • Identify organizational strategies for staff, training, equipment, accessibility upgrades, and other needs • Identify an organizational champion

Step 2: Identify Determinants and Implementation Strategies

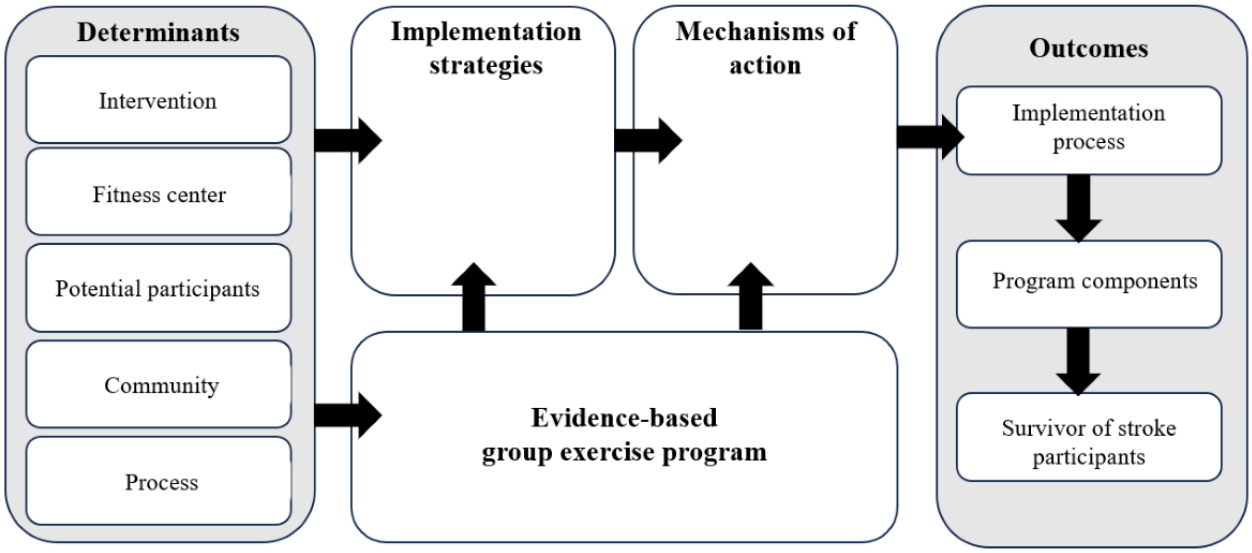
Following the EPIS framework, the preparation stage begins with specifying the determinants based on results in step 1. Determinants include contextual factors for the outer context (potential participants and community) and inner context (fitness facility), process components, and intervention components [19]. From the determinants, an evidenced-based exercise program will be selected, and implementation strategies for exercise programming and related services created (Figure 2 and Table 1) [19]. Implementation strategies are approaches to address the necessary modifications of the exercise program, the training and resources needed for the inner context, and any other required innovations to adapt to the local community.

All results of the qualitative content analysis, triangulation with survey data, and the determinants will be verified through member checking with updates made as necessary.

Step 3: Identify Mechanisms, Outcomes, and Create Logic Model

Identifying the mechanisms of action, selecting outcomes, and creating the logic model addresses the preparation step of the EPIS framework. Mechanisms of action are the implementation strategy processes to affect the outcomes [28]. Examples include education, skill building, efficacy, and motivation [28]. Finally, outcome measures for the participants (clinical effectiveness), implementation process (fidelity), and program components (service) will be identified. A logic model will be created based on the results of steps 2 and 3 to organize the determinants, implementation strategies, exercise programs, mechanisms of action, and outcomes. A logic model demonstrates the study design elements for the hybrid type I model and their complex interactions [19]. The standard logic model format by Smith et al [19] is presented in Figure 3 [19,20].

Figure 3. The implementation research logic model standard form with intervention (adapted from Smith et al [19], which is published under Creative Commons Attribution 4.0 International License [20]). The logic model will serve as a roadmap for the implementation protocol for the evidence-based group exercise program for people after a stroke. Determinants include contextual factors, process components, and intervention components. Implementation strategies are actions to address the unique determinants through mechanisms of action (ie, education and skill building) to ensure success. Outcomes are process, program, and participant-driven.



Ethical Considerations

The study has been reviewed by the University of South Carolina Institutional Review Board and classified as exempt human participant research. Letters of information are provided to participants outlining the study. Data will be collected and stored in REDCap cloud storage or other password-protected cloud storage at the University of South Carolina. Transcripts will be deidentified prior to data analysis. Participants will be compensated with a US $25 gift card upon completion of interviews.

Results

As of March 2024, the project is in process. The literature review has been completed. A total of 4 fitness professionals, 4 physical therapists, 1 physiatrist, 2 directors at Able South Carolina (a nonprofit community organization), 7 survivors of stroke, and 1 care partner have been interviewed. Two potential exercise facilities have been identified.

Discussion

Protocol Goals and Anticipated Outcomes

This protocol will evaluate the desires and needs of the local community for an evidence-based group exercise program for people after stroke and the planning required to implement the program. The use of community-based participatory research at the early stage of implementation planning will enhance the fit and success of the future community program [18]. Involving the community in the planning stages builds trust and identifies shared values toward a common goal [18]. The selection of the evidence-based program will be based on identified needs and desires [17]. The needs assessment will also provide a rationale for required modifications to the standard program [17]. If no evidence-based program meets the majority of the needs of the community, a unique program drawing on available evidence-based resources will be developed.

Performing a needs assessment before implementing it in the community allows for early identification of the complex relationships between the inner and outer contexts of a community program [17,19]. A result is an ability to preplan implementation strategies to address problems that cannot be anticipated in controlled effectiveness research. Capacity building, education and training, and recruitment and retention strategies will be identified and built into the action plan [17,19].

Study Strengths and Limitations

Using the EPIS framework, implementation mapping processes and the implementation logic model are strengths of this protocol [17,19,29]. The use of EPIS and related practical application tools creates a systematic approach to a complex task [17,19,29].

Potential study limitations include difficulty finding willing participants, reduced completion of surveys, and difficulty matching an evidence-based program to the needs of the community. These potential pitfalls are mediated by the ability to leverage existing academic-community relationships, multiple sources of data collection, and the existence of multiple potential evidence-based programs to choose from. Existing evidence-based community programs for people after stroke or for older individuals may be adapted through this process to meet the community's needs and desires.

Conclusions

Performing thorough evaluation and preparation prior to the implementation of a community exercise program will enhance its ability to be successful, valued, and sustained in the community. A robust process that includes community partners, applied theory, and implementation process tools enhance the protocol.

Abstract

Background: Conducting a health needs assessment for older adults is important, particularly for early detection and management of frailty. Such assessments can help to improve health outcomes, maintain overall well-being, and support older adults in retaining their independence as they age at home.

Objective: In this study, a systematic approach to health needs assessment is adopted in order to reflect real-world practices in municipal health care and capture the nuances of frailty. The aim is to assess changes in frailty levels in home-living older adults over 5 months and to examine the observable functional changes from a prestudy baseline (t1) to a poststudy period (t2). Additionally, the study explores the feasibility of conducting the health needs assessment from the perspective of home-living older adults and their informal caregivers.

Methods: Interprofessional teams of registered nurses, physiotherapists, and occupational therapists will conduct 2 health needs assessments covering physical, cognitive, psychological, social, and behavioral domains. The study includes 40 home-living older adults of 75 years of age or older, who have applied for municipal health and care services in Norway. A quantitative approach will be applied to assess changes in frailty levels in home-living older adults over 5 months. In addition, we will examine the observable functional changes from t1 to t2 and how these changes correlate to frailty levels. Following this, a qualitative approach will be used to examine the perspectives of participants and their informal caregivers regarding the health needs assessment and its feasibility. The final sample size for the qualitative phase will be determined based on the participant's willingness to be interviewed. The quantitative data consist of descriptive statistics, simple tests, and present plots and correlation coefficients. For the qualitative analysis, we will apply thematic analysis.

Results: The initial baseline assessments were completed in July 2023, and the second health needs assessments are ongoing. We expect the results to be available for analysis in the spring of 2024.

Conclusions: This study has potential benefits for not only older adults and their informal caregivers but also health care professionals. Moreover, it can be used to inform future studies focused on health needs assessments of this specific demographic

group. The study also provides meaningful insights for local policy makers, with potential future implications at the national level.

Introduction

Across the globe, the population is aging rapidly. There are around 1.4 billion people aged 60 years and older in the world today, and this figure will double by 2050 [1]. Norway is no exception to this demographic transition. It is anticipated that the number of people aged 65 years and older will exceed the population aged 0-19 years by 2030 [2]. As is widely known, the older segment of the population tends to have a higher prevalence of chronic diseases and disabilities [3,4]. This implies that the demographic shift could come at a great cost to older adults themselves and society [3,5]. Direct challenges at the societal level may include a strain on public finances and the welfare system, increased demand for health services, and rising health care costs [6,7].

One way to mitigate the impacts of an aging population is to support aging in place [8,9]. The term “aging in place” refers to meeting an older adult’s needs and supporting them to live independently or with some assistance in their own home for as long as possible [8]. Most older adults prefer to live at home because it enables them to maintain their independence, autonomy, and identity, as well as their connection to social support [10]. In addition to being the preferred choice for many older adults, aging in place is viewed as a cost-effective strategy for addressing the aging population’s needs, as it can reduce the expenses associated with institutional care [11]. Given these positive effects, encouraging older adults to continue living at home could be an essential part of the solution to meeting the challenges of population aging.

Many older adults are able to live independently without much support; others, however, may have age-related issues that prevent them from aging in place [12]. These age-related issues often lead to frailty, resulting in increased functional limitations, increased risk of falls, disability, institutionalization, hospitalization, and mortality [13,14]. As frailty progresses, efforts to mitigate, manage, or reverse this decline become increasingly difficult to implement [15]. Hence, there is a broad consensus on the importance of assessing frailty [14,16,17], particularly in relation to older adults aged 70 years and older [16,18]. In general, early assessment of frailty can prevent, reduce onset, or slow its progression in older adults [19], contributing to better quality of life and healthy aging [18,20].

There is currently no consensus on the definition of frailty [17,21]. At its simplest, frailty is a condition that indicates increased vulnerability to negative health outcomes [22]. Despite varying definitions, there is general consensus that frailty is multidimensional and involves complex interactions between physical, psychological, social, cognitive, and behavioral factors [17,19]. The diversity of definitions and the wide range of contributing factors also explain why there is a variety of measures of frailty [16,17].

Incorporating frailty into health needs assessments is, therefore, crucial, as this can help identify specific areas of need, set clear goals to meet those needs, and ultimately contribute to the health promotion of this population [23]. The term “health needs assessment” refers to a systematic method of identifying unmet health and care needs of a population, leading to agreed priorities and resource allocation that will improve health outcomes [24].

While our knowledge of frailty has improved [14], our understanding of the factors that contribute to frailty is still incomplete, and the understanding of how these factors relate to frailty is still limited [19]. These knowledge gaps are a clear indication that considerable efforts are still needed in this area.

Given the complexity of frailty as a construct and its enormous impact on the lives of older adults, adopting a collaborative approach is deemed essential to improving our understanding and achieving meaningful progress. This is further supported by research that highlights the benefits of fostering collaboration between health care professionals, individual service users, families, researchers, and other stakeholders to improve health service outcomes [25-27].

Such collaboration enables all relevant aspects of older adults’ health to be assessed, and essential information can be collected to develop effective, locally applicable, and relevant solutions [28]. With this in mind, we have established partnerships with health care professionals and other stakeholders in a Norwegian municipality, actively involving them in the planning and implementation phase of the project.

Interprofessional teams consisting of registered nurses, physiotherapists, and occupational therapists will be involved in this study. They will perform 2 health needs assessments of home-living older adults, initially at baseline and then after a period of 5 months. These assessments cover several factors, including physical (mobility and sensory), cognitive, psychological (depression), social (loneliness), and behavioral (alcohol consumption). The objectives of our study are 3-fold: first, to assess changes in frailty levels in home-living older adults over 5 months; second, to explore the observable functional changes from a prestudy baseline (t1) to a poststudy period (t2) and how these changes correlate to frailty levels; and finally, to gain deeper insight into the perspectives of older adults and their informal caregivers to enhance the feasibility

of implementing this type of health needs assessment within municipal health and care services.

The research questions that guide the study are (1) What observable changes, if any, can be identified in the frailty levels of home-living older adults over a period of 5 months? (2) Are there identifiable changes in functions that can be observed from t1 to t2, and how these changes relate to frailty levels? and (3) What are the perceptions of home-living older adults regarding the feasibility of the health needs assessment, with regard to its content, delivery, and procedures?

Methods

Study Design

This pre-post study, registered on ClinicalTrials.gov (NCT05837728), is based on a case-only design to conduct health needs assessments, initially at the baseline and then after 5 months. The study is conducted as part of the research project "More good days at home: Advancing health-promoting practices in municipal health care services for older recipients of home care," funded by the Norwegian Research Council (320622).

To gain in-depth insights, we use a 2-step research process. In the first step, a quantitative approach will be applied to examine changes in frailty levels in home-living older adults over 5 months. In addition, we will examine observable functional changes from t1 to t2 and how these changes correlate to frailty levels.

Following this, a qualitative approach will be used to investigate the perspectives of participants and their informal caregivers concerning the health needs assessment and its acceptability.

Setting

This study is placed in the context of the Norwegian health care system, known for its universal health care. This system ensures everyone has equal access to health care regardless of socioeconomic status or geographical location [29]. The system is based on a clearly defined division of responsibilities between the local municipalities and the central government.

The local municipalities are tasked with organizing primary, preventive, and nursing care services [29] and are committed to providing the necessary health services, such as home and personal care, free of charge to all home-living older adults [30]. These services are universally available and tailored to the specific needs of each older adult. To access these services, older adults are required to submit an application to the district office in their municipality [31]. Once the application is submitted, it will be reviewed by health care professionals in the health and welfare services office. After this phase, the health care professionals will reach out to the older adults to proceed further.

While municipalities manage the above care services, central government oversees specialist care, which includes hospital services. This clear division ensures comprehensive health care for all citizens [29]. This study takes place in a municipality in Western Norway with a population of approximately 146,011. In this population, 9874 individuals are older adults aged 75 years or older [32].

Study Sample

Inclusion Criteria

To be eligible for the study, the older adults must be aged 75 years or older and have applied for municipal health and care services. These services may include medical emergency alarms, senior activity centers, home-based nursing services, and practical assistance with daily chores. In addition, older adults who received follow-up care after a hospital stay, were discharged from rehabilitation, or received emergency medical care are also eligible.

Exclusion Criteria

This study does not include home-living older adults who are younger than 75 years of age, have a cognitive impairment, or are undergoing palliative care. In this study, cognitive impairment refers to the inability to understand the study and provide informed consent to participate.

Recruitment

Participant recruitment was conducted in collaboration with 3 health and welfare service departments in a municipality in the western region of Norway between February 1 and June 26, 2023. Health care professionals purposively selected participants according to the eligibility criteria. During their initial phone contact with potential participants, health care professionals used their professional judgment to assess the individual's ability to understand the research project and provide informed consent to participate.

Subsequently, health care professionals asked a designated research team member, a nurse with experience in mental health, to obtain informed consent from those who meet the initial criteria. To ensure consistency in the process, the same nurse visited all potential participants for the consent process. Potential participants were then given time to consider this information before giving their written consent.

The design of our health needs assessment package includes a cognitive assessment. This approach ensures that participants identified with cognitive impairment in the first assessment are not included in the second assessment.

We aim to enroll 40 participants in the quantitative phase of this study, in line with the agreement made with the municipality at the beginning of the project, taking into account their resource limitations. In the next phase, which uses a qualitative approach, we plan to invite all 40 participants for an interview, with the actual number of interviews conducted depending on the participants' consent to participate. To capture diverse perspectives, we will strive to include a group of home-living older adults who differ in terms of age, gender, marital status, living situations, and health care needs.

The aforementioned sample size takes into account the limited resources available for the project, including budget constraints, personnel resources, and time limitations, while ensuring the collection of meaningful data to address the research questions.

Data Collection

To respond to the diverse needs of older adults, we have interprofessional teams consisting of registered nurses, physiotherapists, or occupational therapists to carry out the health needs assessments. The assessment is conducted twice at the participant's home. To facilitate successful implementation, we provided simulation-based training and debriefings. We have also produced webinars available in Norwegian to enhance learning. The link to the webinars can be provided upon request. Our study is ongoing, so we will publish it upon completion.

The interprofessional teams will use an iPad (Apple Inc) to administer assessments covering the various factors—physical (mobility and sensory), cognitive, psychological (depression), social (loneliness), and behavioral (alcohol consumption). The collected data will be registered electronically and directly submitted to Services for Sensitive Data (*Tjenester for Sensitive Data* [TSD]) for secure storage and processing.

After the initial assessment, interprofessional teams will collaboratively review the results to determine whether, and to what extent, the older adult is eligible for assistance and to determine what type of support is available and appropriate for the individual [33]. Examples of such support include practical help with everyday tasks, provision of medical emergency alarms, access to walking aids, recommendations for physiotherapy sessions, referrals to hearing or vision centers, encouragement to participate in senior activity centers, and facilitating contact with primary care physicians.

After 5 months, the same interprofessional teams will conduct the second health needs assessment to determine whether the support provided at the first assessment is suitable for helping participants maintain their quality of life.

With regard to the qualitative approach, we will use 2 data collection methods in order to minimize mono-method bias [34]—in-depth individual interviews and dyadic interviews. We will use a general interview guide approach to collecting data from all the participants, which will give us the flexibility to modify or adapt questions based on responses to previous questions [35]. To maintain consistency, the topics and questions in the 2 interview methods will be identical and guided by the Theoretical Framework of Acceptability (TFA) proposed by Sekhon et al [36]. The questions will include, for example, (1) how the participant thinks and feels about the assessment, (2) what the participant thinks about the effort required to participate in this type of assessment, (3) the participant's understanding of the assessment process, (4) what benefits or value they believe the assessment will have for them, and (5) whether they feel the assessment was conducted respectfully or not. Finally, the interviews will be audio recorded and transcribed verbatim to ensure accuracy in the data analysis.

Measure Descriptions

The selection of measures was informed by a comprehensive review of existing literature, consultation with experts, and input from stakeholders involved in the project. Many of the measures have been validated in different contexts, including the Norwegian context. The study also includes novel scales that will be tested for validity within this particular sample of home-living older adults. The measures in the study are described below, and an overview is given in Table 1.

Table 1. Overview of the measures used in the study.

Variables	Questionnaires and tests used in assessments
Demographics	
Gender	Male, female, or other?
Age	How old are you (years)?
Household	Do you live alone or with others?
Children	Do you have any children?
Residential suitability	Is your residence suitable for your needs?
Transportation	Do you use private or public transport?
Physical function	
Mobility: lower extremity function	To assess the lower extremity function, we will use the SPPB[a], a well-established instrument commonly used in home-living older adults [37-40]. The Norwegian version of SPPB, translated by Bergh et al [41], has been tested for reliability, and the result shows that it has high reliability when used by trained physiotherapists on older populations [42]. Other reasons for using SPPB are that it is fast, safe, and easy to administer; requires little training; and uses simple equipment [43]. The test assesses standing balance, walking, and rising from a chair. The result from the test is quantified by scores. In addition, the test is claimed to be highly sensitive to changes over time [37,44].
Sensory: hearing	To detect hearing impairment, we will use the KAS[b]-Screen interview guide [45]. The questions used in our study stem from the hearing and verbal communication or social life subscales. Previous evaluation and validation found this test to be an adequate tool for detecting hearing impairment in older adults and provides important information on how this impairment can affect the daily life of older adults [45,46].
Sensory: vision	To detect vision impairment, we will use a structured vision assessment tool called KROSS[c] developed by the University of South-Eastern Norway in collaboration with the Vestre Viken Hospital Trust and stroke survivor organizations. The KROSS tool includes assessments of visual acuity, visual field, eye alignment and movements, and visual in attention [47,48].
Cognitive function	
Cognitive function	To identify possible cognitive impairment, the Mini-Cog test will be used. This takes approximately 3 minutes to administer and consists of 2 cognitive tasks: 3-item word recall and a clock drawing test [49]. Mini-Cog was preferred to other cognitive screening tools because it is simple and concise, requires no special equipment, is easily incorporated into general practice and different senior settings, and has high sensitivity and specificity [49,50]. Additionally, it has been suggested that Mini-Cog performs well as a screening test among older adults in communities [51]. The Norwegian version of Mini-Cog was translated by Rostoft et al [52].
Psychological function	
Depression	To assess depression in old age, we will use the 4-item GDS[d]. Although other versions of GDS can be used to identify common symptoms of depression in older individuals, the 4-item GDS is reported to be most suitable for detecting depression in older adults who live at home [53,54]. Overall, the 4-item GDS has been shown to be a valid and reliable tool for evaluating depression in older adults, with a sensitivity of 100% and 62% specificity [54]. Another benefit of using this scale is that it is a relatively short scale, which reduces the burden on the respondent and the time it takes for health professionals to administer the test [54].
Social function	
Loneliness	The validated UCLA[e] 3-Item Loneliness Scale will be used to assess loneliness. This scale is designed to measure loneliness based on individual perceptions of how often a person feels (1) a lack of companionship, (2) left out, and (3) isolated from others [55]. In terms of reliability, this scale has been found to have good internal consistency, and test-retest reliability has shown that the scale produces consistent results over time [56,57]. In terms of validity, it was demonstrated that this scale correlates well with other measures of loneliness and discriminates well between loneliness and other constructs [55]. Additionally, this measure is chosen because it is quick to administer, has been used in large surveys, has been tested in older populations, and measures overall loneliness quite well [55,58]. The Norwegian version of this scale was translated by Arumugam et al [59].
Behavioral function	
Alcohol consumption	For a brief assessment of alcohol consumption, we will use the AUDIT[f] developed by the World Health Organization [60]. Our study will use AUDIT-4, which consists of 3 questions from AUDIT-C and the 10th item of the original scale [61]. In terms of reliability and validity, previous research with different samples has shown that AUDIT-4 has good internal consistency, criterion validity, and convergent validity [62,63].

Variables	Questionnaires and tests used in assessments
Assessment of frailty	To assess frailty, we will use the CFS[g]. The CFS, a tool based on clinical judgment, assesses key areas such as multimorbidity, cognition, and other functional areas [64]. CFS has been shown to be a strong predictor of several outcomes, including falls, length of hospitalization, multimorbidity, and mortality [65]. The CFS was translated into Norwegian by Rostoft et al [66] and has been used to assess frailty in various settings in Norway, including emergencies and intensive care [67,68]. Its simplicity and predictive power in assessing physical health and potential outcomes for frail older adults [17,69] make it an appropriate choice for use in municipal health care settings.

[a]SPPB: Short Physical Performance Battery.

[b]KAS: *Kombinert Alvorlig Sansesvikt* (Combined Serious Sensory Impairment).

[c]KROSS: *Kompetanse om Rehabilitering Om Syn og Slag* (Competence, Rehabilitation of Sight after Stroke).

[d]GDS: Geriatric Depression Scale.

[e]UCLA: University of California, Los Angeles.

[f]AUDIT: Alcohol Use Disorders Identification Test.

[g]CFS: Clinical Frailty Scale.

Outcome Measures

This study has two primary outcome measures: (1) identifying changes in frailty levels of home-living older adults over a period of 5 months and (2) assessing any observed changes in functions from t1 to t2 and how these changes relate to the level of frailty.

In addition to the primary outcome measures, this study will also evaluate the feasibility of the health needs assessment. Emphasis will be placed on the acceptability of the assessment among older adults and their informal caregivers, as well as the practicality of implementation in relation to time and resource constraints.

Data Analysis

Quantitative Analyses

The statistical package SPSS (version 29; IBM Corp) will be used for all statistical analyses. Descriptive statistics will be used to provide an overview of the demographic variables. Given the exploratory nature of this study and the limited sample size, our analysis involves looking at the data from multiple perspectives. The aim is to uncover patterns and relationships that could inform the development of hypotheses for future studies.

To answer the research questions, we will first calculate descriptive statistics for changes in frailty levels between 2 time points, using mean and SD or median and IQR for a skewed distribution. This will be followed by paired comparisons using either 2-tailed *t* test or the Wilcoxon test. We will also examine the association between the changes in frailty and baseline levels by plotting and estimating correlation coefficients (Pearson and Spearman). We will further assess changes in functional variables and the bivariate associations between these changes and the change in frailty.

Qualitative Analyses

The interview transcripts will be read thoroughly and reread to ensure familiarity with the content. NVivo (version 12; Lumivero) software will be used to help organize and code the data. The data analysis will be carried out using a thematic analytical approach based on the guidelines of Braun and Clarke [70].

Patient and Public Involvement

In this study, older adult participants were not involved in developing the study design or objectives. The study design and objectives were developed by the researchers of this study in collaboration with the local municipality stakeholders. The Service User Association for Older Adults in Norway (*Pensjonistforbundet*) contributed insights to the grant application, which was successfully funded by the Research Council of Norway. Furthermore, details about the study design and recruitment procedures were provided to health care professionals prior to data collection.

Ethical Considerations

Ethics approval was obtained from the Regional Committees for Medicine and Health Research Ethics (REK) of West Norway on November 15, 2022 (523455). The project was subsequently approved by the Norwegian Agency for Shared Services in Education and Research (SIKT) on January 19, 2023 (100847), which ensures that adequate safeguards are in place to protect the privacy of participants and to maintain the confidentiality of data. This study will be conducted in accordance with the Declaration of Helsinki guidelines [71] from REK and the Data Protection Impact Assessment (DPIA). It will also be conducted under the principle of informed consent. Prior to data collection, all the participants who agreed to participate in the study will sign a consent form, which includes a description of the study, its objectives, and participants' involvement and rights. Participation in the study is entirely voluntary and participants can withdraw at any time. Additionally, participants are entitled to access the information documented about them and to make necessary corrections to any errors discovered.

Data Management

Overview

The project manager will supervise the day-to-day operation of the project and be responsible for ensuring that DPIA guidelines are followed.

Data Collected From the Frailty Assessment

The collected data will be registered electronically and directly submitted to TSD for secure storage and processing. The code list that links personal identification information to the

individual participant will be secured by the project manager to ensure there is no unauthorized access to the information. Only the selected project team members will have access to the anonymized data sets. No other party will have access to the research data prior to dissemination. Furthermore, other paper-based research data will be anonymized and kept in locked cabinets or archives that are only accessible to project team members.

Data Collected From the Interview

Only a designated member of the research project and the project manager will have access to the audio files stored at Nettskjema. The interview will be transcribed into written text and all personal identifiers will be removed to ensure anonymity. The transcription will be shared with other project team members as appropriate. This data will be retained until December 31, 2026, and then deleted from TSD.

Results

The initial baseline assessments were completed in July 2023, and the second health needs assessments are ongoing. We expect the results to be available for analysis in the spring of 2024.

Discussion

Principal Considerations

Studies have documented that frail older adults have an elevated risk of negative health outcomes [13,14]. Early assessment of frailty in older adults is, therefore, crucial, and is recommended. Despite its recognized importance, assessing frailty is not considered a standard clinical practice in many health care systems [18], including in Norway [72]. This situation is understandable as such an assessment often requires significant resources, which many health care facilities lack [73].

Our study is carefully designed to reflect real-world applications and settings, with a particular focus on municipal health care in Norway, where health care professionals tend to have heavy workloads. These conditions pose a challenge to incorporating additional tasks, such as a frailty assessment, into routine health needs assessments. As mentioned earlier, older adults typically turn to their local municipality for home care services and health care professionals make home visits to assess their care needs. This assessment process uses the standardized tool (The Norwegian Information System for the Nursing and Care Sector [*Individbasert pleie- og omsorgsstatistikk*; IPLOS]), which was developed to optimize care needs assessments in Norway [33]. Despite being a standardized tool, IPLOS has been criticized for being too subjective, as assessments appear to vary widely among health care professionals [74].

In response to these challenges, we aim to refine the health needs assessment process to improve objectivity and consistency, and to highlight the critical needs to incorporate frailty assessments into routine municipal care practices. The path begins with selecting appropriate measurement tools that are meaningful and practical, and training interprofessional teams to implement them. Part of this training process includes the task of conducting assessments and discussing the results to make informed decisions.

Beyond integrating assessments, our study aims to shed light on the dynamic nature of frailty and provide a deeper understanding of the factors that impact its progression. This insight could potentially help older adults and their informal caregivers to manage frailty. Additionally, it can better prepare health care professionals to develop and implement strategies aimed at delaying and mitigating the progression of frailty.

Strengths and Limitations

This study has several strengths. First, it deepens our understanding of frailty as a complex condition and highlights how levels of frailty and related functional changes can differ. Moreover, because the study is designed to reflect the real-world settings and applications, it can help improve health care practices in the municipal sector. The involvement of local stakeholders in the municipality from the planning to the implementation phase ensures that the study remains relevant and applicable, thereby facilitating the translation of knowledge into practice. Additionally, the inclusion of home-living older adults' and their informal caregivers' perspectives can help facilitate improvement in the feasibility of the assessment.

As with other studies, this study has its limitations, particularly with regard to the relatively small sample size and the absence of a control group. This could lead to misinterpretation of the observed changes, either in the support or services for participants, other confounding factors, or due to a habituation effect over the 5-month period. Consequently, this limitation may also potentially impact the internal validity of the study, as well as the construct validity of the study [75]. To address this challenge, we will carefully compare our findings with those of previous studies investigating similar approaches to aiding the interpretation of outcomes.

Despite its inherent limitations, this study will serve as an important first step in developing a more systematic health needs assessment for home-living older adults and the development of health promotion strategies that can improve these older adults' quality of life.

Nonetheless, the results should be interpreted with caution due to the absence of a control group, the limited sample size, and the potential underrepresentation of all home-living older adults. These limitations suggest that the results indicate possible correlations and patterns, rather than confirming a definite relationship or establishing specific cause-and-effect relationships.

Acknowledgments

The authors would like to express their sincere gratitude to the municipality health care professionals who participated and contributed to the design of this study. We would also like to acknowledge other local municipality stakeholders who supported us in planning the recruitment process and implementing the research project.

Data Availability

The data sets generated and analyzed during this study are not publicly available due to ethical considerations inherent in this research but are available from the corresponding author on reasonable request.

Authors' Contributions

All authors made a substantial contribution to this work. FK contributed to the study design and protocol, drafting, writing original draft, and revising and refining the paper. BHL contributed to the study design and data collection tools and feedback and comments on the study protocol. GE contributed to the study design and data collection tools and feedback and comments on the study protocol. HKF contributed to the study design and data collection tools and feedback and comments on the study protocol. ID contributed to the data analysis and statistics and feedback and comments on the study protocol. SH contributed to the study design and collaboration between health care professionals and researchers. MS contributed to the study design, development of data collection tools, prepared all essential documentation for ethical approval, and participated in writing, commenting, and refining the paper. All authors read and approved the final version of the paper.

Abstract

Background: Approximately 20%-25% of patients with metastatic castration-resistant prostate cancer (mCRPC) harbor a deleterious germline or somatic mutation in the homologous recombination repair (HRR) pathway genes, which is involved in the repair of double-stranded DNA damage. Half of these mutations are germline, while the remaining are exclusively somatic. While polyadenosine 5'diphosphoribose [poly (ADP-ribose)] polymerase inhibitors, such as olaparib and rucaparib, are effective in this subgroup, their widespread use is limited due to the associated high cost, especially in resource-constrained settings. Notably, platinum agents like carboplatin have exquisite sensitivity to cells with defective DNA repair machinery. Carboplatin, a conventional, inexpensive chemotherapeutic agent, offers a potential alternative treatment in such patients. Several retrospective small case series support this hypothesis. However, there are no prospective clinical trials of carboplatin in patients with mCRPC with HRR mutations.

Objective: The primary objective is to assess the objective response rate of 3 weekly carboplatin treatments in patients with mCRPC harboring deleterious mutations in the HRR pathway genes and previously treated with a taxane or a novel antiandrogen agent. The secondary objectives include progression-free survival, health-related quality of life, and safety profile of carboplatin.

Methods: Patients diagnosed with mCRPC harboring HRR pathway mutations previously treated with docetaxel or novel antiandrogen agents (abiraterone, enzalutamide, apalutamide, or darolutamide) or both will be eligible. Genes involved directly or indirectly in the HRR pathway will be tested. In this single-arm phase II study, we will screen approximately 200 patients to enroll 49 patients, and carboplatin (dosing at the area under curve=5) will be administered every 3 weeks until progression or intolerable side effects. The primary end point will be assessed as the proportion of patients with a reduction of serum prostate-specific antigen by more than 50% from enrollment. Secondary outcomes include progression-free survival—soft-tissue disease progression (by response evaluation criteria in solid tumors, version 1.1, and bone lesion progression using Prostate Cancer Clinical Trials Working Group 3 criteria), health-related quality of life during carboplatin treatment using the Functional Assessment of Cancer Therapy—Prostate questionnaire and the European Organisation for Research and Treatment of Cancer questionnaire and safety profile of carboplatin (National Cancer Institute's Common Terminology Criteria for Adverse Events version 5.0).

Results: The trial started enrollment in September 2023. This trial is ongoing, and 12 patients have been recruited to date. All 49 participants will be enrolled according to plan.

Conclusions: This prospective phase II trial represents a critical step toward addressing the therapeutic gap in patients with mCRPC harboring HRR pathway mutations, particularly in demographic regions with limited access to poly (ADP-ribose) polymerase inhibitors. Outcomes from this study will inform clinical practice and guide future phase III randomized trials, ultimately improving patient outcomes globally.

Introduction

Patients with metastatic prostate cancer are treated with androgen deprivation therapy, chemotherapeutic agents, or novel antiandrogen agents [1]. These patients eventually develop resistance to androgen deprivation therapy, and this state, known as castration-resistant prostate cancer, is incurable despite the advent of several newer therapies [2]. The therapeutic landscape for metastatic castration-resistant prostate cancer (mCRPC) includes chemotherapeutic agents, novel antiandrogen agents, and radioligand therapies [3].

Pritchard et al [4] reported that 11.8% of men with metastatic prostate cancer harbor deleterious germline mutations, primarily in *BRCA2*, followed by *ATM*, *CHEK2*, *BRCA1*, *RAD51D*, and *PALB41* genes. Subsequent studies evaluated the prevalence of deleterious somatic mutations within the homologous recombination repair (HRR) pathway in 25%-30% of patients with mCRPC [5]. Polyadenosine 5'diphosphoribose (poly [ADP-ribose]) polymerase inhibitor (PARP) inhibitors employ a strategy of synthetic lethality, inhibiting the base excision repair pathway, leading to the accumulation of unrepaired DNA breaks within HRR-deficient tumor cells, culminating in cancer cell death [6-8]. Olaparib, a PARP inhibitor, demonstrated an impressive 88% response rate in patients with mCRPC with HRR gene abnormalities, in contrast to a minimal 3% response in those without these mutations [9,10]. The pivotal PROfound trial supported these findings, leading to Food and Drug Administration approval for patients with mCRPC harboring HRR gene mutations [5]. Similar efficacy was observed with other PARP inhibitors, including rucaparib and talazoparib [11,12]. However, most patients with mCRPC harboring HRR gene mutations residing in low- and middle-income countries do not have access to PARP inhibitors due to the high cost.

Interestingly, HRR-deficient tumors also exhibit increased sensitivity to platinum chemotherapeutic agents (eg, carboplatin) due to their reliance on the HRR pathway for DNA double-strand break repair. This vulnerability has been exploited by platinum-containing treatments in breast and ovarian tumors [13,14]. Initial retrospective studies involving carboplatin in unselected patients with mCRPC showed encouraging efficacy, particularly within the subset carrying HRR gene alterations [15-17]. However, these studies are limited by several biases.

Despite a strong scientific rationale and encouraging preliminary data from real-world studies, no prospective study has been reported to assess the role of carboplatin in this subset of patients. Therefore, we planned this phase II single-arm study to evaluate the efficacy of carboplatin in patients with metastatic prostate cancer harboring mutations in the HRR pathway.

Methods

Objectives

This study is an investigator-initiated, prospective phase II, single-arm clinical trial. The primary objective of this study is to assess the prostate-specific antigen (PSA) response rate of 3 weekly carboplatin (dose at area under the curve 5) in patients with mCRPC harboring deleterious or likely deleterious mutations in the HRR genes and previously treated with a taxane or a novel antiandrogen (proportion of patients with more than 50% serum PSA decline).

The secondary objectives are to compare the effect of oral gabapentin with placebo on the following:

- Progression-free survival—soft-tissue disease progression (by response evaluation criteria in solid tumors, version 1.1) and bone lesion progression (by Prostate Cancer Clinical Trials Working Group 3 criteria)
- Health-related quality of life during carboplatin treatment (Functional Assessment of Cancer Therapy—Prostate questionnaire and European Organisation for Research and Treatment of Cancer questionnaire)
- The safety profile of carboplatin (National Cancer Institute's Common Terminology Criteria for Adverse Events, version 5.0)

Study Setting

This study is being conducted in the outpatient department of Dr BR Ambedkar Institute Rotary Cancer Hospital, New Delhi, India, and the National Cancer Institute, Jhajjar, the 2 cancer blocks of the All India Institute of Medical Sciences, New Delhi, a central government-funded tertiary care teaching hospital.

The catchment area includes an over 20 million population from the Northern states of India, with approximately 15,000 patients with cancer being treated every year.

Eligibility Criteria

All the following criteria must be met for enrollment:

- Histological diagnosis of prostate cancer.
- Serum testosterone <50 ng/dL within 28 days before screening.
- Documented current evidence of mCRPC, where metastatic status is defined as at least one documented metastatic lesion on either a bone scan, computed tomography, or magnetic resonance imaging scan.
- Prior treatment with docetaxel or at least one of the novel antiandrogen agents (abiraterone, enzalutamide, apalutamide, or darolutamide) or both.
- Mutation (germline or somatic) in the HRR pathway in either blood or biopsy samples.
- Written informed consent to participate.
- Eastern Cooperative Oncology Group performance status of 0-1.
- Aged older than 18 years.
- Adequate organ function:
  - Absolute neutrophil count ≥1.5 × 109/L
  - Hemoglobin ≥10.0 g/dL with no blood transfusions in the past 28 days.
  - Platelet count ≥100 × 109/L.
  - Total bilirubin ≤1.5 × institutional upper limit of normal (ULN).
  - Aspartate aminotransferase (serum glutamic oxaloacetic transaminase) or alanine aminotransferase (serum glutamic pyruvate transaminase) ≤2.5 × institutional ULN unless liver metastases are present in which case, they must be ≤5 × ULN.
  - Subjects must have an estimated creatinine clearance using the Cockcroft-Gault equation for men of ≥40 mL/minute.

Patients with any of the following will be excluded from the trial:

- Patients with symptomatic brain metastases. A scan to confirm the absence of brain metastases is unnecessary in all patients.
- Patients with spinal cord compression, unless considered to have received definitive treatment for this and evidence of clinically stable disease for 28 days.
- Patients are considered as poor medical risk due to a serious, uncontrolled medical disorder, nonmalignant systemic disease, or active, uncontrolled infection. Examples include but are not limited to uncontrolled ventricular arrhythmia, recent (within 3 months) myocardial infarction, uncontrolled major seizure disorder, unstable spinal cord compression, superior vena cava syndrome, extensive interstitial bilateral lung disease on high-resolution computed tomography scan, or any psychiatric disorder that prohibits obtaining informed consent.
- Patients with a known hypersensitivity to carboplatin.

One of this study's investigators will obtain written informed consent from every patient before enrollment, during which the benefits and risks of participation will be informed in the local language (Hindi or English) that the patient comprehends. The study consists of two parts: (1) screening of tumor tissue or blood for mutations in the HRR pathway and (2) administration of carboplatin in patients found to harbor a deleterious or likely deleterious mutation in the HRR pathway.

Screening of mutations in the HRR pathway will be performed in the tumor tissue for the HRR genes using next-generation sequencing. The initial archived biopsy sample will be retrieved after informed consent is obtained. In patients where the initial biopsy sample is inaccessible or deemed to be of inadequate quality for next-generation sequencing, blood samples will be sent to assess germline mutations in the HRR pathway.

Interventions

Patients who agree to participate in this study will be tested for the presence of known deleterious mutations in the archived tumor tissue in genes involved directly or indirectly in HRR pathway: *BRCA1*, *BRCA2*, *ATM*, *BRIP1*, *BARD1*, *CDK12*, *CHEK1*, *CHEK2*, *FANCL*, *MSH2*, *PALB2*, *PPP2R2A*, *RAD51B*, *RAD51C*, *RAD51D*, and *RAD54L*.

Those found to have a pathogenic or likely pathogenic mutation in one of these genes will be treated with 3 weekly carboplatin. The dose will be calculated according to the estimated glomerular filtration rate determined by the Cockcroft-Gault equation and then administered at the area under the curve (5) with a dose capped at 750 mg per cycle. Chemotherapy will continue until progression (clinical, biochemical, or radiographic) or intolerable adverse events, whichever occurs earlier. If the patient misses a follow-up visit, this study's team will contact the patient and reinforce adherence to this study.

The relevant concomitant care permitted or prohibited during the trial includes the following. Palliative radiation for patients who develop urgent local complications in previously documented disease sites. The ideal gap between palliative radiotherapy and the first dose of carboplatin would be at least one week, and there would be no capping dose of palliative therapy.

Continuation of protocol therapy, if medically appropriate, should be discussed with the principal investigator at the site. The following medications and treatments are permitted in this study: (1) rescue medications for nausea or vomiting, (2) antibiotics, and (3) bisphosphonates or denosumab.

Certain medications may interact negatively with carboplatin or interfere with its effectiveness. The medications that may have significant interactions or should generally be avoided with carboplatin:

- Aminoglycoside antibiotics: these antibiotics, such as gentamicin or amikacin, may increase the risk of kidney damage when used concomitantly with carboplatin.
- Nonsteroidal anti-inflammatory drug: these drugs, including ibuprofen, naproxen, and aspirin, may increase the risk of bleeding or kidney damage when used concurrently with carboplatin.

- Live vaccines: live vaccines, such as the measles, mumps, rubella vaccine or varicella (chickenpox) vaccine, should generally be avoided during chemotherapy treatment, including carboplatin. These vaccines contain weakened live viruses that may pose a risk to immunocompromised individuals.
- Other nephrotoxic drugs: carboplatin can cause kidney toxicity, and combining it with other medications that have nephrotoxic effects, such as certain antibiotics or antifungal medications, may increase the risk of kidney damage.
- Anticoagulant medications: combining carboplatin with anticoagulants such as warfarin or heparin may increase the risk of bleeding. Close monitoring of blood clotting parameters is essential if these medications must be used together.
- Vaccines containing weakened or killed viruses or bacteria: while certain vaccines may be necessary for specific situations, it is important to discuss with a health care professional, as the timing and administration of vaccines should be carefully considered during chemotherapy treatment.

There are no medications or treatments that are specifically prohibited during this study.

All concomitant medications will be recorded at the time of registration.

Patients meeting either of the following criteria will discontinue this study's treatment:

- Permanent discontinuation of carboplatin by treating physician (unacceptable toxicity or progression of underlying cancer).
- The investigator determines that continuing this study's treatment is not in the patient's best interest.
- Occurrence of an exclusion criterion affecting patient safety.
- Concomitant treatment that is not permitted.
- Failure to comply with the protocol. Suppose a patient consistently fails to attend scheduled assessments in this study. In that case, the investigator will determine the reasons and document the circumstances in the medical records as thoroughly and accurately as possible.
- The patient declines subsequent treatment or withdraws consent.

Posttrial care would be administered based on the treating physician's discretion. Patients will be followed up until disease progression. Data collected for this study comprise clinical characteristics obtained from hospital records and routine laboratory investigations, including but not limited to baseline demographics, outcome measures, treatment details, and adverse events.

Data Collection and Management

The research staff will collect data on site, using premade questionnaires on a paper case record form (CRF). All the parameters assessed in this study are defined a priori in a data dictionary, elucidating standards for data collection. Table 1 outlines the schedule of assessments.

Participating patients will be assessed before initiating a cycle of carboplatin-based chemotherapy and 3 weeks after the last dose of carboplatin. Subjects will be contacted by telephone if they miss their clinic appointment with the treating oncologist. Data entry will be done by using paper CRF. Data will be stored securely with limited access to authorized individuals. Biological samples will be collected as a part of this study at baseline. Formalin-fixed paraffin-embedded prostate tissue samples would be collected for HRR mutation testing. The patients' blood samples would also be collected for germline testing of HRR mutations.

Table 1. Schedule of assessments.

	Screening	Baseline	Every cycle (3 weekly)	3 monthly
Informed consent	✓	—[a]	—	—
Serum testosterone	✓	—	—	—
Clinic assessment	—	✓	✓	—
Concomitant medications	—	✓	✓	—
Adverse events	—	—	✓	—
CBC[b]/LFT[c]/RFT[d]	—	✓	✓	—
Serum PSA[e]	—	✓	✓	—
Quality of life assessments	—	✓	✓	—
PSMA[f] PET[g] scan or CECT[h] chest abdomen and bone scan	—	—	—	✓

[a]Not available.

[b]CBC: complete blood count.

[c]LFT: liver function test.

[d]RFT: renal function test.

[e]PSA: prostate-specific antigen.

[f]PSMA: prostate-specific membrane antigen.

[g]PET: positron emission tomography.

[h]CECT: contrast-enhanced computed tomography.

Statistical Methods

The primary end point (confirmed PSA response rate) will be presented as a proportion to be tested against a 1-sided alternative.

Patient demographics, clinical and treatment characteristics, and other study outcomes will be described using mean, SD and range, or median, IQR and range for continuous variables, frequencies, and percentages for categorical variables, and the Kaplan Meier method for time-to-event variables. The effect sizes and 95% CIs will be presented where possible.

Simon's [18] 2-stage design will be used. The null hypothesis that the true response rate (serum PSA decline of more than 50%) is 20% will be tested against a 1-sided alternative. In the first stage, 24 patients will be accrued. If there are 5 or fewer responses in these 24 patients, this study will be stopped. Otherwise, 25 additional patients will be accrued for a total of 49. The null hypothesis will be rejected if 15 or more responses are observed in 49 patients. This design yields a type I error rate of 5% and a power of 90% when the true response rate is 40%.

To include 49 patients with mCRPC harboring HRR mutations, we must screen approximately 200 patients, assuming a 30% prevalence and tissue inadequacy of 20%. The type of HRR mutation will analyze subgroups. Regression models (using the Cox proportional hazards model) will be used for exploratory analyses.

Oversight and Monitoring

The principal investigator at the All India Institute of Medical Sciences, New Delhi, will coordinate this study and be responsible for data acquisition management and statistical analysis. Investigators from the Department of Medical Oncology at this study's site will constitute the trial steering committee. The trial steering committee will evaluate any serious adverse events and report promptly to the Institute Ethics Sub Committee for Monitoring of Adverse Events in Clinical Trials at the site. Guideline-based collection of adverse event data will be ensured. Additionally, serious adverse reactions will be reported on time to the Institute Ethics Sub Committee for Monitoring of Adverse Events in Clinical Trials at the site. There will be no compensation offered for adverse events or serious adverse events to participants. After the initiation of this study, the trial steering committee will regularly audit the process of consenting, protocol adherence, and data collection biannually. Additionally, the data may be audited or inspected by the Institute Ethics Committee. Amendments made to the protocol will be communicated on time to the Institute Ethics Committee and the Clinical Trials Registry of India. One protocol amendment has been done in which we added the European Organisation for Research and Treatment of Cancer prostate cancer 25 questionnaire to the assessment and included the option of contrast-enhanced computed tomography chest abdomen and bone scan in place of a prostate-specific membrane antigen–positron emission tomography scan.

This trial will be published in a peer-reviewed journal with individual investigators as authors. Full credit will be given to the collaborating investigators and research staff involved in this study. All authors will review and approve this paper before submission and comply with internationally accepted requirements. We also plan to present this study's results at major scientific meetings. The availability of results to all participants will be ensured.

Ethical Considerations

The ethical approval has been obtained from the Institute Ethics Committee of the All India Institute of Medical Sciences, New Delhi who approved this study's protocol on April 20, 2023 (IECPG-255/20.04.2023). Informed consent of each participant in the local language will be taken. The identifying information of participants will be removed as much as possible. Each participant will be given a study identification number, and the CRFs will contain only the deidentified data. Consent forms (with identifying patient data) will be safeguarded in locked compartments at this study's site that can exclusively be accessed by authorized personnel. No monetary compensation will be provided to the enrolled participants. No identification of individual participants or users in any images of the paper or supplementary material is possible.

The protocol and final paper will be published as described by the International Committee of Medical Journal Editors guidelines. No professional writers will be employed to write the final paper. The supplementary material of the final paper will contain the full protocol. The deidentified data set and statistical code will be made available to the corresponding author at a reasonable request.

Results

The trial started enrollment in September 2023. This trial is ongoing, and 12 patients have been recruited to date. All 49 participants will be enrolled according to plan.

Discussion

Relevance of the Study

This prospective phase II study will provide efficacy data of carboplatin in patients with mCRPC with deficient HRR. If this study provides positive results, it will provide a treatment option for patients with mCRPC. Further multicentric phase III noninferiority trials may be conducted to compare the efficacy with PARP inhibitors. Importantly, this study will provide a rationale for using carboplatin in resource-limited settings worldwide.

The limitation of this study is that it will have a screen failure rate of around 70%, as the prevalence of deleterious mutations in the HRR pathway is approximately 30%. Further, the availability of tumor tissue and the quality of archived specimens can also impair the technical ability to detect mutations in the HRR pathway. Therefore, approximately 200 patients with mCRPC will be screened to enroll 49 patients in this study.

There had only been small retrospective trials for using carboplatin in mCRPC. This would be the first phase II trial to evaluate the efficacy of carboplatin in patients with metastatic prostate cancer harboring mutations in the HRR pathway.

Conclusions

This prospective phase II clinical trial addresses a critical unmet need in the management of patients with mCRPC harboring HRR gene mutations. With a focus on evaluating the efficacy of carboplatin, an affordable chemotherapy agent, this study holds promise as a new therapeutic option. The trial's approach builds upon the concept of synthetic lethality, harnessed by both PARP inhibitors and carboplatin. If successful, carboplatin could emerge as a practical and accessible treatment strategy for this specific patient subset, potentially improving their outcomes and quality of life. By bridging the gap between high-cost therapies and broader patient accessibility, this study can potentially transform the landscape of mCRPC treatment, offering hope to patients worldwide.

Acknowledgments

We thank the Indian Council of Medical Research for funding this clinical trial. As an investigator-initiated study, the sponsor is a teaching hospital employing the principal investigator. This study is conducted via the administrative, logistic, and other supports provided by the hospital. ICMR is providing funding for manpower and HRR testing. The protocol is dated August 1, 2023 (version 2.0). All authors declared that they had insufficient or no funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this article.

Data Availability

The supplementary material of the final paper will contain the full protocol. The deidentified data will be available upon reasonable request to the corresponding author after the publication of the final results.

Authors' Contributions

RJ conceptualized the study and drafted and revised the manuscript. AK, Atul S, RKS, SK, Aparna S, BN, SAS, HKP, CJD, and A Seth conceptualized the study. AB conceptualized the study, designed the trial and statistical analysis, and drafted and revised the manuscript.

Abstract

Background: A better understanding of SARS-CoV-2 infection risk among Hispanic and Latino populations and in low-resource settings in the United States is needed to inform control efforts and strategies to improve health equity. Puerto Rico has a high poverty rate and other population characteristics associated with increased vulnerability to COVID-19, and there are limited data to date to determine community incidence.

Objective: This study describes the protocol and baseline seroprevalence of SARS-CoV-2 in a prospective community-based cohort study (COPA COVID-19 [COCOVID] study) to investigate SARS-CoV-2 infection incidence and morbidity in Ponce, Puerto Rico.

Methods: In June 2020, we implemented the COCOVID study within the Communities Organized to Prevent Arboviruses project platform among residents of 15 communities in Ponce, Puerto Rico, aged 1 year or older. Weekly, participants answered questionnaires on acute symptoms and preventive behaviors and provided anterior nasal swab samples for SARS-CoV-2 polymerase chain reaction testing; additional anterior nasal swabs were collected for expedited polymerase chain reaction testing from participants that reported 1 or more COVID-19–like symptoms. At enrollment and every 6 months during follow-up, participants answered more comprehensive questionnaires and provided venous blood samples for multiantigen SARS-CoV-2 immunoglobulin G antibody testing (an indicator of seroprevalence). Weekly follow-up activities concluded in April 2022 and 6-month follow-up visits concluded in August 2022. Primary study outcome measures include SARS-CoV-2 infection incidence and seroprevalence, relative risk of SARS-CoV-2 infection by participant characteristics, SARS-CoV-2 household attack rate, and COVID-19 illness characteristics and outcomes. In this study, we describe the characteristics of COCOVID participants overall and by SARS-CoV-2 seroprevalence status at baseline.

Results: We enrolled a total of 1030 participants from 388 households. Relative to the general populations of Ponce and Puerto Rico, our cohort overrepresented middle-income households, employed and middle-aged adults, and older children (P<.001). Almost all participants (1021/1025, 99.61%) identified as Latino/a, 17.07% (175/1025) had annual household incomes less than

US $10,000, and 45.66% (463/1014) reported 1 or more chronic medical conditions. Baseline SARS-CoV-2 seroprevalence was low (16/1030, 1.55%) overall and increased significantly with later study enrollment time (P=.003).

Conclusions: The COCOVID study will provide a valuable opportunity to better estimate the burden of SARS-CoV-2 and associated risk factors in a primarily Hispanic or Latino population, assess the limitations of surveillance, and inform mitigation measures in Puerto Rico and other similar populations.

KEYWORDS

cohort studies; COVID-19; epidemiologic studies; Hispanic or Latino; incidence; prospective studies; research methodology; SARS-CoV-2; seroprevalence

Introduction

After the first detection of SARS-CoV-2 in late 2019, the virus has become a significant threat to health and economies globally, particularly in populations with high economic inequality and low access to health resources and infrastructure [1,2]. In the United States, racial and ethnic groups with well-documented socioeconomic disparities have also been disproportionately affected by SARS-CoV-2, with the highest COVID-19 morbidity and mortality rates among American Indian or Alaska Native, non-Hispanic Black, and Hispanic or Latino populations [3,4]. Despite tremendous progress in our understanding of SARS-CoV-2 and the development of COVID-19 treatment and vaccines, control efforts have been hindered by the emergence of new, more contagious variants and vaccine hesitancy [5-9]. A better understanding of risk and risk factors for SARS-CoV-2 infection and transmission dynamics in minority groups and low-resource settings is needed to inform ongoing control efforts and develop strategies to improve health equity.

Puerto Rico, a Caribbean island and US Commonwealth, has a high prevalence of population characteristics associated with increased vulnerability to COVID-19. Among approximately 3.3 million Puerto Rico residents, almost all (99%) identify as Hispanic or Latino, and 43% live below the federal poverty level [10]. Additionally, risk factors for severe COVID-19, including older age and chronic disease, are higher among Puerto Ricans relative to residents of the continental United States, and economic crises and natural disasters have weakened the local health care infrastructure over the past decade [11-13]. As in many regions, facility-based public health surveillance and seroprevalence data from blood banks have been and continue to be the primary sources of SARS-CoV-2 incidence and prevalence data in Puerto Rico [14-16]. While valuable, these data are limited in depth and scope due to reliance on patient health care seeking behavior and passive reporting by providers and diagnostic laboratories. Systematic diagnostic testing and follow-up of a defined population can better capture the spectrum of COVID-19 disease, determine true infection rates, and help identify risk factors for infection and morbidity.

As part of the COVID-19 emergency response efforts, the US Centers for Disease Control and Prevention (CDC) supported multiple community-based cohort studies to better understand SARS-CoV-2 transmission and risk in different settings [17-19]. The ongoing Communities Organized to Prevent Arboviruses (COPA) cohort study in Ponce, Puerto Rico—implemented in 2018 through the collaboration of the Ponce Health Sciences University, Puerto Rico Vector Control Unit, and the CDC Dengue Branch (DB)—was identified as an existing platform that could be expanded to estimate SARS-CoV-2 community infection rates and other COVID-19 research objectives in the region. In June 2020, we implemented the COPA COVID-19 (COCOVID) study, a prospective, community-based cohort to investigate the incidence of and risk factors for SARS-CoV-2 infection and morbidity among COPA participants and other residents of 15 community areas.

In this study, we describe the protocol, baseline population demographics, and seroprevalence of SARS-CoV-2 in the COCOVID cohort. The study included weekly molecular testing and multiantigen serology testing at baseline and every 6 months for SARS-CoV-2. We also collected sociodemographic data, weekly mobility and personal preventive behavior patterns, COVID-19 vaccination status, symptoms, and long-term outcomes among individuals with and without incident SARS-CoV-2 infection during the study period. To date, few longitudinal COVID-19 studies with regular SARS-CoV-2 molecular testing have included the United States or Hispanic or Latino populations [20,21], and none have been conducted in Puerto Rico. Thus, data from the COCOVID study have the potential to enhance general knowledge of SARS-CoV-2 epidemiology in addition to providing unique insights into the COVID-19 epidemic in Puerto Rico, which may have implications for prevention efforts and future epidemics in geographically or demographically similar populations.

Methods

Ethical Considerations

Local ethics review and approval for the COPA project and COCOVID substudy protocols were obtained through the Ponce Medical School Foundation, Inc's institutional review board (study #171110-VR). CDC also reviewed COPA and COCOVID protocols and determined the activities were conducted in a manner consistent with applicable federal law and CDC policy (refer to 45 C.F.R. part 46; 21 C.F.R. part 56).

Adult consent, minor assent, and parental or guardian permission were obtained at enrollment and subsequent 6-month follow-up visits and documented using paper forms. The receipt of consent and assent for all participants was also confirmed daily and

tracked electronically by study coordinators. All participants under the age of 21 years, the age of majority in Puerto Rico, were considered minors except for those emancipated by marriage or judicial decree. Before the interview or specimen collection, staff explained project activities and important points of informed consent to participants, answered any questions raised, and provided a paper copy of the consent form to the household. The household representative (an adult or an emancipated minor that was present at the time of visit) consented to provide household-level information and allow study staff to invite other household members to participate in the study.

All adults and emancipated minors (including household representatives) were asked to provide written consent for each of the following: providing contact information, responding to the COPA annual interview questions and providing blood and nasal swab specimens (where applicable), being contacted weekly for acute illness surveillance (AIS) and annually for cohort follow-up, responding to the COCOVID questionnaire and providing blood specimens every 6 months and nasal swabs weekly, storage of specimens remaining after testing for future studies, and permission for children for which they were the parent or legal guardian to participate in the same project activities.

The adult consent document requested a separate enumeration of each child for which they had parental or guardianship rights to account for any differences in the activities in which each child could participate. For minors aged between 14 and 20 years, written consent was obtained using a designated form simplified from the adult version. Verbal assent was documented in a designated form for minors aged between 7 and 13 years, and only parent or guardian consent was documented for minors aged between 1 and 6 years. All consent and assent forms and questionnaires were available in both Spanish and English and were written at an eighth grade or lower reading level.

This project involved the collection of personal identifying information and included safeguard measures to ensure the privacy and confidentiality of participants. Households and individual participants were assigned project-specific identifiers to track their location of residence and study status. Barcode stickers were used to link specimen tubes and paper forms to each participant's visit during the project. All specimens were securely transported to and stored at the study office site, the CDC DB, and other laboratory sites. All personnel involved in this study were required to complete ethics training requirements set by the institutional review board and adhere to an unwavering code of conduct regarding the confidentiality of patients' information.

Only study personnel have access to participant responses or laboratory results. Study questionnaires, laboratory test results, and other collected data are electronically stored in locations approved by the CDC for storage of personal data, including a limited-access encrypted server and shared drive within the CDC internal network, and, in the case of paper forms, in locked cabinets. Paper records will be maintained for at least 3 years and then destroyed. Where possible, deidentified data sets will be created and used for analysis, and individual participants will not be identified for any presentations or publications based on the study results.

For compensation for the time dedicated to the COCOVID study activities, participants received US $5 each week upon staff receipt of the completed weekly questionnaire and self-collected respiratory specimen, which was given in US $20 installments for every 4 successful transfers of weekly questionnaires and specimens. Participants also received US $20 at each study appointment (enrollment, 6 months, 12 months, 18 months, and 24 months) when they completed serum specimen collection and the questionnaire. If these appointments overlapped with COPA annual follow-up visits (enrollment, 12 months, and 24 months), an additional US $20 (between June 2021 and February 2022) or US $30 (between March and August 2022) in compensation was given for both activities for a total of US $40 or US $50.

Study Overview

In June 2020, we implemented the COCOVID substudy among residents of 15 community areas in Ponce. We aimed to enroll between 900 and 1000 participants for regular surveys and specimen collection, including weekly anterior nasal swab collection for SARS-CoV-2 polymerase chain reaction (PCR) testing and venous blood draws for multiantigen immunoglobulin (Ig) G antibody testing at baseline and every 6 months. Participants were also included in activities for the larger COPA cohort for at least the same period that they were active in the COCOVID study, including weekly reporting of acute COVID-19–like symptoms through SMS text message and additional SARS-CoV-2 PCR testing among symptomatic participants.

COPA Platform

The COPA study established an ongoing cohort of approximately 3800 participants in 38 community areas in Ponce, Puerto Rico (Figure 1) to measure the incidence and prevalence of arboviral infections and evaluate vector control interventions through a cluster randomized controlled trial design [22,23]. Recruitment activities are conducted primarily through house-to-house visits, and random selections of residences in each community area are made until sample size goals are reached or all residences have been approached for recruitment. Eligible individuals are aged between 1 and 50 years, spend 4 or more nights a week in the selected residence, and have no definite plans to move in the next 12 months. Follow-up is conducted annually and includes serum collection for antibody testing for dengue and the administration of a questionnaire (Figure 2). Cohort enrollment began in March 2018.

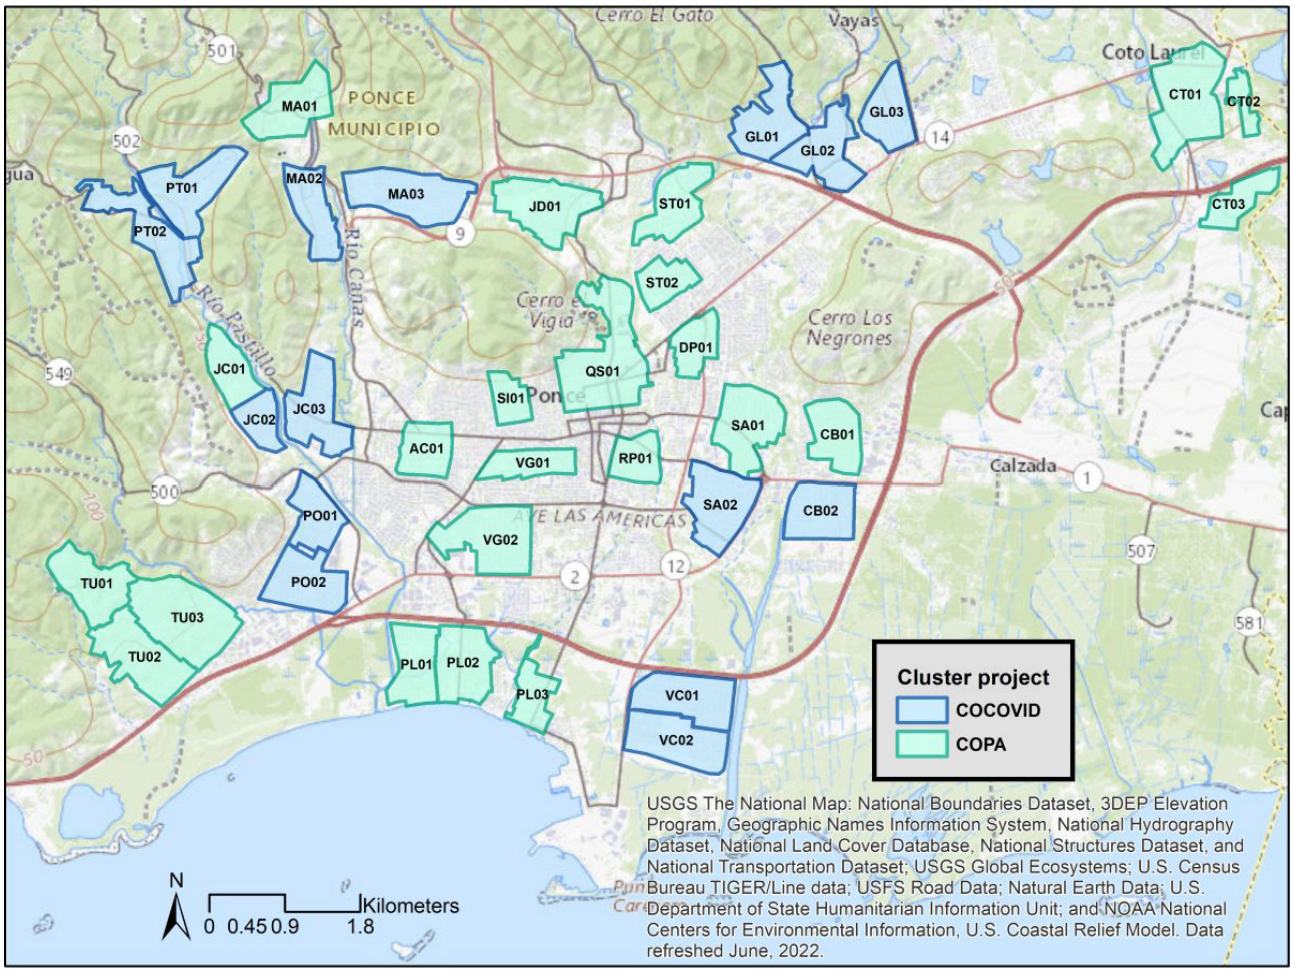

Figure 2. Timeline of key Communities Organized to Prevent Arboviruses (COPA) and COPA COVID-19 (COCOVID) cohort study activities in Ponce, Puerto Rico, between January 2020 and December 2022. CDC: Centers for Disease Control and Prevention; mo: months; PCR: polymerase chain reaction; PMSF: Ponce Medical School Foundation; yrs: years.

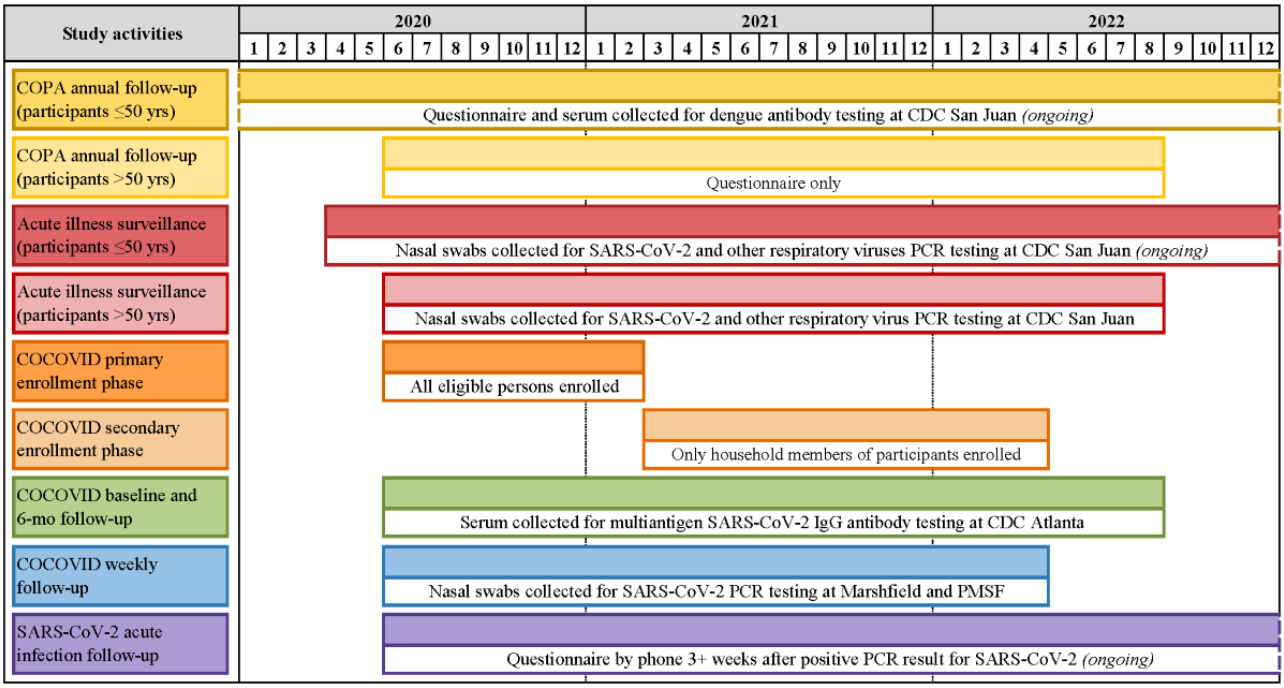

In April 2020, questions related to risk and perceptions of COVID-19 were added to the annual questionnaire, and an AIS component was implemented (Figure 2). The AIS component is ongoing and uses an automated SMS text messaging system to contact adult participants weekly to inquire if any household members have experienced fever or other COVID-19–like symptoms (ie, cough, shortness of breath, sore throat, body pain, diarrhea, and loss of taste or smell) in the past 7 days (Figure 2). Participants that report fever are offered testing for dengue virus (DENV) by real-time reverse transcriptase–polymerase chain reaction (rRT-PCR) testing in serum, and those that report any qualifying symptom are offered an anterior nasal swab for SARS-CoV-2 and other respiratory virus rRT-PCR testing. Beginning in December 2021, participants were also asked to provide an additional anterior nasal swab for SARS-CoV-2 rapid antigen testing. To ensure the consistency of the sample collection method for both tests, all nasal swabs are collected by a nurse or medical technologist. At the time of specimen collection, project staff also administer an AIS questionnaire on recent exposures, symptoms, and health care–seeking behaviors.

Study Population and Enrollment

Enrollment activities for the COCOVID substudy for COVID-19 began in late June of 2020. We initially selected 12 of the 38 COPA study communities for COCOVID activities, and an additional 3 community areas were added during the enrollment process to meet sample size goals (Figure 1). We prioritized the selection of community areas with high numbers of individuals aged 18 years or younger and those aged 50 years or older in COPA-participating households to increase the participation of these age groups. We also considered logistical priorities, including proximity to other selected clusters and ease of access to residential areas, in the selection process. Eligibility for COCOVID participation was expanded beyond that of COPA to include residents aged 50 years or older, in addition to spending 4 or more nights per week at a residence in a selected community area and having no definite plans to move in the next 12 months. COCOVID participants agree to participate in COPA annual follow-up questionnaires and, for participants aged between 1 and 50 years, the collection of blood specimens for arbovirus antibody testing for at least the substudy duration; participation in the AIS activities was not required for COCOVID enrollment.

Using a standardized script, study staff contacted households with 1 or more COPA participants by phone to explain the study, offer enrollment to eligible household members, and schedule an initial study visit to complete consent processes and data and specimen collection activities. Enrollment of all eligible household members was encouraged but not required, and participants were also asked to refer family and neighbors residing in the 15 community areas. The primary enrollment phase occurred between June 2020 and February 2021. Subsequently, only the enrollment of members of households with 1 or more active participants was permitted to avoid major changes to study logistics and increases in resource use (secondary enrollment phase, Figure 2). Following the completion of the primary enrollment phase, we planned to continue participants' weekly follow-up activities for a minimum of 12 months (through February 2022) and 6-month activities for a minimum of 18 months (through August 2022).

Sample Size Calculation

The sample size for the COCOVID substudy was based on the primary study objective of estimating community incidence of SARS-CoV-2 infection, which included allowing for comparisons by age group, accounting for potential similarity among participants within cluster areas, and assuming a cumulative incidence of infection of 10%-30% over the study period. Age groups were defined to allow infection risk comparisons of pediatric (1-17 years) and older adult (≥50 years) populations with the general population (18-49 years); gender-based sample size estimates were not made as we assumed our household-based recruitment methods would result in representative samples by gender. Our calculations assumed the enrollment of approximately equal numbers of participants across the 3 age groups and from the initially selected 12 community areas. Additionally, it was assumed that participants who were infected with SARS-CoV-2 before enrollment would not be at lower risk of further infection during the study period.

We expected a high coefficient of variation among the clusters for SARS-CoV-2 transmission, and calculations were made using a range of values from 0.5 to 0.8. We also expected a high intracluster correlation among the responses within a cluster due to the rapid spread of SARS-CoV-2, and calculations were made using values of 0.2 and 0.25. The precision of incidence is estimated by computing the 95% CI for 1 proportion in a cluster sampling design. Scenarios were run considering different cumulative incidence proportions with different intracluster correlations, coefficients of variation, and sample sizes for each cluster. Calculations showed that to reach a CI half width of 0.19 or less, a sample size of 215 participants per age group, or a total of 645 participants, was needed. To account for up to 20%-30% loss to follow-up (a high estimate to also allow for probable unequal recruitment across age groups) and an estimated 5% prevalence of previous SARS-CoV-2 infection at enrollment, we estimated that we needed to enroll a total of 900-1000 participants.

Baseline and 6-Month Follow-Up

Baseline and subsequent 6-month visits took place at the COPA central office facilities, a designated outdoor drive-through site, or the participant's home, depending on local social distancing regulations and participant preferences. After completing informed consent processes, study staff administered a questionnaire on chronic conditions, recent COVID-19 exposures, preventive behaviors, and, for participants that reported an acute COVID–like illness in the past 7 days, symptoms and health care seeking behaviors. Questions on COVID-19 vaccination status were added in January 2021, and questions on employment status and category, long-term COVID-19 symptoms (persisting or appearing more than 1 month after illness onset), and diagnosis of new chronic conditions after an acute SARS-CoV-2 infection were added in September 2021. A trained phlebotomist collected blood for multiantigen SARS-CoV-2 IgG antibody testing by venipuncture using aseptic techniques. Approximately 7.5 milliliters of blood were collected from participants aged between 1 and 4 years,

and approximately 15 milliliters from participants aged 5 years or older.

To reduce study burden, COPA annual activities were conducted at the same time as COCOVID baseline and 6-month follow-up visits, where possible (Figure 2). In these cases, an additional ~7.5 mL of blood for dengue antibody testing were collected during the COCOVID visit for participants aged between 1 and 50 years, and the COPA annual questionnaire was administered to all participants by phone. This questionnaire included questions about household composition and income, demographics, employment status, and COVID-19 risk perception. The 6-month follow-up activities were conducted through August 2022 (Figure 2).

Weekly Follow-Up

Each week, participants self-collected (or had a parent or guardian assist them in collecting) a flocked swab of the anterior nares (anterior nasal swab) and completed a paper questionnaire on new or worsening symptoms, illness among household members, and behaviors such as leaving their home for activities with people outside of their household, places visited, mask use, and social distancing. Before distribution, a unique barcode label was applied to a specimen collection tube and corresponding weekly questionnaire, and questionnaires were prefilled with the participant's name, date of birth, and study identifier. At the enrollment appointment, the first weekly nasal swab specimen and accompanying questionnaire were completed under study staff instruction and supervision, and an initial 4-week supply of paper questionnaires and nasal swab specimen collection supplies were provided. Participants were asked to collect nasal swab specimens and fill out the accompanying questionnaire on a consistent day of the week within 0-12 hours of a scheduled transfer to study staff.

Study staff drove to the participating houses on an agreed-upon day and time for specimen and questionnaire pick-up each week. Households that were unavailable for scheduled pick-up (incidentally or always) were asked to drop off collected specimens and questionnaires at an agreed-upon day and time at the COPA office site. An automated SMS text-messaging system through Twilio MessagingX (Twilio, Inc) was used to send reminders to households on the day of their scheduled pick-up or drop-off for respiratory specimen collection, and study staff contacted participants by phone within 0-2 days if specimen and questionnaire receipt was delayed without notice and to resolve other issues related to received specimens and questionnaires, such as specimen leaks and missing responses. If scheduled receipt of a weekly respiratory specimen was delayed by 4 or more days, no additional opportunities for specimen transfer were offered, and the specimen was considered missing for that week. Additional 4-week supplies of respiratory specimen collection kits and questionnaires were distributed to participants as needed during pick-up and drop-off activities.

Weekly follow-up activities were initially planned to conclude in February 2022, after 12 months of the end of the primary enrollment period. However, investigators agreed to extend the weekly follow-up period due to an increase in SARS-CoV-2 transmission following the introduction of the Omicron variant in Puerto Rico. Study materials and funds were identified to permit a 2-month extension of weekly follow-up to a total of 98 weeks from June 2020 to April 2022 (Figure 2).

Follow-Up for Participants With Symptoms or SARS-CoV-2 Infection

Participants that reported fever, cough, shortness of breath, sore throat, body pain, diarrhea, or loss of taste or smell in the weekly questionnaires (or through the AIS SMS text message system) were asked to participate in a COPA AIS visit to collect additional samples for expedited testing for dengue, SARS-CoV-2, and other respiratory viruses and answer the AIS questionnaire.

Participants with a positive SARS-CoV-2 molecular test from nasal swab specimens collected during weekly COCOVID follow-up or as part of AIS were contacted by phone at least 4 weeks after specimen collection (depending on delays in receipt of positive test results) to complete a follow-up questionnaire on symptoms and illness duration, health care seeking behavior, travel, and other exposures before infection, and to take measures to prevent household transmission while sick (Figure 2).

Specimen Storage, Transport, and Testing

Participants were asked to store weekly anterior nasal swab specimens in their home refrigerators until they were transferred to study staff. Upon receipt of nasal swab specimens, staff stored them in the COPA laboratory refrigerator at 4 °C or according to current CDC specimen storage guidelines. Staff centrifuged whole blood specimens within 4 hours of collection to separate out serum and stored them in the COPA laboratory refrigerator until transport. Specimens were transported by a courier 3 times weekly from the COPA office site to the CDC DB laboratory in San Juan, Puerto Rico, for accessioning, processing, and storage at –70 °C. Frozen nasal swab specimens from COCOVID weekly collection activities were shipped every 1-3 months, and serum aliquots from COCOVID 6-month collection were shipped every 3-6 months to designated laboratories for testing.

Weekly nasal swab specimens were tested by multiplex rRT-PCR assays to detect SARS-CoV-2 RNA, including the Quidel Lyra SARS-CoV-2 Assay [24], Thermo Fisher Scientific TaqPath COVID-19 Combo Kit [25], Thermo Fisher Scientific TaqPath COVID-19, FluA, FluB Combo Kit [26], and Roche Cobas SARS-CoV-2 assay [27]. Cycle threshold values for assay targets were provided for positive specimens, and overall test result interpretations were provided for all tested specimens. Specimens collected between June 2020 and February 2022 were tested by Marshfield Labs in Marshfield, Wisconsin; those collected between March and April 2022 were tested by the Ponce Medical Sciences Foundation Immunology Reference Laboratory in Ponce, Puerto Rico. Whole genome sequencing is ongoing and being performed at CDC headquarters (Atlanta, Georgia) or DB laboratories for weekly nasal swabs that tested positive by rRT-PCR and have sufficiently low cycle threshold values for the nucleocapsid (N) protein target (≤30 for headquarters and ≤27 for DB laboratories). Information on the detected variant lineage (through Pangolin COVID-19 Lineage

Assigner software version 3.1.7; Centre for Genomic Pathogen Surveillance) is provided in accordance with CDC guidance [28].

Serum specimens collected for baseline and 6-month follow-up visits were tested by the Luminex xMAP SARS-CoV-2 multiantigen IgG assay to detect previous infection with SARS-CoV-2 [29]. This assay has 3 antigen targets: the N structural protein, the S1 subunit, and the receptor binding domain (RBD), which are part of the spike (S) protein. Interim guidelines for SARS-CoV-2 testing from the US CDC recommend using anti-N IgG antibody testing to evaluate previous SARS-CoV-2 infection in vaccinated individuals, as COVID-19 vaccines are designed to encode the S protein or a portion of it. Thus, to reduce potential misclassification due to vaccination versus past SARS-CoV-2 infection, specimens were only determined to be positive if IgG antibodies against the N protein, in addition to those against at least 1 of the other 2 targets (S1 and RBD), were detected. The CDC Microbial Pathogenesis and Immune Response Laboratory in Atlanta, Georgia, conducted testing on all serum specimens collected during the study period.

Serum and nasal swab specimens collected for AIS activities were tested at the CDC DB laboratory. Serum samples were tested by the CDC DENV-1-4 rRT-PCR Multiplex Assay to detect RNA for DENVs 1, 2, 3, and 4 and by the DENV Detect IgM Capture enzyme-linked immunosorbent assay kit to detect IgM antibodies for DENV antigens [30,31]. Anterior nasal swabs were tested by an in-house respiratory virus rRT-PCR multiplex assay to detect RNA for SARS-CoV-2, influenza A and B viruses, parainfluenza viruses, adenovirus, respiratory syncytial virus, and human metapneumovirus. The DENV and respiratory virus rRT-PCR assays for AIS specimens were run weekly or more often, and participants with positive results were notified by phone and given recommendations on preventing transmission and following up with their health care providers as needed.

Data Collection and Management

Baseline and 6-Month Questionnaire

Between June 2020 and February 2022, the EpiInfo mobile app was used on Samsung tablets to administer the baseline and 6-month questionnaires and record responses, including participant identifiers and specimen collection data [32]. Beginning in March 2022, the Research Electronic Data Capture (REDCap; Vanderbilt University) mobile application was used to administer these questionnaires [33,34]. Paper questionnaire forms were available for use as a backup in case of electronic data collection failure. Paper forms were entered into the mobile app either daily or every 6 months as part of the data review and cleaning processes. Questionnaire data were transferred daily from tablets to a secure, limited-access CDC server through the Secure Shell File Transfer Protocol.

Weekly Questionnaire

A paper version of the weekly questionnaire was completed by participants and received by study staff at scheduled specimen pick-up and drop-off activities. Staff reviewed the form for completeness and filled out the laboratory section to accompany the corresponding weekly nasal swab specimen. After the specimens were transported to and accessioned by the CDC DB laboratory, the forms were scanned into the CDC laboratory samples database, where they underwent automated data extraction using Microsoft Azure Form Recognizer software or manual data entry in cases of software extraction failure [35].

Preliminary data cleaning was performed in EpiInfo or REDCap daily by study field staff and the data quality team. Additional data cleaning processes were performed weekly using the R environment for statistical computing (R Core Team) and involved data validation and standardization, including the identification of missing forms, data inconsistencies, and variable completeness [36]. Final data checks and standardizations were also performed using R statistical software at 6-month intervals to generate analytic data sets.

Data Analysis

Outcome Measures

The primary outcome measures of interest for this study are (1) the incidence of SARS-CoV-2 infection as defined by detection of SARS-CoV-2 RNA by PCR testing of participant specimens collected as part of weekly follow-up or AIS visits, and (2) the relative risks of incident SARS-CoV-2 infection by participant demographics, health history, and behaviors. Secondary outcomes included the (1) seroprevalence of SARS-CoV-2 defined by detection of N and either S1 or RBD IgG antibodies by enzyme-linked immunosorbent assay, (2) household attack rate among households with at least 2 participants and 1 participant with an incident SARS-CoV-2 infection, and (3) the frequency of illness characteristics and outcomes (ie, symptom status and severity, health care seeking, death, and post–COVID conditions) among participants with incident SARS-CoV-2 infections.

Planned Statistical Analyses

SARS-CoV-2 Infection Incidence and Risk Factors

Using the number of incident SARS-CoV-2 infection events detected through PCR testing divided by the total person-time at risk contributed, we calculated SARS-CoV-2 infection incidence rates overall and approximately every 6 months during the study period (between June 2020 and August 2022). We will also estimate the incidence rates separately for primary and secondary infections, during the circulation of major SARS-CoV-2 variants, and by COVID-19 vaccination status. We will use Poisson regression to estimate adjusted infection risks by age group, primary SARS-CoV-2 variant circulating at the time of infection, previous SARS-CoV-2 infection status, and COVID-19 vaccination status, and identify other potential risk factors for infection in our cohort. Household will be accounted for as a clustering effect in the regression, using the sandwich estimator framework to calculate a clustered SE [37]. We will extrapolate the cumulative incidence of SARS-CoV-2 infections in the cohort to the general population in the Ponce region during the study, using population age and sex estimates from US census data numbers, and compare this extrapolated estimate to surveillance data from the same time period.

SARS-CoV-2 Infection Seroprevalence

Using the overall interpretation for the SARS-CoV-2 IgG antibody testing (positive only when N and either S1 or RBD antibodies are detected), we will estimate the seroprevalence of SARS-CoV-2 infection among participants of the COCOVID cohort approximately every 6 months during the study period, using specimens collected during those periods. The frequency of seroconversion, defined as a positive SARS-CoV-2 IgG antibody test result following a negative result, will be assessed over the study period at the individual and household level. For the period during which both PCR and antibody testing were occurring (between June 2020 and April 2022), we will compare the proportion of participants with seroconversion detected with SARS-CoV-2 incidence estimates from weekly PCR testing. This comparison will be used to evaluate the sensitivity and specificity of repeated serology testing at 6-month intervals in estimating infection incidence. We will also use the results of this comparison to inform estimates of SARS-CoV-2 infection incidence in the cohort that occurred between May and August 2022, when only SARS-CoV-2 IgG test results were available.

Household Attack Rate

We will assess potential household transmission of SARS-CoV-2 among households with at least 2 participating members and 1 participating member with an incident SARS-CoV-2 infection (index case) during study follow-up. Additional household cases will be defined based on the detection of SARS-CoV-2 RNA by PCR testing in a household member within 14 days of the index case. We will calculate a crude household attack rate from the proportion of additional cases among all household members deemed susceptible to acquiring SARS-CoV-2 infection from an index case. To account for household transmissions from nonindex cases and identify factors associated with household transmission, we will consider using a chain binomial transmission model to estimate the household attack rate and identify factors associated with increased and decreased likelihood of intrahousehold transmission [38,39].

Frequency of Illness Characteristics and Outcomes

Among COCOVID participants with incident infections, we will assess the frequency of symptomatic versus asymptomatic infection, self-reported symptoms, illness duration, health care seeking behaviors, and outcomes, including uncomplicated recovery, hospitalization, death, and the development of post–COVID conditions. If sample size permits, we propose using robust Poisson regression models to identify participant demographics, symptoms, and comorbidities associated with seeking care and being diagnosed with COVID-19, severe disease, and the development of self-reported post–COVID-19 conditions [40]. We will compare acute illness events reported in COCOVID weekly questionnaires associated with an incident SARS-CoV-2 infection to those not associated with SARS-CoV-2 infection to identify symptoms and symptom combinations that are highly indicative of infection [41].

Statistical Analyses of Baseline Data

In this study, we describe the baseline characteristics of the COCOVID cohort using data collected from questionnaires applied at COCOVID enrollment or within the previous year for participants previously enrolled in COPA. Frequency statistics are presented overall for the COCOVID cohort and compared to the populations of Ponce and Puerto Rico based on data from the US Census American Community Survey 2021 1-Year estimates [10,42]. Pearson chi-square tests were used for comparisons of the cohort population with those of Ponce and Puerto Rico at a household and individual level; multiple comparisons were conducted for variables with more than 2 categories, and Bonferroni-adjusted *P* values are presented. For the cohort population, individual frequency statistics were also presented by serological evidence of previous SARS-CoV-2 infection at baseline, as indicated by IgG antibody testing by timing of study enrollment, age group, sex, and annual household income. Pearson chi-square or Fisher exact tests, in the case of 1 or more expected values of <5, were used to compare categorical variables by baseline serostatus. A significance level of .05 was assumed for all comparisons, including following Bonferroni adjustment where applicable.

All analyses were conducted using R (version 4.0.4; R Core Team) [36].

Results

During the first phase of enrollment (between June 2020 and February 2021), a total of 1012 individuals from 388 households were enrolled in the COCOVID cohort; an additional 18 members of participating households were enrolled in the secondary enrollment phase, with the last participant enrolled in November 2021. Among 388 households with at least 1 COCOVID participant, 83.03% (1042/1255) of all household members were enrolled, with a mean of 3.2 participants per household; 40.27% (151/375) of households had an annual income under US $20,000 (Table 1). Of the 1030 total participants, 56.21% (579/1030) had previously participated in the COPA study, the mean age was 35.9 (range 1-97) years, and 53.40% (550/1030) were female (Table 2). Most participants identified as Latino/a (1021/1025, 99.61%) and Puerto Rican (1015/1024, 99.12%), and around two-thirds (682/1016, 67.13%) identified as White. There were 719 adult participants (aged 21 years or older; 69.8%) enrolled, of which approximately two-thirds had college or technical school degrees (197/716, 27.51%) or postgraduate study (278/716, 27.36%) and half were employed (380/717, 53.00%). More than half (389/719, 54.10%) of adult participants and 45.66% (463/1014) of all participants reported having been diagnosed with at least 1 chronic health condition.

Table 1. Annual income of households with ≥1 participant in the COPA COVID-19 (COCOVID) cohort study at baseline, between June 2020 and November 2021, compared to those of the Ponce municipality and Puerto Rico populations according to 2020 and 2021 US Census American Community Survey estimates.

Annual household income (US $)[a]	Households with ≥1 COCOVID participant (N=388), n (%)	Households in Ponce municipality (N=50,007), n (%)	*P* value[b]	Households in Puerto Rico (N=1,165,982), n (%)	*P* value[b]
<10,000	61 (16.3)	16,659 (33.3)	<.001	286,499 (24.6)	<.001
10,000-19,999	90 (24)	9,783 (19.6)	.16	250,325 (21.5)	>.99
20,000-29,999	86 (22.9)	6,792 (13.6)	<.001	176,614 (15.1)	<.001
30,000-49,999	90 (24)	7,719 (15.4)	<.001	208,722 (17.9)	.01
>50,000	48 (12.8)	9,054 (18.1)	.04	243,822 (20.9)	<.001

[a]Participants or households who declined to respond or were missing a response were excluded from the denominator in percentage calculations (<4%).

[b]*P* values for characteristics with more than 2 categories were adjusted for multiple comparisons by Bonferroni correction.

Table 2. Demographics of all participants in the COPA COVID-19 (COCOVID) cohort study at baseline, between June 2020 and November 2021, compared to those of the Ponce municipality and Puerto Rico populations according to 2020 and 2021 US Census American Community Survey estimates.

	COCOVID study participant (N=1,030), n (%)	Ponce municipality residents (N=135,084), n (%)	*P* value[a]	Puerto Rico residents (N=3,263,584), n (%)	*P* value[a]

[a]*P* values for characteristics with more than 2 categories were adjusted for multiple comparisons by Bonferroni correction.

[b]Participants or households who declined to respond or were missing a response were excluded from the denominator in percentage calculations (<4%).

Compared to the overall populations of both Ponce and Puerto Rico, the COCOVID cohort population differed significantly by annual household income, age group, race, education level, and employment status (Tables 1-3). Households with at least 1 COCOVID participant more frequently belonged to middle income groups of US $20,000-US $29,999 (86/375, 22.93% in cohort vs 6792/50,007, 13.58% in Ponce and 176,614/1,165,982, 15.15% in Puerto Rico) and US $30,000-US $49,000 (90/375, 24.00% vs 7719/50,007, 15.44% and 208,722/1,165,982, 17.90%), and less frequently the highest, >US $50,000 (48/375, 12.80% vs 9054/50,007, 18.11% and 243,822/1,165,982, 20.91%), and lowest, <US $10,000 (61/375, 16.27% vs 16,659/50,007, 33.31% and 286,499/1,165,982, 24.57%), income groups (*P*<.05; Table 1). The cohort had relatively high proportions of participants in the age groups of 10-17 years (174/1030, 16.89% in cohort vs 12,603/135,084, 9.33% in Ponce and 291,750/3,263,584, 8.94% in Puerto Rico), 35-44 years (181/1030, 17.57% vs 14,827/135,084, 10.98% and 400,607/3,263,584, 12.28%), and 45-54 years (198/1030, 19.22% vs 15,391/135,084, 11.39% and 415,974/3,263,584, 12.75%), and low proportions of participants in the oldest age groups, 55-64 years (52/1030, 5.05% vs 17,600/135,084, 13.03% and 442,138/3,263,584, 13.55%), and ≥65 years (102/1030, 9.90% vs 33,075/135,084, 24.48% and 740,486/3,263,584, 22.69%; *P*<.001; Table 2). Cohort participants were more frequently identified as White (683/990, 68.99% in the cohort

vs 45,980/135,084, 34.04% in Ponce and 913,840/3,263,584, 28.00% in Puerto Rico) or Black (102/990, 10.30% vs 5171/135,084, 3.83% and 200,391/3,263,584, 6.14%) and less frequently as another race (47/990, 4.75% vs 13,477/135,084, 9.98% and 981,183/3,263,584, 30.06%) or mixed race (159/990, 16.06% vs 70,456/135,084, 52.16% and 1,167,170/3,263,584, 35.76%; *P*<.001). For populations 25 years and older, cohort participants were less likely to have a less than high school education (38/659, 5.77% in cohort vs 19,235/98,553, 19.52% in Ponce and 488,780/2,401,409, 20.35% in Puerto Rico) and more likely to have some college or associate degree (186/659, 28.22% vs 21,209/98,553, 21.52% and 556,795/2,401,409, 23.19%) and a bachelor's degree or higher (268/659, 40.67% vs 31,402/98,553, 31.86% and 683,894/2,401,409, 28.48%; *P*<.001; Table 3). Additionally, cohort participants aged 25 years or older were more likely to be in the labor force relative to Ponce and Puerto Rico residents in the same age group, including in employed (356/644, 55.28% vs 35,976/98,553, 36.50% and 977,860/2,401,409, 40.72%) and unemployed groups (74/644, 11.49% vs 6037/98,553, 6.13% and 119,812/2,401,409, 4.99%; *P*<.001).

At enrollment, 1.55% (16/1030) of COCOVID participants were seropositive for SARS-CoV-2, of which the median age was 46 (IQR 33-51) years, 56.25% (9/16) were male, and half (50.00%, 8/16) reported chronic health conditions (Table 4). There was a significant difference in the timing of study enrollment among participants with and without baseline seropositivity for SARS-CoV-2, with a higher proportion of seropositive participants recruited in the later months of the study (*P*=.003). No significant differences by age group, sex, or household income were observed among participants that were seropositive and those that were seronegative at baseline.

Table 3. Education level and employment status of adult participants aged ≥25 years in the COPA COVID-19 (COCOVID) cohort study at baseline, between June 2020 and November 2021, compared to those of the Ponce municipality and Puerto Rico populations according to 2020 and 2021 US Census American Community Survey estimates.

	COCOVID study participants aged ≥25 years (N=662), n (%)	Ponce municipality residents aged ≥25 years (N=98,553), n (%)	*P* value[a]	Puerto Rico residents aged ≥25 years (N=2,401,409), n (%)	*P* value[a]

Discussion

Few studies with prospective assessments of incident SARS-CoV-2 infections at the community level have been described to date, and none have been implemented in Puerto Rico or other primarily Latino or Hispanic US populations [17-19,43-45]. The COCOVID community-based cohort study provides a unique opportunity to assess SARS-CoV-2 infection incidence, risk factors, and outcomes in Puerto Rico and also help further characterize asymptomatic infections, household transmission, and serological and molecular testing dynamics. We were able to build the COCOVID study into an existing cohort study platform, allowing for rapid enrollment and the implementation of extensive data collection activities. Prospective follow-up through weekly PCR testing of participants and regular serology testing enabled comprehensive detection of SARS-CoV-2 infections within the cohort population. Additionally, our large sample size and extended follow-up period strengthened our assessment of SARS-CoV-2 incidence and outcomes by time-dependent factors, including lockdown measures, circulating SARS-CoV-2 variants, and COVID-19 vaccination status.

COCOVID surpassed its enrollment goal with 1030 participants with minimum sample size goals (n=215) reached in the 3 age groups of interest (1-17 years, 18-49 years, and ≥50 years). The cohort included participants with characteristics associated with increased COVID-19 morbidity risk [3,46,47], although sometimes with lower frequency than the general populations for Ponce and Puerto Rico. Consistent with these populations, almost all COCOVID participants identified as Latino/a. Chronic health condition prevalence was high among adults in the cohort and in accordance with estimates from the Behavioral Risk Factor Surveillance System [48]. The cohort had relatively low proportions of participants in the oldest (≥65 years) age group and households in the lowest (<US $10,000) annual income group compared to Ponce and Puerto Rico populations. However, these groups still accounted for at least 10% of cohort participants and households, respectively, which should facilitate adjusted analyses and extrapolation of results to the general population. SARS-CoV-2 seroprevalence at enrollment was low and increased among cohort participants enrolled later in the study period. The low but increasing seroprevalence of SARS-CoV-2 observed among study participants at baseline over time is consistent with surveillance data from the region [14]. As a result, there was a limited sample size to assess differences in SARS-CoV-2 seroprevalence by age group and other characteristics, and factors associated with the seroprevalence of SARS-CoV-2 infection will be explored more fully using follow-up data from the study.

We did not use a formal sampling frame, but rather our sampling strategy was determined by logistic constraints to include a limited selection of community areas with primarily single-resident homes and no public housing or large apartment buildings. Additionally, most of our participants were previously enrolled in the larger COPA cohort, whose eligibility was restricted to participants younger than 50 years. This likely led to the observed oversampling of larger, middle-income households and employed, middle-aged adults and their children relative to the overall populations of Ponce and Puerto Rico. Additionally, individuals who agreed to enroll in COCOVID (and COPA) may be more concerned about disease risks and more likely to take measures to prevent SARS-CoV-2 infection than the general populations of Ponce and Puerto Rico. However, there was diversity across sociodemographic indicators in our study population, and the detailed data collected on household and individual characteristics and preventive behaviors can be used to adjust for these potential impacts on SARS-CoV-2–related outcomes and extrapolate our findings to the general population, where possible.

Despite tremendous progress in our understanding of SARS-CoV-2 transmission and control, including the development of effective vaccines, the persistence of health inequities and other challenges underpin the need for more comprehensive data to inform mitigation measures and prevent future outbreaks. The COCOVID study provides a valuable opportunity to investigate community and household SARS-CoV-2 infections in a primarily Hispanic or Latino population with diversity across several risk factors for COVID-19. Study methodology supports thorough detection of asymptomatic and symptomatic infections to help us better estimate the burden of SARS-CoV-2 in the region and assess the limitations of surveillance, which currently remains the primary resource for SARS-CoV-2 data for the island.

Acknowledgments

The authors would like to acknowledge the hard work of our study field team, including Emma Ramírez, Suheil Albizu, Lismarie Santiago Vargas, Aimara Medina, Evelynette Pérez, Juan Santiago, Kasey Kinzel, Nicole León, Wilmarie Rivera, Jared Abraham, Aurora Castillo, and José Molina, and the support of CDC staff and deployers in conducting participant recruitment, data collection, and cleaning activities. We would like to thank Ronald Cancel Santiago, Cindia Díaz, and Oscar Padro for designing and implementing critical data management systems, including those for weekly visit tracking and automated data entry of paper questionnaires.

Authors affiliated with Ponce Health Sciences University and Ponce Research Institute wish to provide acknowledgement of their grant (U01CK000580).

Abstract

Background: US military veterans who have experienced homelessness often have high rates of housing transition. Disruptions caused by these transitions likely exacerbate this population's health problems and interfere with access to care and treatment engagement. Individuals experiencing homelessness increasingly use smartphones, contributing to improved access to medical and social services. Few studies have used smartphones as a data collection tool to systematically collect information about the daily life events that precede and contribute to housing transitions, in-the-moment emotions, behaviors, geographic movements, and perceived social support.

Objective: The study aims to develop and test a smartphone app to collect longitudinal data from veterans experiencing homelessness (VEH) and to evaluate the feasibility and acceptability of using the app in a population that is unstably housed or homeless.

Methods: This study's design had 3 phases. Phase 1 used ethnographic methods to capture detailed data on day-to-day lived experiences of up to 30 VEH on topics such as housing stability, health, and health behaviors. Phase 2 involved focus groups and usability testing to develop and refine mobile phone data collection methods. Phase 3 piloted the smartphone mobile data collection with 30 VEH. We included mobile ethnography, real-time surveys through an app, and the collection of GPS data in phase 3.

Results: The project was launched in June 2020, and at this point, some data collection and analysis for phases 1 and 2 are complete. This project is currently in progress.

Conclusions: This multiphase study will provide rich data on the context and immediate events leading to housing transitions among VEH. This study will ensure the development of a smartphone app that will match the actual needs of VEH by involving

them in the design process from the beginning. Finally, this study will offer important insights into how best to develop a smartphone app that can help intervene among VEH to reduce housing transitions.

KEYWORDS

ethnography; homelessness; housing transitions; longitudinal data; military; mobile technology; smartphone; social support; veterans

Introduction

Background and Rationale

US military veterans are at greater risk of homelessness compared to their civilian counterparts [1,2]. Those experiencing homelessness are at increased risk of premature mortality, with a 2-decade–shorter life expectancy than the general population [3]. They experience an elevated burden of mental illness, substance use disorder, hypertension, and cardiovascular disease [4-6] as well as infectious diseases such as HIV or AIDS, tuberculosis, and hepatitis C [7]. Although homelessness is often episodic, it can occur over a long period of time for some. Commonly, those experiencing homelessness transition between different types of accommodations: homeless shelters, doubled-up with family or friends, or staying in places not meant for human habitation (eg, encampments, vehicles, and abandoned buildings) [1]. These frequent housing transitions likely exacerbate poor health, social well-being, and economic vulnerability [8,9]. There is a major gap in detailed, contextual knowledge of these transitions, such as information about in-the-moment emotions, behaviors, geographic movements, and perceived social support.

Having a greater understanding of these in-the-moment experiences may help inform efforts to better identify people who are at risk of an unexpected or unwanted housing transition and intervene to prevent a homeless episode. Without real-time information, it is difficult to understand the point-in-time contextual nuances of an individual's housing transition and provide support to mitigate these transitions. Previous work, whether quantitative or ethnographic, has been limited by the methodological difficulty of retrospectively gathering this type of contextual data about distinct points in time in the past [10,11]. Studies show that perceptions of emotions and behaviors are unreliable when gathered retrospectively [12,13]. Another factor that has limited understanding of the nuances of transition among veterans experiencing homelessness (VEH) is their lack of trust in people generally and in certain entities in particular (eg, "government") [14]. Previous research indicates that smartphones are already being widely used by homeless populations, and those populations view smartphones as a trusted source to communicate and receive information [15,16]. Smartphone technology shows promise for enhancing our understanding of short-term precipitants and helping us gain a better understanding of the in-the-moment experiences that lead to housing transitions.

Smartphone apps support the collection of real-time data, which involves the use of ecological momentary assessment (EMA). EMA allows researchers to measure participants' real-world emotions and behaviors in real-time in their natural environments [17]. Mood has been identified in numerous studies as being predictive of activity; it interacts with social support [18], is an indicator of daily stressors [19], and acts as a mediator of a variety of outcomes [20]. Additionally, technology such as GPS, which can be collected through smartphones, can provide accompanying information on daily changes in geographic movement. When analyzed with other data, this may provide insight on potential factors that precipitate a housing transition. Yet few studies have used smartphone apps to gather detailed, contextual knowledge on housing transitions among VEH. Notably, smartphone ownership among persons experiencing homelessness is growing and almost equivalent to that of the general population [21,22].

Thus, this study is among the first to design and test the feasibility and acceptability of a smartphone app that uses real-time surveys and GPS to collect longitudinal data from a population that is unstably housed. This protocol paper details the specific phases and methods used to prepare for and conduct a longitudinal smartphone data collection study with a sample of veterans.

Objective

We aim to develop and test a smartphone app to collect longitudinal data from VEH and to evaluate the feasibility and acceptability of using the app in a population that is unstably housed or homeless.

Methods

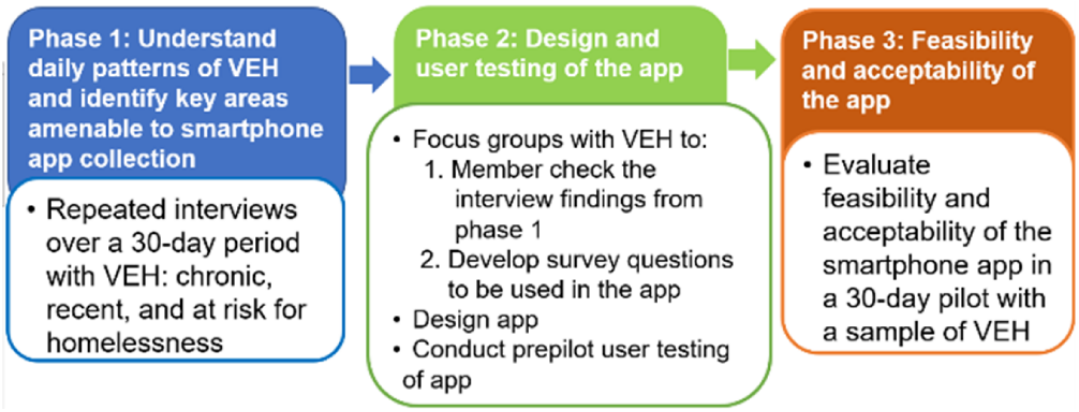
Participating Institutions

The US Department of Veterans Affairs (VA) Center for Healthcare Organization and Implementation Research (CHOIR) leads the study. CHOIR invited university partners to participate to provide the types of additional expertise needed for this initiative. Joining the team are members of Boston University's Software and Application Innovation Lab (SAIL). SAIL is a professional research, software engineering, and consulting lab that acts as both a driver and a collaborative partner for computational and data-oriented research efforts. Also joining are RK, a demographer from the University of California Los Angeles, and NFS, a sociologist from the University of California Irvine. RK brings expertise in defining study populations, including extensive experience studying and conducting interventions for persons experiencing homelessness, and NFS has a depth of expertise in developing smartphone data collection tools for vulnerable populations.

Design

This multistage study involves identifying the needs of VEH, designing an app, and pilot-testing it (Figure 1). Phase 1 involves repeated interviews over a 30-day period to understand app use and contexts of app use among persons at risk for or experiencing either chronic or recent homelessness. Phase 2 involves focus group discussions with VEH to members check the interview findings from phase 1 and develop survey questions to be used in the designed app. Additionally, user testing methods will be used to refine questions as needed. Lastly, in phase 3, we will test the feasibility and acceptability of the developed app with a sample of VEH.

Figure 1. Project design showing the 3 phases of the project. VEH: veterans experiencing homelessness.



Study Settings

The study is being conducted at 2 locations in the northeastern region of the United States to achieve diversity in the participant samples. Site 1 is one of the VA health care system's 172 medical centers, located about 15 miles north of a major city. It is one of the largest providers of services to VEH and provides a range of health and social services to veterans living in suburban and rural areas. This site is a multiservice residential program serving veterans who are experiencing homelessness or at risk for homelessness. Site 2 is located in the center of a dense urban area. This site is a multiservice community-based residential program serving veterans who are experiencing homelessness and at risk for homelessness.

Phase 1: Understand Daily Patterns of VEH and Identify Key Areas Amenable to Smartphone App Collection

Sampling of Participants and Recruitment

Using a convenience sampling strategy, we will recruit participants from 3 locations with a range of experiences with homelessness, including chronic homelessness, a recent onset of homelessness, or being at-risk for homelessness. For the purposes of this study, we define chronic homelessness as having a pattern of multiple episodes (or a single long episode) of homelessness over an extended period (ie, a year or more). We define recent onset as newly homeless, with the period of homelessness having begun in the last 6 months but not having a history of being chronically homeless. Lastly, we define being at risk as being at imminent risk of losing one's housing [23]. Recruitment will begin with the study team hosting informational sessions, followed by sharing and posting flyers at the residential programs at sites 1 and 2. Those who express interest will be approached by study team members during informational sessions or later contacted by telephone. They will then be screened for their current homeless experience (chronic, recent-onset, and at-risk) to confirm that they meet eligibility criteria.

Procedures

A 30-day focused ethnographic data collection design will be used to understand the daily patterns of VEH and identify key areas amenable to smartphone app collection. Individuals will be interviewed multiple times over a 30-day period. This time frame will be consistent with the one planned for the phase 3 pilot study of smartphone-enabled data collection and will offer proof of the concept of engagement in this later work. The focused ethnographic approach will include four different types of interviews. Interview types will include (1) a baseline, historical interview (with structured and open-ended components) that will last between 60 and 90 minutes; (2) long interviews that will focus on a "special topic" (perceptions of health, social services, and technology, including the use of smartphones) of interest to the study and will last approximately 60 minutes; (3) a general short interview, twice a week, that will last approximately 15 minutes; and (4) a final follow-up interview to obtain feedback on participation in the multiweek study. Textbox 1 shows an overview of the interview schedule, and Textbox 2 shows a description of interview topics.

Both the long and short interviews will provide an opportunity to ask VEH their opinions about the most important things to ask on a regular basis that might influence stability in housing, how to ask about sensitive topics like substance use, and about potential concerns with answering questions through a smartphone app.

Textbox 1. Phase 1 30-day illustrative interview schedule.

Weeks and interview schedule

- Week 1: baseline interview 1, short interview 2, short interview 3, and long interview 4
- Week 2: short interview 5, short interview 6, and long interview 7
- Week 3: short interview 8, short interview 9, and long interview 10
- Week 4: short interview 11, short interview 12, and final interview 13

Textbox 2. Interview types and the structured and unstructured ethnographic data collected over the course of the phase 1 30-day interviews.

Interview types and descriptions

- Baseline interview: This interview is designed to:
  - Gain a deeper understanding of participants' housing history using a modified Residential Time-Line Follow-Back Inventory [24].
  - Collect information on key social relationships, military experiences, and employment opportunities that may have influenced the life course of veterans experiencing homelessness.
  - Collect and record demographic information on a short survey form.
- Long qualitative interviews: longer "special topic" interviews to gain insights into 3 different topics
  - Physical and mental health (eg, perception of overall health, experience with physical and mental health conditions and the extent to which they impact everyday life, and perceptions of the impact of health conditions on housing stability) and its impact on housing stability.
  - Access to and use of social services (eg, places participants go for financial, logistical, or social support to meet needs, facilitators, and barriers to accessing different types of support, and perceptions of how support influences housing stability).
  - Use of technology (eg, types and uses of phones, including common apps and phone features).
- Short qualitative interviews: interviews will occur 2-3 times per week, last approximately 15 minutes, and happen between the longer special topic interviews. These interviews will explore participants' feelings, where they slept the night before, and any changes in their lives since the last conversation.
- Final interview: a 60-minute interview to obtain feedback from participants on the experience of engaging with a research team over a prolonged period.

Analysis Phase 1

Quantitative Data Analyses

Demographic characteristics like recent life experiences, homelessness episodes, overall health and health conditions, and social service use of participants will be entered into an Excel (Microsoft Corporation) spreadsheet. We will use descriptive statistics to summarize the characteristics of these participants.

Qualitative Data Analyses

All interviews will be professionally transcribed verbatim. Data will be analyzed using a Rapid Assessment, Response, and Evaluation approach [25], which uses a multidisciplinary team to collect different types of data that can be synthesized and analyzed iteratively and efficiently to generate an understanding of critical health and public health issues. Each participant in phase 1 will have a portfolio of data from their multiweek study period. Analysis will entail attention to both the cumulative story and key changes that might impact housing transitions or health. Once the transcript of each interview is available, a standardized template will be created to systematically summarize data with attention to transitions in housing and health for each participant. The summarized information will be examined to identify patterns, common concepts, and emerging ideas about current events and experiences that influence transitions in housing and health. For each participant, the lead interviewer will compile and analyze the portfolio of data. They will create a summary template that systematically synthesizes the data across the 4 weeks of data collection. This summary template will contain key fields such as transitions in housing and health for each participant, as well as key events such as fluctuations in mood and disposition, social networks, and experience with health and social services. After completion, a second team member, not involved in that participant's data collection, will review the summary template. The team will discuss the data until consensus is reached. This process will ensure consistency, clarity, and rigor. Following this process, team members will be designated to draft questions aligned with transitions in housing, health, and key events. These members will be instructed to first look for validated questions that may be appropriate. If none exist, they will draft questions for group review. Through a series of meetings, the full team will review all drafted questions and make decisions about which ones to include, exclude, and modify for a smartphone app format. This information will be used to inform phase 2 data collection and analysis.

Phase 2: Design and User Testing of the App

Sampling of Participants and Recruitment

Phase 2 will use the same recruitment and consenting strategy as phase 1. Phase 2 focus group participants will be recruited from site 2.

Procedures

Focus Groups

Focus groups will take place at a nearby VA hospital and on-site at the residential program. These discussions will provide an opportunity to build on the phase 1 findings and further explore how to recruit, enroll, and retain VEH in a future, app-based study planned in the next phase. The focus group participants will be asked for their general perceptions of taking part in a research study that uses a smartphone app for data collection and recommendations regarding how to (1) introduce and explain a study that uses the collection of data through a smartphone app, (2) explain the ways in which privacy and confidentiality will be maintained, (3) ask about potentially sensitive topics, such as substance use and relationship conflict, and (4) assess capacity to participate using a smartphone app. Participants will also be provided a brief questionnaire to obtain specific information about their access to and use of technology generally, and specifically smartphones.

We will also inquire about what types of information participants would be willing to provide researchers through their mobile phones, the acceptability of having GPS locations tracked, and any locations where they would not want GPS. We will show the focus group participants a mockup data map of an individual's GPS generated locations and movements to facilitate discussion. We will also inquire about other data collection methods, such as passively collected call logs. We will share with participants mockups of what call log data would look like to researcher team members. We will also emphasize that there will be encryption built into the software to address concerns about privacy. Feedback from the focus groups will be used to adjust the prototype of the smartphone app and guide revisions to phase 3 protocols. Focus group discussions will last approximately 60 minutes and will be facilitated by one of the anthropologists on the study team.

Development and Usability Testing

Smartphone app development will be informed by data from phase 1 ethnographic and phase 2 focus group findings. Usability testing will involve 5 VEH participants reviewing app mockups. Participants will be asked to provide feedback about the home screen, survey screen layouts, survey response options, and settings screen. Usability testing will occur approximately 2-3 months after the focus groups, when the mobile app has reached functionality. SAIL team members will provide mobile phones preloaded with the app. A member of the study team with qualitative expertise will record notes in a data collection template about overall design, ease of use, and specific wording and phrases used in the app during usability testing. Participants will use a smartphone to complete a defined set of tasks, such as turning on the phone, turning GPS off and on, responding to EMA and survey questions, etc. We will follow usability protocols and assessments, including time to complete tasks, participant error rates, software errors, etc. The team member will also ask participants about the burden of answering questions and about issues of privacy and trust. The SAIL development team will incorporate lessons from focus groups and usability assessment into the final version of the smartphone app for the phase 3 pilot. Usability assessments will be conducted by research staff who have been trained in usability assessment procedures by the SAIL mobile development group.

Analysis Phase 2

Phase 2 Focus Groups

The phase 2 focus groups and mobile app design data will include (1) the use of focus groups to gather information about the frequency of data collection, privacy issues, and incentives, and (2) the use of both phase 1 ethnographic data and phase 2 focus group data to develop a smartphone app and perform app usability testing.

Qualitative Data Analyses

All focus groups will be professionally transcribed verbatim. Thematic analysis [26] will be used by the focus group leads to analyze the data, which will be shared with the full team for an analytic discussion. Transcripts will later be combined with the phase 1 data for a global discussion of implications for the phase 3 pilot.

Phase 3: Feasibility and Acceptability Pilot of the App

Sampling of Participants and Recruitment

Phase 3 will use the same recruitment and consenting strategies as the previous phases. Phase 3 participants will also be recruited from sites 1 and 2.

Procedures

Baseline Interview and Demographics

At enrollment in phase 3, study team members will conduct semistructured qualitative interviews to gather structured data on demographics, recent life experiences, homelessness episodes, overall health and well-being, impairments, supportive relationships, and technology use. During the interview period, participants will be guided on how to download the app and will be provided with an orientation on how to use the app. The baseline interview will last about an hour.

30-day Smartphone App Data Collection

We will recruit up to 30 participants who will use the app to daily answer survey questions related to housing transitions, health service usage, medication adherence, emotional states, and social relationships [27,28]. About 2 days a week (Wednesday and Saturday evening), participants will receive a longer app survey with additional questions about health care, substance use, and the ongoing quality of specific social relationships. The questions on substance use and social relationship quality will be based on data collected during the baseline survey and qualitative interview. We will also collect information on veterans' activity space (the local areas within which people move or travel over the course of their daily activities) and proximity to health or social services by using

GPS [29]. GPS data will primarily be used to characterize the overall extent and variability of the activity space.

Follow-Up Interview

At the end of the 30-day pilot, a final follow-up interview will be conducted, using both structured and qualitative components. The interview will be conducted to document participant experiences and perceptions about the app data collection, including issues relating to trust, data security, maintaining phones, and the usability of EMA and mobile surveys. Participants will be allowed to view their survey and GPS data to offer insight into specific ambiguous survey responses and validate the general accuracy of the data set. This information will be used in a later analysis.

Analysis Phase 3

The phase 3 feasibility and acceptability pilot of mobile phone data will include 2 interviews (baseline and follow-up), as well as the mobile survey, GPS, and EMA data.

Qualitative Data Analyses

Baseline and final interview data will be organized and analyzed using the processes described in phase 1. The coding will closely follow the topics covered in the interview guide around performance and effort expectancy, social norms, facilitating factors, and trust.

Quantitative Data Analyses

First, we will use descriptive statistics to summarize the structured items collected from the baseline interviews, including information about participants' demographic characteristics, recent life experiences, homelessness episodes, overall health and health conditions, and social service use. Second, we will use sequence analysis to identify distinct patterns of housing transitions. Third, we will perform convergent integration of the qualitative and quantitative data to assess how contextual characteristics, including mood, activity space size, social support, medication adherence, and usage of health services, are related to housing transition patterns. Fourth, we will use mixed effects regression models to assess how daily changes in contextual characteristics are associated with daily experiences of housing stability (and major health events).

Ethical Considerations

Ethical approval was given by the VA Bedford Institutional Review Board (1626836-16), in accordance with VA guidelines. Written informed consent will be sought from all participants. Phase 1 participants will be provided written informed consent and will receive up to US $185 reimbursement over the course of the study (US $25 for the baseline, follow-up, and long interviews and US $10 for each brief interview). Phase 2 participants will receive US $25 upon completion of their focus group. Phase 3 participants will be offered US $30 for the baseline and follow-up interviews and US $5 per survey completed in the app for a possible total compensation of US $340. Study ID numbers will be assigned to participants to ensure confidentiality. We sought additional protections and obtained a federal Certificate of Confidentiality from the US National Institutes of Health because of the sensitive nature of the study discussions. Certificates of confidentiality protect the privacy of research subjects by prohibiting the disclosure of identifiable, sensitive research information to anyone not connected to the research except when the subject consents or in a few other specific situations. It is not possible to create a minimal data set with this qualitative data.

Results

The project was launched in June 2020, and as of December 2022, we had enrolled 10 participants for phase 1 and 9 participants for phase 2. Data collection and analysis for phases 1 and 2 are complete. This project is currently in progress.

Discussion

Principal Results

VEH are extremely vulnerable to experiencing housing transitions compared to their civilian counterparts [1,2]. A significant gap remains in research approaches to understanding the short-term precipitants and influences upon housing transitions. The use of smartphone apps can help fill the significant gaps in our knowledge, including, (1) the sequence of events leading up to and immediately after housing-related transitions; (2) information about the housing status of veterans not included in administrative systems, such as those who are living double-up or are street homeless; and (3) potential "early warning" signals gleaned from near-real–time reports of mood, activities, social support, and activity spaces (constructed from passively collected GPS data) that may presage increasing housing instability, a homelessness episode, or a major health event. This protocol paper details the specific phases and methods that will be used to develop and test a smartphone app to collect longitudinal data from VEH and to evaluate the feasibility and acceptability of using the app in a population that is unstably housed or homeless. This multiphased research will provide contextual knowledge on how in-the-moment experiences precipitate housing transitions from the perspective of VEH.

Furthermore, engaging participants from a range of housing situations—street homeless, transitional housing, residential treatment programs, and shelters—in the development of the smartphone app will allow us to capture what VEH thinks is significant to include in the app, thus enhancing its potential uptake [30,31]. To our knowledge, this will be the first test of active and passive smartphone-enabled data collection applied to the study of homelessness among veterans. At a minimum, the information gained from this project will lay the groundwork for enhancements to clinical programs that incorporate smartphone data for early intervention or use smartphone tools for 2-way communication between patients and clinical teams to improve care access and engagement for vulnerable populations.

Limitations

While our design methods during phases 1 and 2 will offer rich and nuanced insights to guide the content and design of the smartphone data collection app, there are a few limitations worth noting. First, there are usually difficulties in contacting and recruiting certain VEH, which could bias this study because we

may miss the most vulnerable and extreme cases. Thus, we will work closely with our staff at sites 1 and 2 to reduce selection bias. Second, VEH tends to report a lack of trust due to poor previous experiences with health care providers and mistrust of government institutions. We will try to establish a relationship of trust between the interviewer and VEH participants to obtain the most reliable data possible. Finally, although this will be an evaluation of VEH, our results may be applicable to non-VEH populations, contexts, and activities.

Conclusions

This multiphased study will provide rich data on the context and immediate events leading to housing transitions among VEH. This study will ensure the development of a smartphone app that will match the actual needs of VEH by involving them in the design process from the beginning. Finally, this study will offer important insights on how best to develop a smartphone app that can help intervene among VEH to reduce housing transitions.

Acknowledgments

Abstract

Background: Asian Americans with metastatic cancer are an understudied population. The Describing Asian American Well-Being and Needs in Cancer (DAWN) Study was designed to understand the supportive care needs of Chinese-, Vietnamese-, and Korean-descent (CVK) patients with metastatic cancer.

Objective: This study aims to present the DAWN Study protocol involving a primarily qualitative, convergent, mixed methods study from multiple perspectives (patients or survivors, caregivers, and health care professionals).

Methods: CVK Americans diagnosed with solid-tumor metastatic cancer and their caregivers were recruited nationwide through various means (registries, community outreach newsletters, newspapers, radio advertisements, etc). Potentially eligible individuals were screened and consented on the web or through a phone interview. The study survey and interview for patients or survivors and caregivers were provided in English, traditional/simplified Chinese and Cantonese/Mandarin, Vietnamese, and Korean, and examined factors related to facing metastatic cancer, including quality of life, cultural values, coping, and cancer-related symptoms. Community-based organizations assisted in recruiting participants, developing and translating study materials, and connecting the team to individuals for conducting interviews in Asian languages. Health care professionals who have experience working with CVK patients or survivors with metastatic solid cancer were recruited through referrals from the DAWN Study community advisory board and were interviewed to understand unmet supportive care needs.

Results: Recruitment began in November 2020; data collection was completed in October 2022. A total of 66 patients or survivors, 13 caregivers, and 15 health care professionals completed all portions of the study. We completed data management in December 2023 and will submit results for patients or survivors and caregivers to publication outlets in 2024.

Conclusions: Future findings related to this protocol will describe and understand the supportive care needs of CVK patients or survivors with metastatic cancer and will help develop culturally appropriate psychosocial interventions that target known predictors of unmet supportive care needs in Chinese, Vietnamese, and Korean Americans with metastatic cancer.

KEYWORDS

Asian American; disparities; metastatic cancer; psychosocial; supportive care; unmet needs; well-being

Introduction

Overview

Cancer is the leading cause of death for Asian Americans, the fastest-growing US immigrant group projected to outnumber Hispanic or Latinx immigrants by 2065 [1]. However, only 0.17% of the National Institutes of Health (NIH)–funded clinical research studies have involved Asian American, Native Hawaiian, and Pacific Islander participants (1992-2018) [2], and other foundational funding sources show a similar disparity for Asian Americans [3]. Of the many mental and physical health topics requiring further investigation [3], metastatic cancer survivorship is a significant priority given that Asian Americans are often diagnosed with a distant stage of cancer [4] such as Chinese Americans and Korean Americans with later staged colorectal cancer [5,6]. While progress in treatments and earlier detection have improved cancer survival rates overall [7], metastatic disease remains the major cause of cancer mortality [8]. The provision of quality supportive care is needed for Asian Americans with metastatic cancer, yet very little is known about the needs and preferences of this population. While the National Cancer Institute has funded cancer survivorship science since 1996, a 2020 analysis of NIH-funded research in advanced or metastatic cancer survivorship reported no studies of Asian Americans with metastatic cancer, and past survivorship research typically focused on survivors without detectable disease or active treatment [9,10]. Moreover, Asian-heritage cancer survivors are more likely to experience care-quality disparities [11], with those who are foreign-born especially likely to report unmet supportive needs after controlling for demographic and socioeconomic factors, health system and health care access, and comorbidities [12].

Psychosocial care needs are particularly important to evaluate, as the highest level of psychosocial distress is found in patients with advanced stages of disease [13]. These include anxiety, depression, death anxiety, demoralization, and a perceived inability to cope effectively, which can result in poor quality of life and premature mortality [14,15]. Patients with metastatic cancer have different needs, goals, and physical and psychosocial symptoms compared to patients with earlier-stage cancer, with individuals with metastatic cancer facing greater uncertainty about their prognosis and fear of disease progression [10,16,17]. Evidence suggests early supportive care needs (ie, after diagnosis in active treatment) should also be examined, as it can result in better quality of life and a reduction in functionally impairing symptoms [18].

Chinese-, Vietnamese-, and Korean-descent (CVK) Americans experience greater cancer-specific mortality in contrast to other Asian ethnic groups [19-22] and likely experience difficulties accessing high-quality care due to 46%-60% reporting limited English proficiency [23]. Very little is known about CVK Americans' metastatic cancer survivorship and how similarities in philosophical traditions, values, and norms may guide distinct views about what is optimal for supportive care in metastatic cancer (eg, Confucian-heritage–based interdependent norms for East and Southeast Asian ethnic groups [24,25]). For example, Confucian-heritage individuals' self-concept often includes close others [26,27] and CVK patients' supportive care needs may be influenced by social harmony-based expectations such as self-sacrifice amid profound stress [28,29] or preferring indirect support [30] to minimize direct discussion of stigmatizing subjects such as cancer [31-33]. Supportive interventions or resources that allow for a reduction in directly verbalizing distress may be preferred (eg, writing [34] or use of web-based or social chat platforms [35]). As such, this generative study aimed to produce an initial glance at the supportive care needs and preferences of CVK patients or survivors. Multiple perspectives were sought as cancer survivorship care is coordinated across multiple levels, including close interpersonal relationships, health care organizational settings, and community settings [36]. This protocol outlines the multilevel assessment undertaken through multiple informants and study components.

Objectives

This study aims to present an embedded mixed methods study protocol for examining the supportive care needs and preferences of CVK patients or survivors with metastatic cancer through multiple informants (patients, caregivers, and health care professionals). To our knowledge, this is the first multiperspective study focused on Asian American metastatic cancer survivorship. This protocol will allow for an understanding of the components of the study, and findings from this study will refer to this protocol to showcase how community-engaged collaboration aided the development of culturally relevant, adapted psychosocial interventions or resources targeting known predictors of continued unmet supportive care needs.

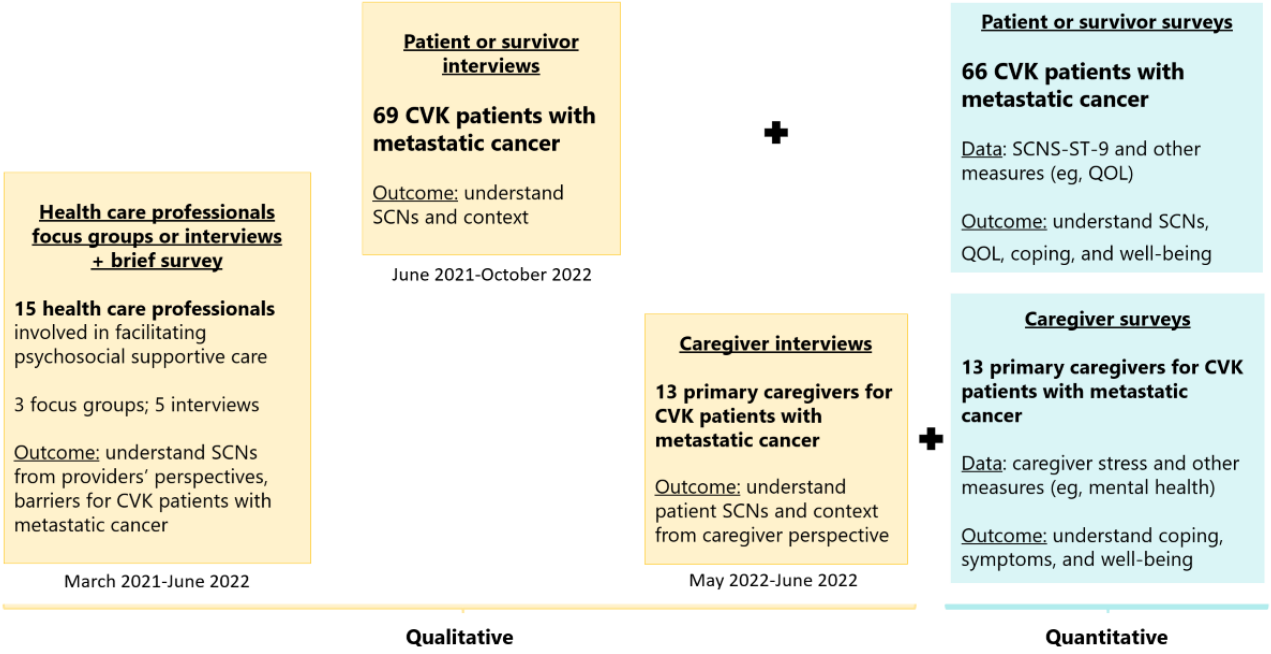
Methods

Overview

We conducted a qualitative (QUAL) and quantitative (quan) convergent mixed methods study on supportive care needs with CVK survivors living in the United States and diagnosed with solid-tumor metastatic cancer (Figure 1). A convergent mixed methods design was selected to provide a rich description of supportive care needs, including any similarities or discrepancies in self-reporting through interview or survey assessment. The strength of a convergent design is its ability to collect both qualitative and quantitative data simultaneously and promptly, which fits well with the generative "snapshot" purpose of this study given the lack of knowledge about conducting research with this understudied population diagnosed with stage IV cancer. With guidance from a qualitative expert (coauthor MKS), the qualitative portion was prioritized to engage an understudied population of cancer survivors who may face cancer-related stigma due to cultural beliefs about cancer. We invited survivors' caregivers to provide their perspective on survivors' supportive care needs through interviews. Health

care professionals' perspectives on the supportive care needs of CVK metastatic cancer patients or survivors and their families were also examined qualitatively. All study materials were matched to participants' language preferences in English, traditional Chinese, simplified Chinese, Vietnamese, and Korean.

Figure 1. Convergent mixed methods design and timeline. CVK: Chinese-, Vietnamese-, and Korean-descent; QOL: quality of life; SCN: supportive care need; SCNS-ST-9: Supportive Care Needs Survey-Screening Tool.



Participants

The study population included CVK individuals with solid-tumor metastatic cancer and caregivers (aged ≥18 years) living in the United States. Patients or survivors and caregivers were primarily recruited through partnered community outreach and supplemented by the University of California, San Francisco CARE (Collaborative Approach for Asian Americans, Native Hawaiians, and Pacific Islanders Research and Education) Registry and the University of California, Los Angeles (UCLA) Cancer Registry. Trained bilingual research assistants who speak English and Chinese (Mandarin or Cantonese), Vietnamese, or Korean called potential patient or survivor and caregiver participants to introduce and explain the study, screen for eligibility, and obtain consent for participation. Patient or survivor and caregiver participants received a US $90 e–gift card upon completing all parts of the study (brief demographic questions, interview, and survey). Patient or survivor participants who started the study but were unable to complete it, or declined to further participate for health reasons were also sent US $90 e–gift cards for their efforts. Health care professionals received a US $100 e–gift card upon completing the study.

Eligibility Criteria

The inclusion criteria for patients or survivors were (1) individuals diagnosed with de novo or recurrent, stage IV, solid tumor metastatic cancer; (2) self-identifying as Chinese, Vietnamese, or Korean and fluent in English, Korean, Cantonese, Mandarin, or Vietnamese; (3) aged 18 years or older; and (4) living in the United States. The inclusion criteria for caregivers were (1) individuals who self-identified or were patient- or survivor-identified as the primary caregiver (a close relative, friend, or partner who is doing most of the work to help take care of daily activities or medical care) for a person diagnosed with de novo or recurrent solid tumor metastatic cancer; (2) aged 18 years or older; and (3) living in the United States. If any patient or survivor or caregiver reported a diagnosis of schizophrenia or bipolar disorder, post hoc exclusion was to be considered based on any evidence of cognitive impairment presented to the research team during interactions or interviews. Health care professionals were eligible if they (1) were involved in facilitating patients' connection to or providing supportive care; (2) have been practicing at their medical or health center-related organization for 6 months or more; and (3) regularly worked with or have worked with at least 2 Chinese, Vietnamese, or Korean American patients with metastatic cancer.

Recruitment

Patient or survivor participants were initially recruited from the Greater Los Angeles Area and Orange County in Southern California. Recruitment was expanded nationwide due to limitations in reach and access resulting from the study being conducted during the height of the COVID-19 pandemic. Advertising and community outreach were focused on locations with a greater presence of Chinese, Vietnamese, and Korean communities (Los Angeles-San Gabriel Valley region, San Francisco Bay Area region, Buena Park, La Palma, Little Saigon area in Orange County, Irvine, Houston, Seattle, New York, etc). A majority of participants were recruited through flyers and community outreach (community organizations, churches, temples, libraries, community centers, senior centers, and ethnic supermarkets), physician referrals, doctor's offices, hospices, coverage on ethnic television, radio, or newspapers, social media

(Facebook and Instagram), and word-of-mouth. Partner community organizations (Chinese American Coalition for Compassionate Care [CACCC] 美華慈心關懷聯盟 and the Vietnamese American Cancer Foundation [VACF] H i Ung Th Vi t M) helped increase word-of-mouth recruitment by using their websites, social media, and radio broadcasts to publicize the research. VACF lay navigators actively distributed study flyers with their community during the organization's events, such as the drive-by COVID-19 relief resource distribution. Participants were also later recruited through the University of California, San Francisco CARE Registry and the UCLA Cancer Registry when open to non-COVID-19 research. Recruitment efforts for caregivers began with paired dyads for more focused qualitative synthesis; thus, we first recruited through patient or survivor participants who identified their primary caregivers and gave assent for contact. Following this, the research team sought to recruit caregivers unpaired with patient or survivor study participants.

Health care professionals were recruited through the Describing Asian American Well-Being and Needs in Cancer (DAWN) Study community advisory board members' referrals of those who may best understand the supportive care needs of CVK adults with metastatic cancer, based mostly in Southern California.

Analysis Plan

The patient or survivor and caregiver interviews were transcribed in English, Mandarin, Cantonese, Korean, and Vietnamese. Asian language transcripts were translated, and English transcripts will be analyzed. The health care professional interviews and focus groups were transcribed in English. All transcription and translation work was reviewed and corrected by the multilingual research team. All qualitative data will be examined for thematic content with reflexive thematic analysis [37,38]. Reflexive thematic analysis is a theoretically flexible approach that allows for the presentation of shared meaning in data by emphasizing researcher reflexivity as a key process in the analysis and acknowledging that the findings are embedded in this context [37,38]. Self-reflexivity will be emphasized before and throughout the analysis and interpretation. Coders and the principal investigator (JHJK) will discuss the influence of their backgrounds and preconceptions and keep memos for a record of analysis and interpretations. As the lead investigator (JHJK) approaches research with a critical realist framework and is a clinical psychologist with knowledge of mental health service use disparities, cultural variations in symptomatology and coping, and stressors faced by immigrant families, findings are likely to be influenced by this perspective.

The research team will first familiarize themselves with the data through independent reading of the interview transcripts and generate initial codes and candidate themes to engage in reflexive thematic analysis. Inductive "bottom-up" coding will be completed first for a full description of participants' perspectives and experiences. Then, deductive "top-down" coding will be performed centered on the research question and any relevant supportive oncology concepts of additional significance. Themes will be reviewed and refined to best represent participant perspectives. Seeking saturation and minimum sample sizes is not compatible with reflexive thematic analysis, and our sampling was pragmatic and acceptable within reflexive thematic analysis (ie, the research team sought to conduct as many qualitative data collections as possible during the project period). Self-reported supportive care needs, demographics, and medical variables will also be summarized with univariate statistics. Chi-square tests will examine any differences in supportive care needs (eg, US- or foreign-born). Joint display results will be produced for the supportive care needs described by CVK patients or survivors. For the health care professionals' parallel-format focus group and interview data, candidate themes were compared across the focus group data and interview data to arrive at final themes.

Data Management and Confidentiality

When participants enrolled in the study, they were assigned a random study ID number to label self-report and interview data. Self-report and interview data were further deidentified. Any potentially identifying records are kept password-protected on a secure server. All analyses will be reported as aggregate data or in an anonymized format for qualitative excerpts.

Data Collection Overview

Patients or Survivors and Caregivers

After obtaining consent, self-reported demographic information (eg, age, sex, ethnicity, education level, income, length of US residency, language use, religion, employment status, insurance status, and subjective social status captured using the community version of the MacArthur Scale of Subjective Social Status [39]), acculturation level (from the Brief Acculturation Scale for Hispanics [40]), and cancer history (eg, type of metastatic cancer, diagnosis date, and treatments) were collected by telephone immediately following the screening call or at another scheduled time. Following the demographic and cancer history questions call, participants were scheduled for a 1-1.5-hour interview over telephone or videoconference through Zoom (Zoom Video Communications). When scheduling and sending reminders for the interview, participants were asked to secure a private location where they could speak freely and confidentially, in addition to a suggestion to use headphones for added privacy. Participants' privacy and comfort with their interview location were confirmed before beginning the interview. In the rare circumstance that the participant needed another location for continued privacy for the interview, participants were offered a break period or to reschedule to continue the interview in a confidential manner. After the interview, participants completed a 30-minute survey on paper or a web-based survey within 1 week of the interview. All participants were encouraged to complete their survey on the same day as the interview, in one sitting, if possible, within 1 week from the interview date. They were reminded to complete the survey through their preferred method of communication. Participants with lower literacy were supported by trained bilingual research assistants over the phone. Caregivers underwent the same study process as patients or survivors (brief demographic questions through phone, 1-hour interview, and 30-minute survey).

Health Care Professionals

Health care professionals were provided study information sheets with the opportunity to ask questions about eligibility before scheduling the 1-hour focus groups or interviews led in English by the principal investigator. Focus groups and parallel key informant interviews took place over Zoom. Focus groups were composed of a minimum of 3 health care professionals to allow for greater depth of responses from each participant attending the focus group, as well as to accommodate scheduling restrictions imposed by their COVID-19 workload. The three focus group compositions were balanced out as much as possible: (1) social worker, bilingual radiation oncologist, and bilingual medical oncologist; (2) social worker, bilingual medical oncologist, and medical oncologist; and (3) chaplain, bilingual hematology oncologist, hematology oncologist, and bilingual medical oncologist. Following the focus groups, parallel-format key informant interviews were the only feasible way to gain additional perspectives due to time limitations from health care professionals' COVID-19 workload—this alternate participation option was pursued when health care professionals could not otherwise participate in the focus groups. In reminders before the interview, participants were asked to secure a private location where they could speak freely and confidentially and were suggested to use headphones for added privacy. Before beginning each focus group or interview, health care professionals confirmed their eligibility and provided oral or web-based survey consent. They also confirmed privacy and comfort with their location of remote participation. The demographics of health care professionals were collected before the interviews through a brief demographic questionnaire on the web. Self-reported demographic information includes age; profession; sex; ethnicity; years since clinical licensure; years since obtaining an MD degree; hospital or clinic affiliation; months employed at the institution, hospital, or clinic; if bilingual in Chinese, Vietnamese, or Korean and if using the endorsed language in clinical practice; years working with patients with metastatic cancer; the number of CVK patients with metastatic cancer seen in the past month and per month before COVID-19; and level of comfort caring for CVK patients with metastatic cancer.

Semistructured Guides for Qualitative Data

Patients or Survivors and Caregivers

All interviews were conducted using semistructured topic guides. Interviews were conducted in English, Chinese (Cantonese or Mandarin), Vietnamese, and Korean by language-matched, trained interviewers and the principal investigator. Interviews lasted 60-90 minutes for both the patients or survivors and their caregivers. Interviews took place through Zoom or telephone calls and were audio-recorded with participants' permission. The main research question domains for patients or survivors and caregivers were (1) cultural influence on coping, needs, and preferences; (2) cultural fit and adequacy of existing or offered supportive care after diagnosis; (3) unmet supportive care needs (physical vs emotional priorities); and (4) psychosocial intervention or resource preferences (modality and timing). Supportive care needs explored included informational, patient care support, daily living, physical, psychological, or emotional, as well as how people's social lives (interpersonal relationships, marriage, sexuality, and spirituality) were affected. Caregivers were asked to provide information regarding their own experiences as well as the patient's or survivor's experiences in these domains and their insights about patients' or survivors' needs. Caregivers were also asked about how their relationship with the patient or survivor had changed or stayed the same if they were married or in a committed relationship. In the fourth domain, participants were asked to rank potential psychosocial interventions based on perceived helpfulness for patients or survivors with metastatic cancer of their ethnicity: writing privately, a website or blog for close family or friends, social media with close family or friends, peer education or support, and professionally trained counseling. Images representing each type of intervention were provided for participants to reference during the interview. For interviews in which participants mentioned end-of-life or openness about mortality, and time permitting, patients or survivors were shown an image of CACCC's Heart to Heart Café cards to ask for their thoughts regarding a culturally based intervention for end-of-life discussions with family or friends. This last intervention image was presented in a tailored manner for each individual because of ethical concerns raised by community and scientific advisors given the known stigma and taboo related to the end of life in Asian cultures [31], the limited scope of the project, and the lack of culturally and linguistically matched supportive or counseling resources available to all participants.

Health Care Professionals

A semistructured interview guide was developed and used for the focus groups and interviews in English. All participants were asked the same questions per the interview guide by the same facilitator. Domains of inquiry included (1) any difference in care provided for CVK patients with metastatic cancer; (2) challenging scenarios for CVK patients with metastatic cancer; (3) health care professionals' perceptions of the most important unmet supportive care needs, barriers to meeting those unmet needs, and potential solutions; and (4) the type of supportive care that would be most helpful and culturally appropriate. Focus group participants were scheduled for an individual follow-up interview if there were any comments to probe for additional clarifying information. Focus group participants' thoughts were shared with parallel-format individual interview participants, as appropriate, to elicit their reactions and thoughts as would occur if they had participated in a focus group.

Survey Measures for Quantitative Data

Overview

All measures for the study were provided in English, Chinese (traditional or simplified), Vietnamese, or Korean. If not already available or needing wording modification, simplified and traditional Chinese, Vietnamese, and Korean versions of measures were developed using a rigorous translation methodology. A total of 2 independent forward translations, 1 independent back translation, and reconciliations of translations were completed with feedback from community partner organization representatives and bilingual research team members from each language group. Feedback from the Chinese,

Vietnamese, and Korean community organization representatives included identifying the best phrasings for the United States context while maintaining the meaning of the original English measure. If not in the public domain, permission was obtained from the measure authors.

Patients or Survivors

The primary survey for a convergent mixed methods examination of patients or survivors with metastatic cancer's supportive care needs was measured by the Supportive Care Needs Survey-Screening Tool [41]. The Functional Assessment of Cancer Therapy General-7 measure was used to assess quality of life [42]. Participants' other patient-reported outcomes were assessed with the National Comprehensive Cancer Network distress thermometer [43], an 8-item Patient Health Questionnaire Depression Scale for depression [44], Generalized Anxiety Disorder Scale for anxiety [45], the Multidimensional Fatigue Symptom Inventory-Short Form physical subscale for fatigue [46], the 6-item Impact of Event Scale for cancer-specific traumatic stress [47], the pain intensity, enjoyment of life, general activity 3-item scale for pain assessment [48], and the 2-item Sleep Condition Indicator for sleep disturbance [49]. Considering the importance of coping in determining quality of life and other patient-reported outcomes, coping was evaluated using the Brief Coping Orientation to Problems Experienced Inventory [50] and the Emotional Approach Coping Scales (emotional processing and emotional expression) [51]. The Mental Health Continuum Short Form examined well-being [52], and other resilience factors were examined with the Gratitude Questionnaire-6 [53], the mindfulness subscale of the Self-Compassion Scale [54], the preparedness subscale of the Quality of Life at the End of Life-Cancer measure [55], the UCLA 3-Item Loneliness Scale [56], and the Social Provisions Scale [57].

We also measured additional exploratory concepts related to cultural factors that may affect supportive care needs and quality of life among CVK adults with metastatic cancer. The Asian American Values Scale was modified as a brief 9-item pilot version to assess how much participants valued family collectivism, conformity to norms, and emotional self-control [58], alongside the harmony subscale of the Brief Collectivism Questionnaire [59]. Other culturally relevant concepts measured include ambivalence of emotional expression with the 4-item Ambivalence Over Emotional Expressiveness Questionnaire [60], internalized metastatic cancer-related stigma (modified Lung Cancer Stigma Inventory subscale) [61], self-perceived burden upon others [32,62], the patient's level of sacrifice for their family using a modified Sacrifice for Close Others Scale [63], and a question about lifetime experience of personal or sociopolitical trauma. All measures were completed in one survey assessment after the interview.

Caregivers

Caregivers filled out the same surveys as patients or survivors for cancer-related coping, mental and physical health symptoms, resilience factors such as gratitude, and cultural values. Additionally, their caregiving relationship was measured with the 4-item Quality of Caregiver-Care Recipient Relationship [64,65] and caregiving stress was measured with the Caregiver Intrapsychic Stress and Strain Scales [66]. All measures were completed in one survey assessment after the interview.

Partnered Community Involvement

The study was conducted in collaboration with community organizations that were cultural and community-based advisors for the research and supported all nonengaged aspects of the study such as prioritizing research questions, informing the design of the study including participant eligibility criteria, recommending culturally relevant concepts to assess (eg, stigma or burden), translating study materials, reviewing the ethics of the research procedures, supporting recruitment efforts, and recommending bilingual research assistant candidates for interviewing participants. The CACCC (美華慈心關懷聯盟) is a coalition in Cupertino, California that addresses issues related to serious illnesses in the Chinese American community and partnered for the Chinese portion of the study. The VACF (H i Ung Th Vi t M) in Orange County, California is an organization that provides cancer education, resources, and services and is involved in research and advocacy for cancer prevention to improve quality of life and outcomes in the Vietnamese community and partnered for the Vietnamese portion of the study. The DAWN Study community advisory board comprising multidisciplinary health care professionals (psychology, oncology, palliative care, or public health), patient advocates, and community-based organizational representatives, also contributed to the development and conduct of the study through quarterly meetings. For example, the eligibility criteria for all participants were informed through community advisory board discussions, with the minimal length of employment for health care professionals set at 6 months for the health care professional to have had time to adjust to their health care system and be able to provide an "insider" perspective. The community advisory board included at least one bilingual representative with cultural knowledge relevant to CVK patients and their families.

Ethical Considerations

Institutional review board approval was obtained from UCLA (20-001554) and the University of California, Irvine (1541;2391). Oral or web-based informed consent was obtained from all participants in this study. Nonregistry-based patient or survivor participants completed a web-based screening and consent form, or expressed interest through email or phone and oral consent was obtained over the phone by trained research assistants. Registry-based patient or survivor participants received a letter or email with the study information sheet and a postage-paid postcard to indicate their interest. Research team members followed up with all potentially eligible registry-based patients or survivors to complete the screening and oral consent by phone if participants had not completed the web-based screening and consent on their own. For all participants who consented through a web-based survey, we ensured informed consent by verbally reconfirming an understanding of the purpose of the study, what participation entails, and rights as participants at the beginning of the first portion of the study.

Results

The study was funded for 2 years, from June 2020 to June 2022, by the NIH-National Cancer Institute with supplement funding from the UCLA Institute of American Cultures and Asian American Studies Center. Recruitment began in November 2020, and data collection was completed in October 2022. A total of 74 patients or survivors enrolled in the study from various US states (66 from California, 3 from Texas, 2 from Washington, 1 from Delaware, 1 from Nevada, and 1 from Connecticut); 69 patients or survivors completed the interview, and 66 patients or survivors completed both the interview and survey. A total of 13 caregivers enrolled in the study (12 from California and 1 from Washington) and completed all portions of the study. All 13 caregivers were linked with a patient or survivor participant in the study; no unlinked caregivers joined the study. A total of 15 health care professionals enrolled in the study, resulting in 3 focus groups and 5 parallel-format interviews. No post hoc exclusions were necessary. We completed the remaining data management in December 2023. A manuscript on health care professionals has been accepted, and manuscripts for convergent mixed method results for patients' or survivors' supportive care needs and caregiver perspectives will be submitted in 2024.

Discussion

This study is one of the first to examine the unmet supportive care needs of Asian Americans with metastatic cancer through interviewing patients or survivors, caregivers, and health care professionals for a more comprehensive understanding, using culturally and linguistically appropriate study materials and community-based participatory research principles. The perspectives of interested parties, which include patients or survivors, caregivers, community members, and health care professionals, will help advocate for this understudied population and inform the next steps to develop, test, and disseminate supportive care resources and interventions that are culturally relevant. By studying adults from Confucian-heritage cultures, this study may uncover cultural factors to be considered in the provision of supportive care. However, given the focus on only CVK adults, the results of this study may not apply to other Asian ethnicities that do not share a Confucian heritage. This research design may be adaptable for other understudied Asian Americans with metastatic cancer to facilitate quality care and intervention development.

Strengths of this study include the involvement of the community through their active participation from the design of the study to the analysis, interpretation, and dissemination of results. Multidisciplinary community advisors who closely work with metastatic cancer survivors and community-based organizations shaped the study to be more culturally appropriate. All steps of the research were available in English, Chinese, Vietnamese, and Korean, and the study was designed to be flexible around participants' schedules (including evenings and weekends) and remove the burden of transportation by being remote.

Challenges encountered in this study include technological and logistical difficulties in offering multiple modalities for participation. Considering that some participants had limited familiarity with technology such as Zoom and SMS text messaging and relied on telephone calls, it was challenging, at times, to connect with individuals to complete every part of the study. Another challenge faced was during the recruitment process, as some participants did not know the staging of their cancer. Diagnoses needed to be clarified through caregivers or with detailed follow-up questions about where the cancer had spread. Though every effort was made to ensure privacy, confidentiality, and independence in participant interviews, one patient strongly preferred that their caregiver be present. Given the patient's physical supportive needs and sporadic difficulty with speech due to cancer, this patient's decision was honored. An explanatory discussion of the research process ensured understanding from both the patient and caregiver that interview and survey responses should be the patient's most direct and honest thoughts. We included this dyad in the study as they were otherwise eligible, and it was deemed the most ethical route per community advisors' recommendations. Lastly, due to COVID-19, opportunities to establish community-based relationships in person were unavailable, and future research participation may be even more plentiful with such efforts. In particular, partnering with locally based community-based organizations and research registries outside of California will be key to reaching a broader US sample, as the majority of the participants in this study were from California.

Acknowledgments

We are grateful to the DAWN Study participants, community advisory board, community organizations, and ethnic media outlets who shared study information broadly. We also thank our community-based interviewers, Sara Kim for translation contributions and Hung Duong for printing service contributions. The research reported in this publication was supported by the National Cancer Institute (K99CA246058), the University of California, Los Angeles Institute of American Cultures and Asian American Studies Center, the National Center for Advancing Translational Science under the University of California, Los Angeles Clinical and Translational Science Institute (UL1TR001881), and the National Institute on Aging (R24AG063718) through the University of California, San Francisco CARE Registry. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Data Availability

The data sets generated during this study are not publicly available. The original consent for study participants did not state such an intention to share the data publicly with others outside of the research team, and some participants are no longer reachable for a reconsent procedure. Confidentiality of participants is of utmost priority, and upon review of the data, there is a possibility that, with known collaborators on this project, demographic characteristics, diagnostic information, interview response patterns, and details, in combination, could make participants recognizable to others in the smaller Asian American network serving metastatic cancer patients or survivors, to participants' health care providers, or to participants' colleagues. Therefore, only restricted data reviews may be discussed with the corresponding author upon reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: Respiratory diseases, including active tuberculosis (TB), asthma, and chronic obstructive pulmonary disease (COPD), constitute substantial global health challenges, necessitating timely and accurate diagnosis for effective treatment and management.

Objective: This research seeks to develop and evaluate a noninvasive user-friendly artificial intelligence (AI)–powered cough audio classifier for detecting these respiratory conditions in rural Tanzania.

Methods: This is a nonexperimental cross-sectional research with the primary objective of collection and analysis of cough sounds from patients with active TB, asthma, and COPD in outpatient clinics to generate and evaluate a noninvasive cough audio classifier. Specialized cough sound recording devices, designed to be nonintrusive and user-friendly, will facilitate the collection of diverse cough sound samples from patients attending outpatient clinics in 20 health care facilities in the Shinyanga region. The collected cough sound data will undergo rigorous analysis, using advanced AI signal processing and machine learning techniques. By comparing acoustic features and patterns associated with TB, asthma, and COPD, a robust algorithm capable of automated disease discrimination will be generated facilitating the development of a smartphone-based cough sound classifier. The classifier will be evaluated against the calculated reference standards including clinical assessments, sputum smear, GeneXpert, chest x-ray, culture and sensitivity, spirometry and peak expiratory flow, and sensitivity and predictive values.

Results: This research represents a vital step toward enhancing the diagnostic capabilities available in outpatient clinics, with the potential to revolutionize the field of respiratory disease diagnosis. Findings from the 4 phases of the study will be presented as descriptions supported by relevant images, tables, and figures. The anticipated outcome of this research is the creation of a reliable, noninvasive diagnostic cough classifier that empowers health care professionals and patients themselves to identify and differentiate these respiratory diseases based on cough sound patterns.

Conclusions: Cough sound classifiers use advanced technology for early detection and management of respiratory conditions, offering a less invasive and more efficient alternative to traditional diagnostics. This technology promises to ease public health burdens, improve patient outcomes, and enhance health care access in under-resourced areas, potentially transforming respiratory disease management globally.

Introduction

Respiratory diseases impose a significant burden on individuals, communities, and health care systems worldwide. These conditions, which encompass a wide range of disorders such as tuberculosis (TB), asthma, chronic obstructive pulmonary disease (COPD), and lung cancer, not only diminish the quality of life for affected individuals but also lead to substantial economic and health care costs particularly in low- and middle-income countries [1]. Patients with respiratory diseases often struggle with symptoms like coughing, shortness of breath, and chest pain, which can limit their ability to perform daily activities and enjoy a normal life [1,2]. The burden of respiratory diseases extends beyond the physical aspect, as they are frequently associated with emotional distress and psychological challenges, contributing to diminished overall well-being for patients and their families.

From a public health perspective, respiratory diseases account for a significant portion of global morbidity and mortality. The World Health Organization (WHO) reports that respiratory infections alone are responsible for millions of deaths each year, particularly affecting vulnerable populations such as children, the elderly, and individuals with compromised immune systems [3,4]. Moreover, the economic costs associated with respiratory diseases are staggering, encompassing medical expenses lost productivity due to illness, and the burden on health care systems. For instance, the total spending across all respiratory conditions increased by US $71.7 billion in the United States by 2016 from 170.8 billion in 1996 with asthma and COPD contributing US $35.5 billion and US $34.3 billion, respectively, of the total increase [3]. TB, asthma, and COPD are said to be common and rising public health burdens in Africa [5]. Preventive measures such as smoking cessation, improved air quality and vaccination are critical to alleviating this burden, as they can reduce the incidence and severity of respiratory diseases and ultimately improve the overall health and well-being of populations around the world [3]. However, respiratory diseases are relatively neglected in sub-Saharan Africa with no tangible public health programs to address them [5,6]. Consequently, the provision of health care for respiratory diseases appears suboptimal and this was further compromised by the COVID-19 pandemic [5].

Taking TB as an example, the WHO continues to emphasize the need for early detection as a strategic approach for reducing the risk of transmitting the disease to others, improving health outcomes, and reducing distress and economic hardship at the family level [7,8]. Much emphasis is now placed on user-friendly, inexpensive, and contextually feasible diagnostic tools that can effectively identify people who probably have active TB [7,8]. Consequently, countries like Tanzania have started incorporating some of the WHO recommendations about using new user-friendly digital techniques for managing TB into their policies. However, due to the need for improved quality of health care workers with essential knowledge and skills, real adoption of such technologies is still less than intended.

The emergence of the COVID-19 pandemic profoundly impacted the diagnosis and management of other respiratory diseases. With health care systems overwhelmed by the surge in COVID-19 cases, resources, personnel, and laboratory capacities were often diverted away from routine health care services, including the diagnosis of respiratory conditions such as TB, asthma, and COPD [5]. For example, most guidelines recommended limiting the use of pulmonary function tests for fear of transmission of COVID-19 which constrained the use of spirometry testing further compromising the diagnosis of chronic respiratory diseases [9]. Furthermore, the fear of contracting COVID-19 in health care settings led many individuals to postpone or avoid seeking medical care for respiratory symptoms, resulting in delayed diagnoses and exacerbation of preexisting conditions [5]. Diagnostic tests and imaging equipment were sometimes repurposed for COVID-19 testing, leaving fewer resources available for the timely detection of other respiratory ailments. As a result, there has been a concerning backlog in the diagnosis of respiratory diseases, potentially leading to worsened health outcomes and increased burden on health care systems as they work to catch up on missed diagnoses and treatments.

One promising avenue for improving the diagnosis of respiratory diseases is the analysis of cough sounds, which can carry valuable information about the underlying respiratory condition. Most importantly, the recent developments in artificial intelligence (AI) and machine learning (ML) have heightened the need for the application of these powerful tools in the diagnosis of respiratory diseases, particularly, through the development of cough sound classifiers [10,11]. These sophisticated algorithms have the capacity to analyze and interpret patterns within cough sounds, providing valuable insights into a patient's respiratory health [10-17]. By training AI models on large data sets of cough audio recordings from both healthy individuals and those with respiratory conditions such as TB, asthma, or COPD, it becomes possible to identify distinctive acoustic signatures associated with different diseases [12-17]. These AI-driven cough classifiers can discern subtle variations in cough frequency, duration, intensity, and spectral characteristics, enabling early and accurate disease detection [12-17]. A good example of how AI and ML have been proven useful is the documentation of their effectiveness in Western countries toward the detection of TB [12], COVID-19 [13,14], asthma, COPD [15,16], and even pertussis [17] and their values have extended beyond sound classification to interpreting and analysis of medical imaging for TB detection [18,19]. Moreover, the noninvasive nature of cough audio analysis makes it a convenient and cost-effective diagnostic tool, particularly in resource-constrained settings [12-17]. Patients can record their cough sounds using smartphones or dedicated devices, and these

recordings can then be processed by AI algorithms for rapid assessment [20-22]. The potential for remote monitoring is especially valuable in the context of respiratory diseases, as it allows for continuous tracking of a patient's condition and response to treatment.

Coughing is a common indication of respiratory illnesses, resulting from a forceful release of air from the air passages. Nevertheless, the impact of coughing on the respiratory system is recognized to be variable [23,24]. For instance, lung ailments can lead to either constriction or blockage of the airways, which can affect the sound characteristics of coughing [24]. Furthermore, it has been suggested that the glottis behaves differently under various pathological conditions, allowing for the differentiation of coughs associated with asthma, bronchitis, and pertussis [25]. As a result, the automatic classification of acoustic signals linked to cough to detect respiratory diseases like TB, asthma, and COPD seems to be a reasonable scholarly endeavor to pursue. Research suggests that conditions such as TB, asthma, and COPD exhibit specific temporal patterns and frequencies in coughing, which can be effectively analyzed with advanced technology [26,27].

As AI and ML continue to advance, the accuracy and precision of cough audio classifiers are expected to improve and may outperform standard tests enhancing their use in both clinical practice and public health initiatives. For example, a recent study in Europe indicated that the sensitivity and positive predictive value of the AI-based algorithm were superior to pulmonologist-based diagnostic category allocation in each of the 8 disease groups evaluated [28]. In essence, these technologies hold great promise in revolutionizing the way we diagnose and manage respiratory diseases, offering early intervention, personalized treatment, and improved patient outcomes. However, a major shortfall with the application of AI and ML is that they have not been fully exploited in cough audio classification in rural African contexts. Given the burgeoning interest in leveraging AI or ML for health care advancements, there is a critical need for empirical research to explore their potential applications in rural African settings. The gap in noninvasive, efficient diagnostic tools for respiratory diseases in low-income Africa necessitates urgent attention. This study aims to develop and assess an AI-powered cough audio classifier designed to detect respiratory conditions in rural Tanzania. Through a systematic approach to collecting and analyzing cough sounds in outpatient settings, this research aims to improve disease identification accuracy and efficiency, offering accessible, user-friendly diagnostic solutions to support health care providers in low-income areas.

Methods

Design

This is nonexperimental cross-sectional research with the primary objective of collection and analysis of cough sounds from patients with active TB, asthma, and COPD in outpatient clinics to generate and evaluate a noninvasive cough audio classifier. The study combines innovative applications of AI or ML to develop cough audio classifiers using data collected from patients with active diseases and evaluation of the classifiers in routine care against the reference standards. To achieve this, a four-phase research process will be implemented involving (1) cough sound collection for 12 months (phase 1), (2) cough sound analysis and algorithm development for 12 months (phase 2), (3) development of cough audio classifier for 6 months (phase 3), and (4) evaluation of cough audio classifier for 18 months (phase 4). The expected primary outcomes are contextualized user-friendly AI-powered cough audio classifier and a rate of patients with active respiratory diseases notified and linked to treatment. The expected secondary outcomes are health care workers' experience with a cough audio classifier, including perspectives on the acceptability, feasibility, and cost of using a cough audio classifier. The comparison of the cost incurred to implement the audio classifier will be compared to the standards of care. The feasibility indicators will include the perceived acceptability and satisfaction of health care providers and patients toward the cough audio classifier. Findings from this study will be useful in further refinement of the cough audio classifier and definitive trials in the broader community. The research will increase the pool of health experts with skills in the application of AI or ML developing diagnostic tests in Tanzania. It is expected that the cough audio classifier if found effective during future definitive trials, can be trademarked.

Settings

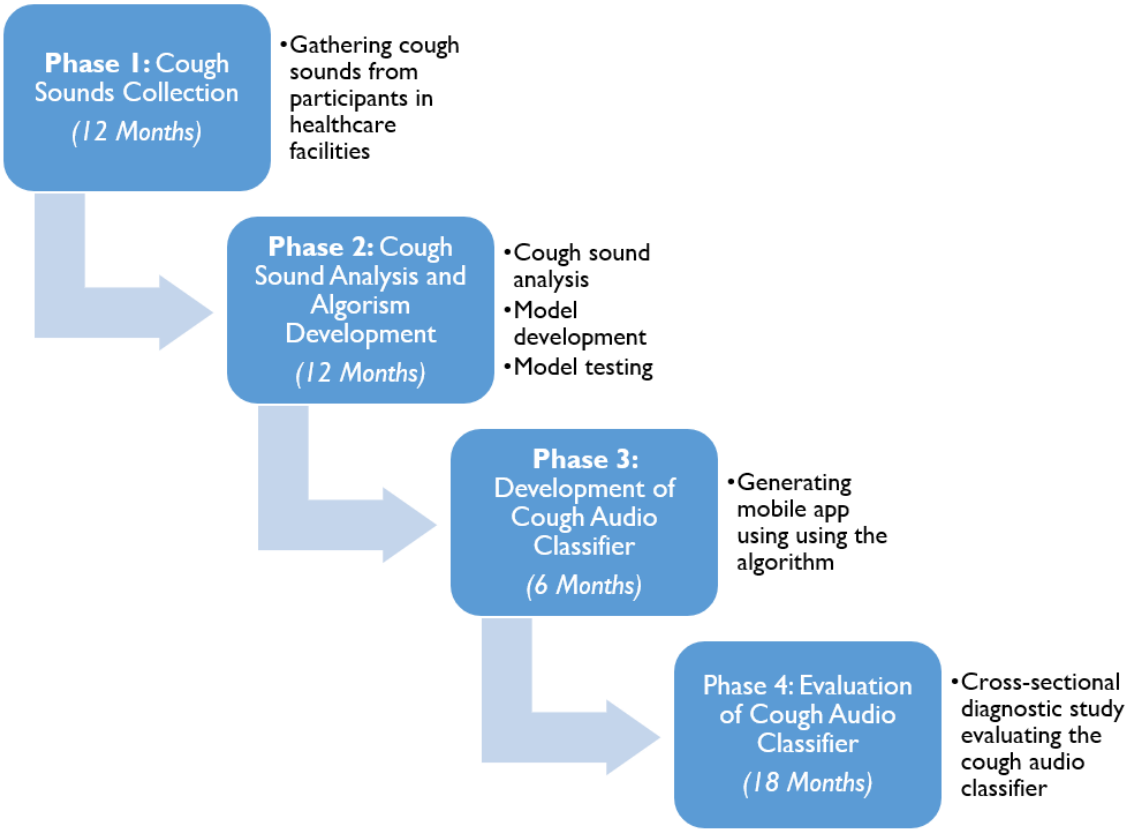
The study will take place across the Shinyanga Region of Tanzania. The Shinyanga Region, predominantly rural with less than 5% urban residency, is detailed further in my prior research [29,30]. More specifically, the study will be conducted in 30 facilities including Shinyanga Referral Hospital, Shinyanga Municipal Hospital, Shinyanga District Council Hospital, Kolandoto Hospital, Kahama Municipal Hospital, Jakaya Kikwete Hospital, Kishapu health centre (HC) Mwadui Hospital, Nindo Dispensary, Tinde HC, Samuye HC, Ngokoro HC, Kambarage HC, Imani Dispensary, Inspire Dispensary, Mwawaza Dispensary, Kizumbi Dispensary, Bubiki Dispensary, Polisi Dispensary, Lubaga Dispensary, Consolata Dispensary, Majengo Dispensary, Maganzo Dispensary, Mwamalili Dispensary, Mwamalili Dispensary, Golden Grace Dispensary, Masekelo Dispensary, Kanisa la Kiinjiri la Kilutheri Tanzania Lutheran Dispensary, Old Shinyanga Dispensary, and Chamaguha Dispensary. These sites are purposefully selected considering ownership (public, private, and faith-based organization), location (urban, peri-urban, and rural), level (hospital, health center, and dispensaries), and access to a wealthy number of clients presenting with coughs. The focus on rural settings stems from the commitment of the principal investigator (PI) to enhancing primary health care [29]; challenges in diagnosing TB, asthma, and COPD due to limited diagnostics; the value of co-designing [30] a cough audio classifier with rural inputs for cultural relevance; and Shinyanga's clear, low-noise environment for optimal cough sound recording.

Study Implementation

Overview

The study implementation is concisely illustrated in Figure 1. A concise summary is provided.

Figure 1. Study implementation framework.



Phase 1: Cough Sounds Collection (12 Months)

The procedures for cough sound collection are adapted from previous research in South Africa [12] considering local contexts. More specifically, cough sound data will be collected from health care facilities using specialized cough sound recording devices equipped with high-quality microphones in a dedicated cross-ventilated room. These devices will be nonintrusive and user-friendly, ensuring patient comfort and compliance. Patients with active TB, asthma, and COPD will be identified in the outpatient department (OPD) clinics and directed to the recording room. During the recording sessions, patients will be instructed to cough into the device several times, producing a diverse set of cough sounds. All audio recordings will be conducted by a health care provider, in selected health care facilities during regular clinic hours, who are trained to operate the recording device. The recording room will not be fitted with additional soundproof materials to mimic the clinical environment where the diagnostic procedures for patients with TB, asthma, and COPD are performed. A comprehensive summary of the audio sound capturing process is detailed in Multimedia Appendix 1 [11,12,31-36].

The research team will adhere to ethical guidelines and ensure the privacy and well-being of participants. The inclusion criteria for patients whose cough sounds will be collected include patients who are older than 18 years of age and with a clinical diagnosis of TB, asthma, or COPD diseases. The exclusion criteria will be patients who provide no consent and those unable to provide a cough sound. The decision to exclude children younger than 18 years of age from our study was driven by the extensive consent process required for minors, compounded by our limited resources. Additionally, previous research has highlighted challenges in collecting cough sounds from this demographic [37-39].

Phase 2: Cough Sound Analysis and Algorithm Development (12 Months)

Once the cough sound data are collected, advanced signal processing and ML techniques will be used to analyze and classify the cough sounds associated with each respiratory disease. By comparing the acoustic features and patterns among the 3 conditions (TB, asthma, and COPD), the study aims to develop a robust algorithm for automated disease discrimination. A proposed approach for audio classification is using TensorFlow applying Librosa software (Librosa Organization) described previously [11,40]. Librosa is an open-source Python package for music and audio analysis and can provide the data and the sampling rate which plays a vital role in audio classification since different sounds have different sample rates [40]. A comprehensive summary of the procedures for cough sound analysis, algorithm or model development, and testing has been summarized in Multimedia Appendix 2 [11,12,34,35,40-46].

The emerging model will be checked whether it correctly predicts the cough sounds. The expected outcome of this process is a reliable model that can assist the research team in developing a mobile app to help health care practitioners identify TB, asthma, and COPD based on cough sound patterns.

Phase 3: Development of Cough Audio Classifier (6 Months)

The developed models for TB, asthma, and COPD will need to be integrated into a noninvasive and user-friendly diagnostic tool. Under the guidance of developers, the development of a mobile app for TB, asthma, and COPD detection will involve the deployment of the developed models to Android with TensorFlow Lite [47]. The sample app will be cloned from GitHub, the sound classification Android app will be imported into Android Studio, and the model will be added (both the soundclassifier.tflite and labels.txt) into the src/main/assets folder replacing the example model that is already there and the app will be built and deployed on the Android device.

Phase 4: Evaluation of Cough Audio Classifier (18 Months)

This will be a cross-sectional diagnostic study evaluating the cough audio classifier for active TB, asthma, and COPD triage and case detection against the reference standards. Clients attending OPD clinics at rural health care facilities and suspected of having TB, asthma, and COPD as per national guidelines will be included in the study, upon written consent. Data will be collected from each of the participating facilities. The results of recorded cough using a cough audio classifier will be compared with the current standard of clinical assessment, spirometry, peak expiratory flow (PEF), GeneXpert, culture and sensitivity, chest x-rays (CXR), clinical assessment, and the specificity and predictive values will be calculated.

Study Design

The study will be a multicenter hospital-based validation cross-sectional diagnostic study evaluating the cough audio classifier for active TB, asthma, and COPD triage and case detection in routine care against the reference standards. This study will involve consecutively enrolled suspects who will be closely evaluated to define their illness. The diagnostic accuracy of automated smartphone-based cough audio will be compared among TB, asthma, and COPD cases and controls. Cases include participants who meet “Definite” or “Probable” TB, asthma, and COPD criteria. Controls include participants who presented with symptoms potentially suggestive of TB, asthma, and COPD, but were not started on treatment and had full clinical resolution at follow-up or had an alternative diagnosis confirmed.

Study Area

The evaluation study will be conducted in similar study settings and the 30 health care facilities in which cough sounds were collected in Shinyanga Region (phase 1).

Participants Recruitment

Patients attending OPD clinics and meeting all eligibility criteria listed in the eligibility criteria will be referred to the study’s research staff primarily by the treating medical officer or nurses during triage at OPD. Once enrolled, participants will be retained in the study by telephone reminders. Research assistants will call the participant to arrange follow-up visits and reminder calls will be placed prior to the expected follow-up visit appointments. If there is significant difficulty with participant retention, the possibility of using community health care workers to conduct home visits will be explored. The participant will be reimbursed for the cost of travel to or from the follow-up appointments.

Eligibility Criteria

Overview

There will be no exceptions to eligibility requirements at the time of enrollment. Questions about eligibility criteria will be administered prior to attempting to enroll the participant. The eligibility criteria for this study have been carefully considered. Patients not meeting the criteria will not be enrolled in the study. Participants will be considered eligible for enrollment in this study if they fulfill all the inclusion criteria and none of the exclusion criteria.

Inclusion Criteria

The criteria for inclusion are (1) patients aged older than 18 years and presenting with cough; (2) clients attending outpatient clinics in the selected study sites; and (3) clients suspected of having tuberculosis, asthma, and COPD as per national guidelines—prioritizing those with cough of any duration.

Exclusion Criteria

The exclusion criteria are (1) refusal to participate and (2) clients who started prescription medications.

Sample Size Estimation

This evaluative study will collect and analyze data for all patients receiving TB, asthma, and COPD care, starting from screening, and ending with the starting of treatment or preventive therapy. A sample size of 348 for each disease condition (a total of 1044) was obtained using the Buderer formula for sensitivity and specificity [48]. Using tuberculosis as an example, the reported sensitivity of 0.98and specificity of 0.84 of using AI in detecting *Mycobacterium tuberculosis* [49,50] and the prevalence of pulmonary TB of 0.335 among patients with presumptive TB [51] were used to compute this sample size at 0.05 precision and 0.1 attrition.

Where n is the required sample size, SN is the anticipated sensitivity, α is the size of the critical region ($1-\alpha$ is the confidence level), $Z1-\alpha 2/$ is the standardized normal variate corresponding to the specified size of the critical region (α), and L is the absolute precision.

Participants’ Service Flow

Patients’ TB, asthma, and COPD service flow all project activities will be consistent with the service standards as outlined in the national policies and guidelines. Currently, in Tanzania, patients’ access to TB, asthma, and COPD services is mainly through facility-based health services. The flow of patients starts with screening for symptoms and signs. Participants who screen positive for TB, asthma, and COPD symptoms (presumptive clients) are either assessed clinically first and referred directly to the laboratory within the same or outside facility for diagnosis (for TB) or receive medical treatment after medical assessments

and investigations (for asthma and COPD). Specifically for TB, health providers then order sputum for smear microscopy or GeneXpert and the sample is collected at the referring entry point or at the laboratory, depending on the client volume and human resources at the site. When the sputum sample is negative, a CXR is ordered to support clinical radiological diagnosis. Sputum samples with positive results are sent to the TB clinic service provider who then liaises with the requesting clinician (at various service delivery points) to ensure that the patient receives their result and initiates TB treatment. Patients may be waiting for their result (same-day diagnosis) or be given an appointment to return to the requesting clinician for follow-up. CXR results are interpreted by trained clinicians if available at the facility level, or by the district TB coordinator. For asthma and COPD, a clinical diagnosis may be made by an attending clinician and medications initiated, occasionally after excluding TB where diagnostic facilities are available.

Clinical Evaluations

A variety of clinical assessments will be conducted, encompassing the collection of demographic and medical data, anthropometric measurements, chest auscultations, spirometry, PEF, and clinical specimen collection. A comprehensive overview of these clinical evaluations is described in Multimedia Appendix 3 [52,53].

Data Management and Analysis

Data Management

Study personnel will be given in-service training by the PI about forms and study procedures before the start of the study and given in-service training periodically throughout the study. Data collection is the responsibility of the research assistants at the site under the supervision of the PI. During the study, the PI will maintain complete and accurate documentation for the study. Data analysis will be the responsibility of the PI, under the mentorship of a biostatistician.

Each subject will be assigned a unique patient ID number. The forms that contain the subjects' names, dates of birth, and contact information will be kept in the PI's office and filed in a secured cabinet. A key linking each participant to their patient ID will be created and kept secured by the PI. All case report forms (CRFs) will be reviewed for accuracy, clarity, and completion, and by the data entry staff for completion. Study-related laboratory reports will be reviewed and signed off by a PI. Data reported on the CRF that are derived from source documents or chart reviews should be consistent with the source documents or the discrepancies should be explained.

Data Capture

Data will be captured using paper CRFs or electronic CRF and transcribed into a secure, password-protected, electronic database. Data capture will be ongoing throughout the period of the study. It is expected that participant CRFs will be reviewed and entered electronically directly or within 7 days of completion of the visit. Data quality control measures will be instituted as outlined in the standard operating procedures, in accordance with data quality control procedures at the study site.

Types of Data

Identifiable information including name and contact information will not be stored electronically, but only on paper. A coded CRF-compliant, secure, password-protected electronic database will house the demographic data, clinical data (including current and past medical history), and laboratory outcome measures (including results of study-related tests or procedures).

Analysis for Outcomes

Results of recorded cough using cough audio classifier will be compared with clinical assessment, GeneXpert, culture and sensitivity, spirometry, PEF and sensitivity, and specificity and predictive values will be calculated. These measures will be collected simultaneously among patients and will serve as benchmarks for comparison purposes. The analysis will be generated for cost, facilitators, and barriers to implementing the cough audio classifier for TB, asthma, and COPD screening in rural community settings.

Audio Classifier-Diagnostic Test

A binomial test will be used to test whether the sensitivity of the audio classifier using the previously reported cut-off is less than 0.8, and receiver operating characteristic analysis will be explored to determine if another cut-off should be used in this patient population. Logistic regression models will be used to determine whether an audio classifier contributes additional information to predicting TB, asthma, and COPD in the presence of clinical and laboratory predictors. Variable assessment will be based on a likelihood ratio test, in which the likelihood of the reduced model will be compared to the likelihood of the full model. As a primary summary measure of discrimination, we will use the c (for concordance) index, a measure that is identical to the area under the receiver operating characteristic curve when the end point is binary.

Risk Factor Analysis

The study will use a similar strategy as described. All models will be adjusted for baseline medical and demographic characteristics of the subjects. Data will be also summarized with respect to the primary and secondary outcome measures, demographics, and baseline characteristics. Quantitative variables will be summarized with standard descriptive statistics while frequency tables will summarize categorical variables. All analyses will be performed in STATA (StataCorp). Before analysis, the outcome will be examined for skew and kurtosis to determine the need for standard transformations to meet normal distribution assumptions. All *P* values are 2-sided and considered statistically significant at a level of .05.

A deductive thematic analysis approach will be used for qualitative data [54] on the barriers and facilitators of cough audio classifier acceptance using NVivo software (Lumivero). More specifically, data transcription and translation will occur simultaneously by the research assistants. After transcription and translation, the interview transcripts will be cross-checked by the PI to ensure that the participants' worldview was not lost during translation. The interview transcripts will then be deidentified, and pseudonyms generated for each participant. The data will then be uploaded into NVivo software for thematic coding. The PI will deductively generate an initial list of codes

from data extracts of the first 3 transcripts. Then, these codes will be reviewed by the research team who had independently reviewed selected transcripts generating a consensual list of codes. The PI will continue coding the rest of the transcripts, refining, and generating more codes upon coming across a new segment of data that could not fit into the initial codes. Codes will then be sorted into potential subthemes and themes, followed by collation of all relevant coded data extracts within identified themes. Throughout coding and refinement, the peer consultation will be maintained to reflect on the subthemes and themes generated.

Ethical Considerations

The study complies with the principles of the Declaration of Helsinki, as amended by 59th World Medical Association General Assembly, Seoul, Korea, October 2008. It will also be conducted in compliance with the approved protocol, the principles of Good Clinical Practice and applicable local laws and guidelines. The study protocol, information, and consent documents will be submitted to the National Institute for Medical Research (Tanzania) for review and approval. Permission will be sought from the President's Office Regional and Local Administrative Government (PORALG), the national TB and leprosy programme (NTLP), and participating health facilities. A comprehensive overview of the informed consent process, along with measures for ensuring confidentiality and data protection, is outlined in Multimedia Appendix 4.

Results

Participants Demographics

The first section of the results will summarize the demographics of participants involved in cough sound collection and evaluation of the cough audio classifier. Participants' gender; age; primary occupations; marital status; presence and duration of cough and other TB, asthma, and COPD symptoms and TB contact and family history; current or chronic medications; and comorbidities are some of the demography that will be presented in a tabular form.

Phase 1: Cough Sounds Collection

The findings will encapsulate a compilation of various cough sounds gathered during the collection process. This compilation will encompass a spectrum of cough characteristics, including frequency, duration, and intensity. Additionally, a summary of the extensive database comprising cough audio recordings, intended for use in subsequent phases, will be provided.

Phase 2: Cough Sound Analysis and Algorithm Development

The findings regarding the methodology and procedures used to analyze patterns and correlations within the cough sound data set, facilitating algorithm development, will be outlined. Additionally, the process, methodologies, and findings related to the initial algorithm development, distinguishing between different cough sounds, and identifying potential classification markers, will be detailed. Furthermore, a summary of the steps taken to refine the algorithms and improve accuracy and efficiency in identifying distinct cough patterns will be provided.

Phase 3: Development of Cough Audio Classifier

The findings will encapsulate an overview of the process and methodologies leading to the successful creation of a functional cough audio classifier, designed as a smartphone-based app, derived from the refined algorithms developed in phase 2. The summary will outline the procedures used to assess the classifier's capacity to accurately differentiate between various types of coughs, specifically identifying those associated with conditions. Similarly, it will highlight the process for evaluating the classifier's adaptability across a broad spectrum of cough variations and its potential for real-time implementation.

Phase 4: Evaluation of Cough Audio Classifier

The study will present findings from a performance evaluation aimed at assessing the accuracy, sensitivity, and specificity of the cough audio classifier in a real-world setting. These results will encompass an evaluation of the classifier's feasibility, acceptability, user experiences, and efficiency among health care providers and patients. Additionally, the study will present findings from a comparative analysis of the cost-effectiveness and practicality of implementing the cough audio classifier in contrast to existing standard practices.

Collectively, these key results from each phase will significantly contribute to a comprehensive understanding of the cough audio classifier's feasibility, accuracy, and its potential for real-world applicability, as developed within this study.

Discussion

Principal Findings

The study aims to enhance the management of TB, asthma, and COPD in health care facilities involved in the research. It aligns with existing patient care pathways for TB, asthma, and COPD by focusing on improving diagnostic capabilities through the integration of services and decentralization, thereby reinforcing referral systems within and between health care facilities. The anticipated primary outcome is the development and validation of a noninvasive, mobile-based cough sound classifier for detecting TB, asthma, and COPD. This research will report on the practical evaluation of the acceptability and effectiveness of the cough audio classifier, with a particular focus on its applicability in rural primary health care settings.

Comparison to Prior Work

The scholarly community is increasingly interested in the potential of AI or ML technologies for developing diagnostic tools. This research aims to develop and explore the feasibility, acceptability, and efficacy of using AI or ML to create cough audio classifiers in Tanzania, marking the first pilot project of its kind in the region. The results of this study will be benchmarked against findings from previous research on cough audio classifiers, some of which have been reviewed in the context of this protocol [13-22], to provide a comparative analysis and contribute to the evolving field of AI or ML applications in health care diagnostics.

Strengths and Limitations

This study represents a groundbreaking effort in the development and evaluation of a noninvasive, user-friendly AI-powered cough audio classifier for 3 respiratory diseases within low-income rural settings. However, conducting a study in rural Tanzania may encounter several limitations. First, access to technology poses a significant challenge. Rural areas may lack the necessary technology infrastructure, including stable internet connections, cough audio processors, reliable power supply for devices, or access to smartphones or suitable devices required for the AI-powered application. To mitigate these challenges, efforts will be made to leverage financial and nonfinancial resources within and beyond Aga Khan University. Second, data quality and quantity could be limited. The availability and quality of cough audio data for training the AI model might be insufficient or biased in rural settings, potentially affecting the model's accuracy. To address this, institutionalized quality assurance measures will be implemented to ensure high-quality data collection. Additionally, the study duration will be adjusted to ensure the collection of sufficient data. Third, language and cultural considerations might impact the classifier's accuracy. The AI model may not be optimized to recognize local dialects or variations in cough sounds due to cultural or linguistic differences. To partly address this, global AI and ML experts and processing protocols will be used to ensure accurate cough audio processing. Fourth, the study targets adults aged 18 years and older, primarily due to the complexities of the consent process, resource constraints, and the difficulties associated with collecting cough audio sounds from children. Given the pilot nature of this research, subsequent studies may consider including children as participants. Consequently, the study aims to exclude participants who have taken prescription medications. This exclusion criterion is based on the premise that prescription medications can markedly modify the characteristics and severity of cough sounds, thereby influencing the precision of our cough audio classifier. Given that certain prescription medications might be available over-the-counter within the study environments, there is a potential for this criterion to substantially diminish the sample size. In response to this challenge, we have expanded the number of health care facilities involved and extended the period of data collection to mitigate the impact on our sample size and ensure robust data acquisition. Finally, limited health care infrastructure in rural areas, including a scarcity of health care facilities and skilled personnel, may hinder the effective implementation of the AI-powered classifier. To counter this, health care workers involved in the study will receive adequate training before engaging in the research. Recognition is made that addressing these limitations are crucial to ensure the successful development, implementation, and evaluation of the AI-powered cough audio classifier for respiratory condition detection in rural Tanzania.

Future Directions

The findings of this study will have a range of social impacts. Although there is a lack of common definitions, conceptualizations and practical tools addressing the acceptability of technological health innovations in sub-Saharan Africa [55], an acknowledgment is made that social and cultural contexts have a significant impact on how humans behave both positively and negatively [56]. This is also the case when we are addressing the adaptation to new innovations among health care providers and community members. Common barriers to acceptance of health innovations may include intrapersonal and interpersonal, community, organizational, and policies or enabling factors [57,58]. Intrapersonal factors encompass attitude, fears, level of income, self-efficacy, and education level, which could play both roles as facilitators and barriers when it comes to the acceptability of these new techniques. For example, a recent review noted fear of a loss of professional autonomy and difficulties in integrating AI into clinical workflows as factors hindering their acceptability [57]. Public fears toward health innovations that they are not fully aware of may also promote negativity toward them [58]. Some of the interpersonal factors include social or family roles and responsibilities, norms, stigma, and community influence. Individuals and communities are seen to be more open to innovations when the intervention is supported by influential people within their communities [58]. Challenges are expected on the issue of acceptability among health care workers and the community since it is a new technology introduced and this can cause some reluctance. Additionally, the issue of smartphone use can be a challenge as some potential health care professionals may not be willing to use their personal devices for clinical diagnostic tasks and patients might not own the smartphone where the app will be installed. Similarly, the sharing of smartphones in the family and at the community level for self-diagnosis can be a potential for spreading communicable respiratory diseases if proper hygiene is not observed. Therefore, this study will navigate through these factors and ensure that they are well-addressed to maximize our outcomes. The focus will be on integrating the end users in the early stages of AI development, offering needs-adjusted training for the use of AI in health care and providing adequate infrastructure [57]. Furthermore, health care providers will be trained as trainer of trainers from the start of the study as they tend to easily pave the way, and consideration of gender roles, ensuring both males and females can participate equally.

Furthermore, the findings will have implications on health economics. Scaling up TB, asthma, and COPD services to achieve national and global targets requires an optimization of available funding. To identify and address the available inefficiencies and consider new interventions at the national level; information on the cost of services is of great necessity. There is a scarcity of data on the cost and technical efficiency of using mobile health (mHealth) for early TB, asthma, and COPD detection in rural communities that once done can aid in the achievement of national goals. Thus, we aim to gather health economics data to assess total and unit costs, cost structure, and cost drivers of this technology provision. The purpose of the health economics component of this study is to inform priority setting within the health sector. This will cover resource allocation across an overall budget or total resource envelope from the health provider's perspective that focuses on costs incurred by the implementing partner but also assesses the costs of services and consumables from other providers (eg, national program) in both financial and costs.

Patient and household expenditures including productivity losses have been barriers to accessing and retention in care. In consultations with health economists, a plan is to collect data on both direct and indirect patient-incurred costs using questionnaires. The study is expected to estimate direct costs incurred by patients such as those related to transport, as well as indirect costs, in terms of productivity losses, related to access to care as well as due to illness-related absenteeism. Together with data on service usage and socioeconomic background, we will be able to analyze patient costs and equity considerations in access and use of care. The study will generate a comprehensive picture of the costs of using mHealth-based cough audio triage testing for active pulmonary TB, asthma, and COPD in health facilities in high-burden settings in Tanzanian communities.

Dissemination Plan

The dissemination of findings will involve communication with key stakeholders, regular reporting through the pertinent channels of the funding agency and the Tanzanian Ministry of Health, engagement in local and international forums, and publication through peer-reviewed open-access journals. By using a methodical and systematic approach to disseminating the study's findings, this research aims to contribute to the expanding knowledge base regarding the use of AI and ML in developing noninvasive diagnostic tools. These tools are designed to assist health care professionals in effectively identifying and distinguishing various diseases, not only within Tanzania but also broadening their application beyond geographical boundaries.

Conclusions

Cough sound classifiers harness the power of advanced technology to offer a promising solution for the early detection and efficient management of various respiratory conditions. By accurately analyzing cough sounds, these innovative tools can identify potential illnesses at an earlier stage than traditional diagnostic methods, facilitating timely intervention and reducing the need for more invasive procedures. This approach not only has the potential to significantly alleviate the burden on public health systems by streamlining the diagnostic process but also aims to improve patient outcomes through faster and more accurate diagnosis. Moreover, the use of cough sound classifiers can democratize health care access, particularly in under-resourced areas, by providing a cost-effective and easily deployable tool for community health workers and primary care settings. Ultimately, the integration of this technology into clinical practice could transform the landscape of respiratory disease management, offering a scalable and efficient solution to global health challenges.

Acknowledgments

The author gratefully acknowledges the technical support received from Amy Strange and Luke Nightingale of the Crick Institute (United Kingdom), as well as Professor Stephen Cose of the Medical Research Council and London School of Hygiene and Tropical Medicine Uganda Research Unit. Additionally, the author expresses sincere gratitude to the leadership of the School of Nursing and Midwifery at the Aga Khan University for offering protected time for the development of this protocol. Finally, we acknowledge using generative artificial intelligence to refine and edit sentences for clarity, while specifying its nonuse in content generation (a sample transcript is provided in Multimedia Appendix 5).

Data Availability

Some data sets generated and analyzed during this study will not be publicly available due ethical reasons and a need to protect participant privacy but will be available from the corresponding author on reasonable request.

Abstract

Background: Diabetes affects more than 4.3 million individuals in the United Kingdom, with 19% to 34% developing diabetes-related foot ulceration (DFU) during their lifespan, which can lead to an amputation. In the United Kingdom, every week, approximately 169 people have an amputation due to diabetes. Preventing first-ever ulcers is the most effective strategy to reduce the occurrence of diabetes-related amputations, but research in this space is lacking.

Objective: This protocol seeks to document the experiences and perspectives of frontline health care professionals who work with people who have diabetes and diabetes-related foot problems. Special attention is given to their perceptions of barriers to effective care, their views about barriers to effective and inclusive engagement with people with diabetes, and their experience with the first-ever DFU. Another aspect of the study is the focus on whether clinical management is affected by data sharing, data availability, and interoperability issues.

Methods: This is a mixed methods explanatory protocol, which is sequential, and its purpose is to use the qualitative data to explain the initial quantitative data collected through a survey of frontline health care professionals. Data analysis of quantitative data will be completed first and then synthesized with the qualitative data analysis. Qualitative data will be analyzed using the framework method. This study will use joint displays to integrate the data. Ethical approval has been granted by the ethics committee of Staffordshire University.

Results: The quantitative data collection started in March 2023 and will close in May 2024. The qualitative interviews commenced in November 2023 with volunteer participants who initially completed the survey.

Conclusions: This study's survey focuses on data interoperability and the interviews focus more on the perspectives and experiences of clinicians and their perceived barriers for the effective management of diabetes foot ulcers. Including a geographically relevant and diverse cohort of health care professionals that spans a wide range of roles and care settings involved in diabetes-related foot care is very important for the successful application of this protocol. Special care is given to advertise and promote participation as widely as possible. The qualitative part of this protocol is also limited to 30-40 interview participants, as it is not realistic to interview higher numbers, due to time and resource constraints.

Introduction

Currently, there are more than 4.3 million people diagnosed with diabetes in the United Kingdom [1], and 19% to 34% of them will develop diabetes-related foot ulceration (DFU) in their lifetime [2]. Out of all DFUs, the literature reports that 10% to 56% will result in amputation [3]. In the United Kingdom, every week, approximately 169 people have an amputation due to diabetes [4,5]. The total direct cost of DFU and diabetes-related foot amputations in England alone is between £837 million (US $1.25 billion) and £962 million (US $1.20 billion) and is steadily rising every year [6]. DFU costs the National Health Service (NHS) more than the 3 most common types of cancer combined [6]; hence, DFU is a major challenge for the financial sustainability of the NHS, and effective prevention could significantly reduce its burden.

Understanding the barriers to effective care and their regional variability is critical for service improvement, leading to fewer diabetes-related foot complications and fewer lower limb amputations [7,8]. A survey of health care professionals working with diabetes-related foot complications, conducted in 2018, highlighted delayed access to specialist care as the most important barrier for effective diabetes-related foot care [9,10]. The key contributors to this problem, which were noted by the responders, included inadequate funding and issues in the areas of referral pathways, patient care, and education [9]. More specifically, about half of the responders indicated a lack of necessary resources. Regarding referrals, the responders of that survey identified inefficiencies in the referral pathways leading to preventable delays. In the area of patient care, the survey indicated a lack of coordination and standardization leading to suboptimal care. The responders also noted that the lack of or ineffective patient education compromises their ability for self-care and leaves them unaware of when to seek help [9].

Structured diabetes education programs are extremely important for promoting effective engagement with health care services and for effective self-management of diabetes-related foot complications [11,12]. To be effective, education needs to be offered to people with diabetes as well as to their families or caregivers [11,12]. It also needs to be designed and delivered in a culturally competent manner [13].

People from ethnic minority groups or socioeconomically disadvantaged communities are disproportionately affected by diabetes and diabetes-related foot complications, experiencing higher morbidity and mortality than majority populations or more affluent communities [13]. Understanding the barriers to effective engagement with these groups is extremely important for effective diabetes-related foot care as well as for robust clinical research.

There is overwhelming evidence that populations from geographical regions that are more actively involved in clinical research tend to benefit from it the most. These benefits include the early adoption and tailoring of new highly effective approaches to care that translate to lower disease prevalence and better patient experience [14,15]. At the same time, regional variations in research participation indicate that the areas and communities with the highest diabetes prevalence are also the least likely to participate in research [16,17]. Ineffective communication and engagement with underserved communities are among the key contributors to this disconcerting discrepancy [14,15], highlighting even further the need to address barriers to effective communication and engagement. Understanding the perceptions of health care professionals about these barriers and how these can be overcome can be helpful to this end.

An exciting new approach for effective DFU care proposed in current literature is to shift medical attention from the management of active DFU to supporting people with diabetes to remain ulcer-free for longer. This can be achieved by focusing efforts to prevent the first-ever DFU from happening [18-20].

Preventing first-ever ulcers (also known as primary ulcers) is the most effective way to reduce the number of diabetes-related amputations and protect the quality of life of people with diabetes. This is because 40% of people with healed first DFU reulcerate within a year (60% reulcerate within 3 years), which significantly increases the risk for amputation [2]. The first-ever DFU incidence is also associated with a 250% increase in the 5-year risk of death [21,22].

Integrated care that combines frequent specialist screening with education and offloading interventions (eg, the use of therapeutic footwear or orthoses) is currently used to prevent recurrent DFU [11,23,24] and is likely to be effective also for the prevention of first-ever ulcers. However, their blanket use across all people with diabetes is practically impossible due to the sheer number of people at risk of their first-ever DFU [18,20,25].

According to current international guidelines, a person with diabetes is considered to be at high risk of DFU when they have had their first-ever DFU or diabetes-related amputation [11,26]. However, as it stands, there is no established method to determine when someone is at high risk of developing their first-ever DFU [11].

Clinical research is needed to develop effective strategies to target preventative care for those at imminent risk for first-ever ulceration [11]. However, studying first-ever ulcers remains significantly more challenging than studying recurrent ulcers. This is due to the scarcity of current and geographically relevant data in the literature to support the design and implementation of research in this area. Moreover, due to their relatively low incidence rate [25], any research on first ulcers is likely to require relatively larger numbers of participants, highlighting the need for effective and inclusive recruitment strategies. To maximize the chances of success, research protocols should be informed by the experience of the health care professionals who will have to lead and deliver this research. This includes identifying strengths to be used and limitations and perceived barriers to participation and recruitment to be addressed [9,27].

In this context, this protocol aims to capture the experience and views of frontline health care professionals working with people

with diabetes-related foot complications regarding previously identified barriers to effective care from the literature [9]. These barriers may include the effectiveness of referral pathways, the efficiency of communication between disciplines and NHS services, and the adequacy of patient education The experience of frontline health care professionals regarding the first-ever DFU will be also captured to inform clinical research toward more effective DFU prevention.

The primary objective is to identify the potential areas of improvement regarding DFU care delivery and patient-clinician engagement.

The secondary objectives are to (1) model qualitatively the lived experiences of frontline health care professionals about diabetes foot care and (2) develop a theoretical model that describes the interaction between their lived experience and identified barriers to effective care and engagement with people with diabetes.

Methods

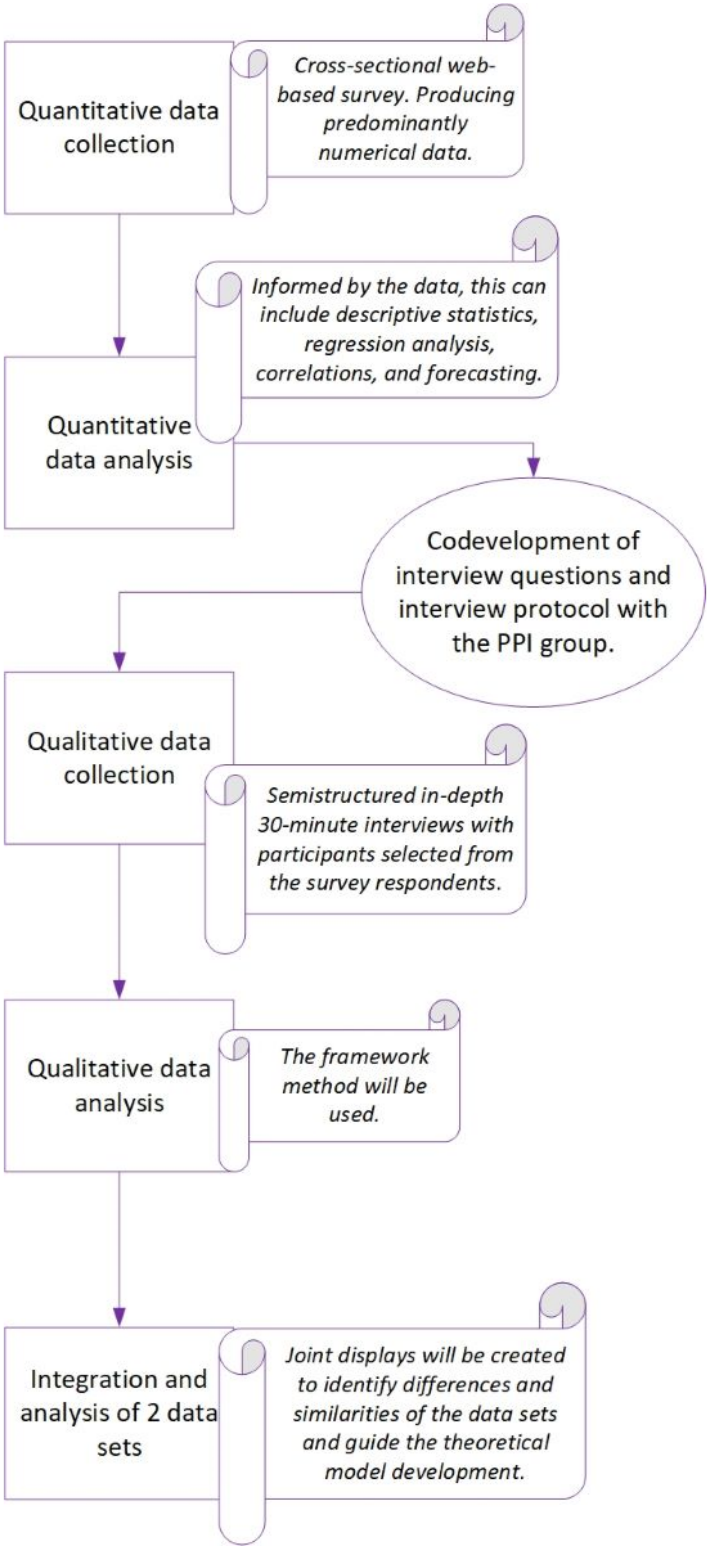
Study Design

In agreement with the Equator's Network mission to improve the reporting of health care research, and in the absence of a comprehensive checklist for mixed methods study design, we have adopted the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement, given that our study is observational [28]. The STROBE statement covers cohort, case-control, and cross-sectional studies and we will follow the relevant statement's sections about the cohort (for our qualitative data) and cross-sectional (for our quantitative data) studies.

This study uses pragmatism and a mixed methods approach, which has been previously used and supported in the field of health informatics [29,30]. The rationale behind choosing mixed methods is that, based on our pragmatic approach, the best way to achieve the aims and objectives was to mix both quantitative and qualitative data, which complement each other enhancing the results of the study [31,32]. This study uses an explanatory design that is sequential, and its purpose is to use the qualitative data to explain the initial quantitative data.

The study has two main components: (1) a survey and (2) semistructured interviews. This study prioritizes the qualitative data as they are used to explain and enhance the findings of the quantitative data [32]. Interview participants were purposefully recruited from the survey responders, mixing the data-gathering methods. Figure 1 illustrates the mixed methods sequential explanatory design stages of this study.

Figure 1. A schematic of the proposed mixed methods sequential explanatory study to capture the experiences and perspectives of frontline health care professionals working in the National Health Service (NHS) in the area of diabetes foot complications. Data collection started in March 2023 and is expected to end in May 2024. PPI: patient and public involvement.



Patients, Sampling, and Recruitment

Recruitment will occur in 2 stages. The first stage includes the recruitment of survey respondents. We aim to attain between 188 and 270 responses that are required for a maximum assumed error of 6% to 5% (90% Cis), respectively [33].

A recruitment strategy, which encompasses a number of different avenues, has been established to enable us to reach out to a diverse audience and maximize the chances of meeting the required target. This includes the distribution of leaflets in relevant scientific conferences, press releases, social media announcements, and dissemination through a network of collaborating NHS trusts and UK universities (and their alumni

associations) that train health care professionals involved in diabetes foot care. Invitation to participate in this survey was also disseminated through the Staffordshire and Shropshire Health Economy Research Partnership [34] through the National Institute for Health and Care Research Clinical Research Network West Midlands [35], special interest groups on diabetes funded by the National Institute for Health and Care Research (Diabesity group), and NHS integrated care boards.

The survey, which is used during this first stage of recruitment, is also used to obtain permission to contact respondents for interviews for the second stage of recruitment. The interviewees will be divided into 3 main cohorts based on their professional work setting (primary, community, or acute care) to discover and model differences in DFU care delivery across contexts. As this study aims for the greatest variation in demographic distribution, the sampling is purposeful [32,36,37]. We intend to interview around 30-40 health care practitioners since the "gold standard" for a purposive sample is to achieve theoretical saturation. It is impossible to predict an absolute number for theoretical saturation; however, based on prior experience and published recommendations, we believe these figures are reasonable given our objectives, scope, and methodology [32,36,38,39].

The interview participants' selection was based on the following criteria in importance ranking to ensure variation in (1) roles within the care pathway for diabetes foot complications, (2) gender, (3) years of experience, and (4) age group.

Inclusion criteria are (1) participant is willing and able to give informed consent for participation in the study, (2) people aged 18 years or older, and (3) any grade or discipline of health care professional working in diabetes foot care.

Exclusion criteria are (1) inadequate spoken English or unable to participate in a web-based interview, (2) health care professionals who are not working in the diabetes foot care field, and (3) health care professionals not working in NHS.

An assumption has been made that everyone who fills the survey and understands English well. Nonetheless, if we suspect that the interviewee's English comprehension and articulation are inadequate, we will exclude them and replace this interview.

Measures

This project will collect quantitative and qualitative data via a web-based survey and further qualitative data from the same group via web-based or telephone interviews.

The survey design was cocreated in conjunction with a patient and public involvement (PPI) group of people with diabetes and diabetes foot complications. The first draft of this survey was cocreated with the 10 health care professionals who also face validated and pilot-tested it. Those health care professionals included a diabetologist, 3 general practitioners, and 6 podiatrists who worked in community, acute, and primary care settings. The survey design can be found in Multimedia Appendix 1. We plan to publish the results of the survey after the analysis is concluded.

Microsoft Excel (Microsoft Corp) will be used for descriptive statistics, while SPSS (IBM Corp) will be used to conduct inferential statistical tests, such as regression analyses and other data-driven tests to assess the association between factors.

For the qualitative component of this protocol, we shall conduct single semistructured interviews (maximum 40 minutes) to explore user experience about the DFU clinical pathway barriers, clinician-patient communication issues, and research participation. We will obtain informed consent and the interviews will be audio recorded and fully transcribed. The interview guide (Multimedia Appendix 2) followed the structure of the NHS Integrated Research Application System guidelines, and it was cocreated with our PPI group.

The framework method [40] will be used for the qualitative data analysis, allowing themes to be produced both inductively (from the interviews) and by adding themes that originate from the survey. The framework method is systematic, comprehensive, and data driven, but it is also adaptable and allows facts to be shown visually [40,41]. The framework method has step-by-step instructions for application, and this study aims to adhere to Gale et al [41] recommendations.

For coding, NVivo (QSR International) will be used. An independent researcher will code a portion of the files (around 25%), and after comparing the themes, the interrater reliability score will be calculated. Following the coding of half of the transcripts, a framework with well-defined and grouped together codes will be created and applied to the remaining transcripts [41]. During data merging, the qualitative data will be interpreted alongside the quantitative.

Having arranged the quantitative and the qualitative data in a format based on thematic relevance to allow merging, further integration will be needed. This study will use joint displays to integrate the data in a similar fashion and to gain a better understanding of the complexity of the observed phenomena [42]. The combined display, should the data collection permit such integration, will have rows representing the participants and columns representing each theme (obstacles in DFU care delivery and research engagement issues, etc), along with the quantitative variables (years of experience, type of employment, etc). This approach may help us better understand the roles of individual themes as enablers or barriers to effective patient care.

Ethics Approval

Ethical approval for this study has been granted by Staffordshire University's ethics committee (approval: SU_22_113). All participants provide informed consent before any quantitative or qualitative data are collected.

All potential responders to the survey are first required to read through the participant information sheet and to fill a specific consent form before accessing the main body of the survey. To ensure that no quantitative data are collected without consent, the participants can only access the survey if they agree to all consenting questions (see consent form in Multimedia Appendix 1).

Consenting to take part in the quantitative part of this mixed methods study does not directly qualify a person to participate also in the follow-up interviews. A separate consenting process

was followed to this end. More specifically, at the end of the survey, it is explained that based on their responses the research team might want to invite them to take part in a semistructured interview. It is explained that the purpose of this interview will be to ask some more specific questions regarding their response to the survey and that the interview will be on the web or over the phone (see follow-up in Multimedia Appendix 1). The questionnaire responder is then asked to indicate whether they consent to be contacted again to arrange the interview. Answering "no" to this question brings the survey to an end, enabling the responder to submit their answers for analysis. Answering "yes" reveals an additional question where the responders are asked to provide their contact details before submitting their survey responses for analysis and exiting the survey. If they are selected to take part in the qualitative data collection, participants who consent to be contacted again are invited to take part in the semistructured interviews. Consent to be interviewed and to have the interview recorded and transcribed is verbally confirmed at the start of each interview. No qualitative data are recorded for survey responders who do not consent to be contacted again. In addition, no qualitative data are recorded for survey responders who consent to be contacted again but fail to provide explicit consent to be interviewed.

All collected personal information will be kept confidential on a password-protected computer. Only members of the research will have access to this information. The contact details of the people who consent to be contacted again will be used to arrange and conduct the interviews and they will be deleted at the end of data collection. Special care will be given during dissemination to ensure that all data are presented in an anonymized form so that no identification of individual participants is possible.

No compensation or financial incentive will be provided to survey responders. Participants taking part in an interview will receive a £10 (US $12.5) shopping voucher.

PPI Involvement

People with diabetes and diabetes foot complications have been involved throughout this research to increase transparency, minimize bias, and maximize clinical relevance. All members of the PPI group were recruited based on posters displayed in Stoke-On-Trend community areas and general practitioner practices as well as social media posts. The selection criteria involved people with diabetes and diabetes foot complications, who are consenting adults, and able to express their opinions.

Early in the design of this study, our aim, objectives, and areas of focus of the survey were discussed within a group of 4 people with diabetes and diabetes foot complications. The final questionnaire was designed based on their feedback. The initial core PPI group has since been extended to include 9 people with diabetes and diabetes foot complications. This extended PPI focus group met at Staffordshire University in June 2023 to discuss plans for the semistructured interviews. Discussions in this meeting enabled identifying topics and specific questions that were important to them. These were then included in the interview script. The final interview script was shared with the members of the PPI group during a separate web-based meeting to ensure that their feedback was correctly used.

Results

So far, this study has had 223 respondents in the web-based survey, and the interview invitations have started. We have invited 30 participants for the interviews, and based on their willingness to be interviewed and their responses, we will keep inviting interviewees, within reason, until theoretical saturation is reached. The study's data collection will close in May 2024. Initial data analysis has commenced, with results expected to be published by the end of 2024.

Discussion

The protocol presented here aims to capture the experience and views of frontline health care professionals working with people with diabetes-related foot complications. Emphasis is given to previously identified barriers to effective care regarding the effectiveness of referral pathways, the efficiency of communication between disciplines and NHS services, and the adequacy of available resources and patient education [9]. This protocol also recognizes the need to help people with diabetes remain ulcer-free for longer [18-20]. With this in mind, the experience of frontline health care professionals regarding the first-ever DFU will be also captured to inform clinical research toward more effective DFU prevention.

To this end, a mixed methods explanatory protocol will be implemented. This protocol is sequential, and its purpose is to use qualitative data to explain the initial quantitative data collected through a survey of frontline health care professionals. Data analysis of quantitative data will be completed first and then synthesized with the qualitative data analysis. Compared to relevant literature, this protocol can offer a more comprehensive overview of the perceptions of frontline clinicians regarding diabetic foot care. It is also the first to include the perspective of health care professionals working in primary care [9].

Regarding the limitations of this protocol, even though special care is given to advertise and promote participation as widely as possible, it is likely that dissemination through institutions that are participating in this research will be more effective, leading to greater numbers of responders. These institutions are based in England, and most of them are based in West Midlands. The inability to attain responses with a representative spread across the country could limit the representativeness of results. This study is also limited to the 30-40 interview participants, as it is not realistic to interview higher numbers, due to time and resource constraints.

Once completed, this study can offer new insight into potential improvements regarding DFU care delivery and patient-clinician engagement toward reduced DFU and amputation rates. It will also provide a contextual evidence base for further studies related to DFU care delivery and DFU care workflow.

Acknowledgments

We would like to acknowledge that this work was supported by the National Institute for Health Research Clinical Research Network West Midlands Improvement and Innovation Strategic Funding. It forms a part of a greater project aiming to establish an ecosystem of research on the first-ever diabetes-related foot ulceration.

Abstract

Background: Multiple myeloma (MM) is the second-most common cancer among hematological malignancies. Patients with active disease may experience several comorbidities, including renal insufficiency and asthma, which may lead to treatment failure. The treatment of relapsed or refractory MM (RRMM) has been associated with multiple factors, causing a decline in progression-free survival as well as overall survival with subsequent lines of therapy. Data about the characteristics of this group of patients in the Greater Gulf region are lacking.

Objective: The primary objective of this study is to describe the disease characteristics and various treatment approaches or regimens used in the management of patients with RRMM in the Greater Gulf region.

Methods: We will conduct a regional, retrospective study collecting real-world and epidemiological data on patients with MM in countries of the Greater Gulf region. Medical records will be used to obtain the required data. Around 150 to 170 patients' records are planned to be retrospectively reviewed over 6 months without any cross-sectional or prospective intervention. Cases will be collected from Saudi Arabia, the United Arab Emirates, Kuwait, Oman, and Qatar. Descriptive as well as analytical statistics will be performed on the extracted data. The calculated sample size will allow us to estimate the percentages of RRMM cases with acceptable precision while complying with the challenges in light of data scarcity. We will obtain a comprehensive description of the demographic profile of patients with MM; treatment outcomes; the proportion of patients with MM with renal impairment and asthma, chronic obstructive pulmonary disease, or both at the time of diagnosis and any subsequent point; and data related to treatment lines, regimens, and MM-associated morbidities.

Results: Patient medical records were reviewed between June 2022 and January 2023 for eligibility and data extraction. A total of 148 patients were eligible for study inclusion, of whom 64.2% (n=95) were male and 35.8% (n=53) were female. The study is currently in its final stages of data analysis. The final manuscript is expected to be published in 2024.

Conclusions: Although MM is a predominant hematological disease, data on its prevalence and patients' characteristics in the Greater Gulf region are scarce. Therefore, this study will give us real-world insights into disease characteristics and various management approaches of patients with MM in the Greater Gulf region.

KEYWORDS

Greater Gulf region; multiple myeloma; pulmonary dysfunction; renal impairment; RRMM; Real-world data

Introduction

Overview

Multiple myeloma (MM) is a malignant clonal cancer of plasma cells of the bone marrow that results in an overproduction of huge amounts of light- and heavy-chain monoclonal immunoglobulins [1,2]. In 2020, MM was revealed as the second most predominant hematological malignancy, representing about 10% of hematologic cancers [1], with 176,404 new cases and 117,077 deaths detected worldwide [3]. The hallmark of monoclonal immunoglobulins in MM is the monoclonal protein (M protein), named after its monoclonal properties, detected in patients with MM's serum and urine [2]. The potential uncontrolled growth of these plasma cells causes destructive bone lesions, kidney injury, anemia, and hypercalcemia [4]. About 15% to 30% of patients have the clinical presentation of hypercalcemia with concomitant renal insufficiency caused by precipitated monoclonal light chains in the collecting tubules [5,6]. However, in asymptomatic patients, the disease is accidentally discovered after detecting anemia or hyperproteinemia [1]. Moreover, around 10% of patients with MM showed a previous history of asthma or chronic obstructive pulmonary disease (COPD). The treatment of MM involves the use of steroids; standard chemotherapy (including cyclophosphamide, melphalan, and bendamustine); proteasome inhibitors such as bortezomib and ixazomib [7]; anti-CD38 monoclonal antibodies (eg, daratumumab and isatuximab), and autologous stem cell transplantation (ASCT) [8].

Guidelines have approved anti-CD38 monoclonal antibodies simultaneously with lenalidomide and dexamethasone for treating relapsed or refractory MM (RRMM) following their remarkable efficacy. Alongside clinical disease complications, the treatment of patients with RRMM relied on 3 key points: the duration of response (DoR), progression-free survival (PFS), and overall survival (OS) reduction with successive lines of therapy [9].

MM shows a socioeconomic burden on the patients as well as their families. Rare data regarding MM in the Middle East have been detected [10]. Nevertheless, the United Arab Emirates (UAE) and Qatar were among the countries with the largest prevalence of MM cases and deaths over the past 30 years across the world [11].

Rationale

The primary objective of this study is to detect the associated characteristics of patients with RRMM and the treatment landscape in the Greater Gulf region. The secondary objectives are to describe MM disease history; assess the prevalence of lenalidomide-refractoriness among patients with RRMM in the Greater Gulf region; assess the prevalence of renal impairment and asthma or COPD among patients with RRMM in countries of the Greater Gulf region, both at diagnosis and throughout the disease course; describe renal response (overall, per treatment line and regimen for patients with renal impairment); describe the overall treatment outcomes for patients with MM and patients with lenalidomide-refractory (per treatment line and regimen); and reveal the percentage of patients with RRMM who are eligible for ASCT.

Methods

Overview

Due to the rarity of MM, this study will be a regional, retrospective study aimed at collecting real-world and epidemiological data from patients with MM's medical records in countries in the Greater Gulf region. In addition, the study will describe the demographic characteristics and treatment

landscape of patients diagnosed with RRMM who have relapsed at least once and maximally 3 times before study entry in the 2 years leading up to data collection. Medical records will be checked for eligibility, and data will be retrieved from all participating countries, including Saudi Arabia, the UAE, Kuwait, Oman, and Qatar.

Participants for whom medical records will be eligible for inclusion, review, and analysis must fulfill the following criteria: male or female patients with RRMM who have relapsed at least once and a maximum of 3 times before study entry in the 2 years leading up to data collection. Patients should be 18 years or older, male or female, diagnosed with RRMM (first, second, and third relapses only, who had 1-3 previous lines of treatment) within a maximum of 2 years before data collection time, and have complete patient medical records from MM diagnosis to date of death or medical abstraction. Patients will be excluded as follows: patients not undergoing treatment for MM or newly diagnosed patients (first-line patients); patients with a history of other malignancies; pregnant patients or those planning for pregnancy; or patients with end-stage renal disease.

This study is based on the secondary use of data; expedited reporting of adverse events or adverse drug reactions is not required. However, the sponsor will report all safety observations made during the conduct of the study in the study report.

All of the data will be obtained from the available records as shown in Textbox 1.

Textbox 1. Study flowchart. All the data will be obtained from the available records. Data will be collected from Saudi Arabia, the United Arab Emirates, Kuwait, Oman, and Qatar.

Evaluation or data points in patients' records

- *Inclusion and exclusion criteria*
- *Patient characteristics*: nationality, gender, age, and race
- *Multiple myeloma (MM) disease history*: year of diagnosis, diagnostic method used, levels of heavy-chain immunoglobulin, hematological biomarkers, other laboratory findings, and symptoms before diagnosis (if available)
- *Cytogenetic abnormalities*
- *MM-associated morbidities*: renal impairment (estimated glomerular filtration rate values or other kidney function tests) and pulmonary impairment (including asthma and chronic obstructive pulmonary disease)
- *Lines of treatment used*: first-line regimens (at diagnosis), second-line regimens (after first relapse), third-line regimens (after second relapse), and fourth-line regimens (after third relapse)
- *Treatment regimens*: monotherapy or combination therapy
- *Reasons for treatment change or discontinuation*
- *Eligibility for stem cell transplant*
- *Lenalidomide refractoriness status*
- *Treatment outcomes*: dates of progression, relapses, and requiring treatment escalation (due to refractoriness or relapse)
- *Time to progression*
- *Minimum residual disease negativity (if applicable)*

Data sources include—but are not limited to—hospital records (medical, clinic, and pharmacy) and office charts; memoranda; evaluation checklists; laboratory reports, radiology reports, and imaging data (eg, ultrasonography and scans on film or digital media); computer printouts; and any other documentation regarding the patient (including the patient diary).

Based on the study by Lecat et al [12], 71% of patients with RRMM became refractory to lenalidomide after an initial response. Considering an observed percentage of 71% (120.7/170) with an absolute precision of 8% and a 95% CI, a sample size of a minimum of 150 patients was calculated based on the below formula:

To estimate an observed percentage of 50% (85/170) with an absolute precision of 8% and a 95% CI, the sample size for this retrospective study was estimated to be 170 patients with the assumption that 10% (15/150) of enrolled patients would not be valuable for the primary analyses due to missing values or unfulfilled inclusion and exclusion criteria.

It is planned to review the medical records of the 170 patients from all participating countries, including Saudi Arabia, the UAE, Kuwait, Oman, and Qatar.

The final study will include 15 medical centers distributed as follows: 10 in Saudi Arabia; 3 in the UAE; and 1 medical center each from Qatar, Oman, and Kuwait.

This study is categorized as a Group E study with no applicable individual case safety reporting; however, either aggregate analysis may provide safety conclusions of interest for the product or, even if the analysis is not intended for safety purposes, it may raise a safety signal. Any potential safety signal will be transmitted to the company's pharmacovigilance department.

All data collected will be analyzed appropriately, and statistical analysis will be carried out by SPSS (version 18 or higher; IBM

Corp). The associated characteristics of RRMM will be described using frequency and percentage with a 95% CI. Other variables will be described using the mean (SD) for continuous variables and counts for categorical variables. Patients' variables will be compared using Mann-Whitney-Wilcoxon tests for continuous variables and chi-square for categorical variables. A probability value of less than 5% (P<.05) will be considered significant.

Primary Analysis

The associated characteristics of RRMM will be described using frequency and percentage with a 95% CI. This analysis will be descriptive and will be conducted on the eligible patients who fulfill the inclusion criteria and who have been selected during the specified study period.

Secondary Analysis

The disease history for MM will be assessed using frequency and percentage with a 95% CI. This analysis will be descriptive and will be conducted on eligible patients. The incidence of lenalidomide-refractoriness among patients with RRMM in the Greater Gulf region and the prevalence of renal impairment and asthma or COPD among patients with RRMM in countries of the Greater Gulf region will be presented using incidence density rates. Comparison will be done using Mann-Whitney-Wilcoxon tests for continuous parameters and chi-square for categorical parameters. The description of renal response (overall, per treatment line and regimen for patients with renal impairment), the overall treatment outcomes for patients with MM and patients with lenalidomide-refractory (per treatment line and regimen), and the percentage of patients with RRMM who are eligible for ASCT will be described using frequency and percentage. Univariate and multivariate analyses will be conducted on lenalidomide-refractoriness among patients with RRMM in the Greater Gulf region and other variables collected.

This section provides specifications for preparing the final statistical analysis plan, which will be issued before the database lock. Therefore, any differences compared to this statistical section should be identified and documented in the final statistical analysis plan.

Statistical Analysis

The data will be analyzed using SPSS version 26 software. Categorical variables will be reported as frequency (n) and percentage (%), while quantitative variables will be reported using descriptive measures such as mean, SD, and range. The chi-square test will be used to determine the association of different risk factors with treatment regimens. A value of P<.05 to determine the significance level will be used. Multivariate logistic regression analysis will be used to analyze the relationship between the dependent variable and multiple predictors or independent variables. PFS and OS will be used accordingly.

Ethical Considerations

This study is being conducted in accordance with the principles established by the 18th World Medical Assembly in Helsinki in 1964, along with all subsequent amendments [13]. All patient data will be handled anonymously to ensure patient confidentiality. In accordance with the institutional review board (IRB) approval obtained for this study, there is no requirement for informed consent. The final study will include 15 medical centers, distributed as follows: 10 in Saudi Arabia; 3 in the UAE; and 1 medical center each from Qatar, Oman, and Kuwait. IRB approvals were obtained from the participating countries. In Saudi Arabia, approval was obtained from Mouwasat Hospital under the IRB NCBE- KACST (H-05-D-12) on October 10, 2022; the Directorate of Health Affairs-Aseer Region (REC-15-06-2022) on June 20, 2022; King Faisal Specialist Hospital and Research Center under IRB 2022-47 on June 22, 2022; King Fahad Medical City under 2 hospitals—Al Mana Hospital (King Fahad Medical City approval as an external site, IRB 22-212E in December 2022) and Alkhobar Comprehensive Cancer Center (22-212 IRB 22-212) on July 26, 2022; King Saud University-Medical City under 22/0626/IRB on August 23, 2022; Prince Mohammed bin Nasser Hospital under 22058 on June 28, 2022; and King Abdullah International Medical Research Center-Al Ahsa and King Abdullah International Medical Research Center-Riyadh (IRB: 1519/22) on August 31, 2022. In UAE, approval was obtained from Burjeel Hospital (DOH/CVDC/2022/1473) on August 11, 2022; Cleveland Clinic Abu Dhabi (DOH/CVDC/2022/1622) on November 10, 2022; and Sheikh Shakhbout Medical City, Abu Dhabi, UAE (DOH/CVDC/2022/740) on April 28, 2022. In Oman, approval was obtained from Sultan Qaboos University Hospital (SQU-EC/174/2022 MREC#2801) on July 13, 2022. In Kuwait, approval was obtained from the ethics committee in the Ministry of Health (2022/1988) on May 17, 2022. In Qatar, approval was obtained from the National Center for Cancer Research (MRC-02-22-37) on October 2, 2022.

Data Analysis

Upon completion of this study, a comprehensive description of the demographic profile of patients with MM, including age, gender, and other relevant data, will be obtained. As well, data on patients undergoing different treatment modalities and regimens, including monotherapy or combination therapy, both overall and for each treatment line, will be collected. Additionally, information on the DoR and time to progression (TTP), both overall and within different treatment lines, will be gathered. This includes assessing the percentage of patients with lenalidomide-refractory in the first, second, and third relapse settings. The study will record the history of MM, including the duration of the disease, laboratory levels of biomarkers, and symptoms before diagnosis. Furthermore, we will investigate the proportion of patients with MM with renal impairment and asthma, COPD, or both at the time of diagnosis and at any point thereafter. These data will be collected for each treatment line and regimen. The changes in estimated glomerular filtration rate and other relevant parameters from baseline to evaluate renal response (whether it remains stable, improves, or worsens) will be analyzed. In addition, information on the proportion of patients prescribed lenalidomide at each treatment line and the treatment regimen for patients with lenalidomide-refractory will be retrieved. TTP and DoR among patients with lenalidomide-refractory in different treatment lines and regimens will be calculated according to the International Myeloma Working Group criteria [2]. For instance, the DoR

will be calculated in the subpopulation experiencing treatment response from the date when the response is first met to the date of the first documented progression, whereas the TTP will be calculated as the length of time from the date of diagnosis or the start of treatment for a disease until disease progression. Moreover, the proportion of patients eligible for ASCT at any time after diagnosis will be determined. The definitions of "relapsed" and "refractory" MM have been varied across clinical studies. While some studies have defined "relapsed" as those patients with recurrent malignancies following a remission or patients who were positively affected by rescue therapy yet experienced disease progression during their follow-up with or without maintenance therapy, others have defined patients with "refractory" MM as those who have a failed response (or showed a limited response) to rescue therapy or who progress within 60 days of their last regimen [14,15]. This study will assess the used definitions and their impact on the OS and PFS of the included patients.

Compliance

RAY-Contract Research Organization (CRO), a third party delegated by Sanofi, is solely responsible for taking all reasonable steps to ensure the proper conduct of the protocol regarding ethics, protocol compliance, and the integrity and validity of the data recorded on the case report form (CRF). The primary responsibility of RAY-CRO is to assist the investigating site in maintaining high standards of ethical, scientific, technical, and regulatory quality throughout the study.

At regular intervals during the study, the site will be contacted, through monitoring visits, letters, or telephone calls, by a representative of the monitoring team to review study progress, investigator and patient compliance with study protocol requirements, and any emergent problems. During these monitoring visits, the following but not exhaustive list of points will be scrutinized by the investigator: IRB approval, documentation and reporting, and quality of data in the CRF.

The main duty of the monitoring team of RAY-CRO will be to assist the investigator and the sponsor in maintaining high ethical, scientific, technical, and regulatory standards throughout the study. Regular monitoring visits, letters, or telephone calls will be made to the site to review study progress, investigator and patient compliance with study protocol requirements, and any emerging issues. During these visits, the investigator will be scrutinized on, but not limited to, the following points: IRB approval, data documentation, and the quality of data in the CRF.

Results

Patient medical records were reviewed between June 2022 and January 2023 for eligibility and data extraction. A total of 148 patients met the study inclusion criteria, of whom 64.2% (n=95) were male and 35.8% (n=53) were female. The study is currently in its final stages of data analysis, and the final manuscript is expected to be published in 2024.

Discussion

Summary

This study is expected to provide reliable data on MM and associated renal and pulmonary impairments in the Greater Gulf region, through the collection of real-world and epidemiological data from the medical records of patients with MM in countries in the Greater Gulf region. In addition, the study will describe the demographic characteristics and treatment landscape of patients diagnosed with RRMM who have relapsed at least once and maximally 3 times before study entry in the 2 years leading up to data collection. All patients who have relapsed at least once and a maximum of 3 times before study entry in the 2 years leading up to data collection will be included. The incidence of lenalidomide-refractoriness among patients with RRMM in the Greater Gulf region, the prevalence of renal impairment and asthma or COPD among patients with RRMM in countries of the Greater Gulf region, renal response, the overall treatment outcomes for patients with MM and patients with lenalidomide-refractory, and the percentage of patients with RRMM who are eligible for ASCT will be presented.

Expected Outcomes and Comparisons With Previous Work

Although MM has been detected at increasing rates in some countries of the Greater Gulf region [11,16], fewer studies have been conducted regarding low-income countries, including the Middle East and North Africa [17]. Nevertheless, the treatment of MM, largely in relapsed cases, poses major challenges. Although new drugs and other therapeutic interventions enhance the prognosis of MM, the availability of these drugs is limited across the Middle East [18]. Hence, this study will provide an overview of the treatment regimens and associated patient characteristics in Greater Gulf countries. Regardless of updated national guidelines established in the Greater Gulf countries, a deficiency in complete data to guide the decision makers of local patients is detected. Educational gaps arise, and bespoke initiatives are required to help oncologists individualize the treatment and translate the evidence-based endorsements into real-world practice [19,20]. With this study, we hope to elucidate the incidence of lenalidomide-refractoriness among patients with RRMM and the overall treatment outcomes for patients with MM and patients with lenalidomide-refractory (per treatment line and regimen) to guide physicians with the best treatment options and better survival outcomes.

Patients who experienced a ≥25% increase in serum or urine M protein have a biochemical relapse, are considered asymptomatic, and are closely monitored without treatment [21]. In contrast, patients with high-risk disease, including those with negative cytogenetics, suboptimal response to previous treatment, or aggressive disease at diagnosis [22], or those who exhibit a rapid escalation in serum or urine M protein levels, for instance, a doubling time of 2 months or less, should initiate therapy immediately [23]. It is expected that if our patients reveal symptomatic relapse, it should be managed based on the criteria of the International Myeloma Working Group. We hope that this study can provide us with the actual management

procedures followed in each country and the consequent responses of those patients.

Regarding the demographic data for MM, age is considered a crucial prognostic factor for patients with MM. Patients aged above 50 years at diagnosis usually exhibit significantly shorter median survival times than younger patients [24]. Nevertheless, recent MM therapy protocols have improved the clinical outcome, particularly in patients younger than 70 years [24,25], while the survival advantage has been recently detected in older patients [26]. This controversial conclusion regarding the improved survival in the older population with MM could be due to the detected variability of the age range included in interventional clinical trials (ie, aged between 60 and 65 years) and the median age of patients with MM at diagnosis (usually around the age of 70 years) in other studies. The median time for diagnosis for these patients usually ranges between 2 and 4 years [23]. According to a study conducted in Jordan, the median age of the included patients was 62 years, the mean OS was 74 months, and the median survival was 38 months [17]. Our anticipated results will provide us with a clear indication of the age range and the influence of age on the prognosis and survival of those patients.

In addition, patients older than the age of 75 years exhibit an increased cumulative incidence of renal insufficiency and cardiovascular disease, from 47.7% at MM diagnosis to 67.8% at the first relapse exhibited. Moreover, in patients with MM aged 75 years or older, the risk of relapse post–second-line therapy increased significantly and alternated by time to the next treatment [11]. Nevertheless, younger patients have exhibited better survival than older populations, particularly those younger than 40 years of age, where they are rarely detected with such comorbid diseases [27]. Additionally, geriatric assessments were recommended to be incorporated into routine clinical practice at the diagnosis of MM and for the exclusion of differential diagnoses in the very elderly. This approach aims to achieve optimum therapy and the adjustment of both dosing and regimens for improved effectiveness and tolerability [28]. As such information is missed among patients with MM in the Greater Gulf countries, this study shall provide us with more details regarding the prognosis of patients aged over 75 years with renal insufficiency, cardiovascular diseases, or both; their management procedure; and the effect of younger age over survival.

For lenalidomide-refractoriness among RRMM, improvement in renal function in patients with RRMM and renal impairment following lenalidomide- or dexamethasone-based treatment has been revealed by many studies [29-31]. Similarly, patients with MM presented with asthma or COPD showed significantly longer time from first- to second-line treatment. Additionally, the OS from first-line therapy was remarkably lower among patients with COPD, with a statistically significant decline in the OS from second-line therapy [32]. As no previous studies in the Middle East and North Africa region have provided the effect of first- or second-line treatment on patients with associated asthma or COPD, this study will assess the OS and PFS in those patients and compare the influence of first- or second-line therapy on survival.

Limitations

Anticipated limitations of this study include the heterogeneity of management guidelines among the included countries, which may restrict the results obtained from real-world data by reflecting actual practice, influenced by patient compliance and environmental factors rather than solely by the efficacy of the drugs. Furthermore, despite the relative consistency of first-line therapy in the countries of the Gulf Cooperation Council, several different treatment options become available after the first relapse. This study may not be able to comprehensively capture the multiple factors influencing the selection of specific regimens at the first stage of progression. Additionally, the proportion of patients receiving anti-CD38 monoclonal antibody therapy such as daratumumab or isatuximab, which has significantly transformed the MM treatment landscape, remains relatively limited to date.

Conclusion

This study will provide a more comprehensive understanding of the management of MM in the Greater Gulf region, with a particular focus on the renal and pulmonary complications that may arise. We will delve into the wider significance of this study, addressing potential predisposing factors and their implications for clinical practice and public health in the region. This study seeks to shed light on how the insights gained can inform healthcare strategies and ultimately enhance the quality of care for patients with MM in this specific geographic area.

Acknowledgments

The authors would like to thank Dr Shimaa Ragab, from RAY-CRO, for her valuable editorial support. The authors also acknowledge Dr Omar M Hussein and Dr Reham Elgarhy, from RAY-CRO, for their valuable review and guidance. The study is conducted by Sanofi Saudi Arabia, Tahlia Street, Nojoud Center, Gate C, Jeddah, Saudi Arabia. Sanofi will provide the basic study material (study outline and protocol template) needed for RAY to develop the study materials, including protocol information, data collection items, a review of the medical manuscript, and approval for journal submission. Furthermore, in accordance with local and international regulations, Sanofi Saudi Arabia will be responsible for the monetary funding for the study conducted and publication, and RAY Clinical Research Organization will ensure operational execution. Also, we confirm that this study protocol was revised by the representative of Sanofi before submission.

Data Availability

Data will be presented in the main manuscript or additional supporting files whenever possible. After completing the study, the data obtained during and/or analyzed during this study will be available upon request through the corresponding author. The authors hereby state that no generative artificial intelligence was used in any portion of the manuscript writing.

Authors' Contributions

The principal investigator for this study is AN, who developed the initial draft of the protocol. Further versions were edited by A Alshehri, A Alhejazi, BU, GE, and HM, while IM, KAF, MA, MS, and RG reviewed the content and development of the paper. All authors provided inputs for the study protocol and approved the final version of the manuscript after their revisions.

Conflicts of Interest

MR and MZC are employees at Sanofi. The authors have no further conflicts to declare.

Abstract

Background: In the last few years, several nicotine products have become available as alternatives to smoking tobacco. While laboratory and limited clinical studies suggest that these devices are less toxic compared to classic tobacco cigarettes, very little is known about their epidemiological impact. Visiting the emergency department (ED) often represents the first or even the only contact of patients with the health care system. Therefore, a study conducted at the ED to assess the impact of these products on health can be reliable and reflect a real-life setting.

Objective: The aim of this noninterventional observational study (SMOPHED study) is to analyze the association between the severity of clinical presentation observed during ED visits among patients using various nicotine products and the subsequent outcomes, specifically hospitalization and mortality.

Methods: Outcomes (hospitalization and mortality in the ED) will be examined in relation to various patterns of nicotine products use. We plan to enroll approximately 2000 participants during triage at the ED. These individuals will be characterized based on their patterns of tobacco and nicotine consumption, identified through a specific questionnaire. This categorization will allow for a detailed analysis of how different usage patterns of nicotine products correlate with the clinical diagnosis made during the ED visits and the consequent outcomes.

Results: Enrollment into the study started in March 2024. We enrolled a total of 901 participants in 1 month (approximately 300 potential participants did not provide the informed consent to participate). The data will be analyzed by a statistician as soon as the database is completed. Full data will be published by December 2024.

Conclusions: There is substantial debate about the harm reduction potential of alternative nicotine products in terms of their smoking-cessation and risk-reduction potential. This study represents an opportunity to document epidemiological data on the link between the use of different types of nicotine products and disease diagnosis and severity during an ED visit, and thus evaluate the harm reduction potential claims for these products.

KEYWORDS

NEWS; National Early Warning Score; emergency department; smoking; nicotine/tobacco use; electronic cigarettes; heated tobacco products

Introduction

Smoking-related diseases are a well-known group of pathologies that are responsible for 8 million deaths per year globally [1]. Despite numerous restrictions, taxation, and communication campaigns, there are still more than 1.3 billion smokers globally. Quitting smoking remains one of the most cost-effective methods to reduce health risks. However, the success rate of smoking cessation methods remains low in real-world settings [2-5]. Additionally, a substantial proportion of smokers are unwilling to use smoking cessation services but would prefer switching to a less harmful alternative product [6,7]. In the last few years, several alternatives to smoking nicotine products have become available, which are commonly referred to as electronic nicotine delivery systems (ENDS), namely e-cigarettes and heated tobacco products (HTPs). While laboratory and limited clinical studies suggest that these products reduce exposure to toxins and may thus reduce health risks [8-12], very little is known about their epidemiological impact.

Several studies have demonstrated a high proportional cigarette smoking prevalence in patients presenting to the emergency department (ED), which is higher than the prevalence in the general population [13-19]. This is expected considering the disease burden caused by smoking, which might result in more ED visits for smokers compared to nonsmokers. Current smoking as well as smoking relapse were found to be significantly associated with ED visits [20-24]. Access to the ED often reflects the first or the only contact of patients with the health care system; thus, the ED visit represents an opportunity to record smoking and nicotine use patterns. However, no studies have systematically recorded use patterns for ENDS in relation to ED visits. Considering the growing popularity of these products and the limited epidemiological evidence on their health effects, a detailed recording of use patterns for all nicotine products is important to monitor their use prevalence, health care system burden, and epidemiological impact.

The National Early Warning Score (NEWS) is a standardized tool used for assessing and responding to acute illness in patients admitted to the ED [24]. The NEWS is based on a straightforward aggregate scoring system, assigning scores to routine physiological measurements taken when patients either present at or are monitored in the hospital. The scoring system is based on six key physiological parameters: (1) respiration rate, (2) oxygen saturation, (3) systolic blood pressure, (4) pulse rate, (5) level of consciousness or new confusion (alert, verbal, pain, unresponsive [AVPU] scale), and (6) temperature.

For patients accessing the ED, the NEWS aids triage nurses in determining the appropriate urgency level for patient examination, which is represented by color codes. This stratification is based on the severity and urgency of the patient's condition.

The aim of this study is to accurately document the patterns of smoking and nicotine product use, including ENDS, in patients visiting the ED. A key focus is to investigate whether the use of ENDS is associated with any measurable differences in disease severity and outcomes compared to conventional tobacco smoking among these patients.

Methods

Study Design

The Smoking or Nicotine Phenotype and Severity of Clinical Presentation at the Emergency Department (SMOPHED) study is an observational study with no intervention or randomization, analyzing the association between the patient's health condition during an ED visit as well as the outcome (hospitalization and death) and different patterns of nicotine products use. Specifically, the study will explore relevant associations according to the smoking and ENDS product use status (current, former, and never use). The pilot phase of the study will take place at a single clinical center, aiming to evaluate its feasibility and analyze the results. Upon successful completion, there are plans to expand the study into a multicenter format involving a national network comprising 10-12 EDs.

Study Population

Inclusion and exclusion criteria are summarized in Textbox 1. Participants will be recruited among patients presenting at the ED of Policlinico Teaching Hospital of Catania, Italy, in 1 month during the diurnal shift. Only patients that access the ED for a nontraumatic reason will be screened, since it is unlikely that smoking or use of other nicotine products can have any causal effect on accident incidence and subsequent diagnosis. The study will take place during daytime working hours owing to organizational constraints. Typically, our ED admits approximately 70-80 patients for nontraumatic issues during a daytime shift, which runs from 8 AM to 8 PM.

We calculated the expected sample size for the study based on available national and regional statistics, providing a practical approach to estimating the study's sample size. The current and former smoking rates in Sicily are estimated at 22.5% and 13.3%, respectively [25], while the combined prevalence of combustion-free products use (e-cigarettes and HTPs) stands at approximately 5% [26]. Considering the annual Catania ED access rate of 80,000 (monthly access rates of 6000-6500) [27], we anticipate recruiting no less than 1500 current smokers and 1000 former smokers per month. Additionally, we expect to enroll no less than 350 users of combined e-cigarettes/HTPs

per month (dual usage is estimated at approximately 50% of the total). Since approximately 70 patients per day access the ED during the diurnal shift for nontraumatic reasons, we expect to enroll approximately 2000 participants in 1 month.

Textbox 1. Inclusion and exclusion criteria for study participation.

Inclusion criteria

- Adult (aged≥18 years)
- Ability to understand and sign the informed consent form

Exclusion criteria

- Accessed the emergency department for a traumatic accident
- Pregnancy

Ethical Considerations

The study will be conducted according to the principles of Good Clinical Practice and the Declaration of Helsinki. Ethical clearance for this protocol was obtained through the ethical review board "Comitato Etico Catania 1" at Policlinico Teaching Hospital of Catania (84/2023/PO del Registro dei pareri del CE) on April 17, 2023. If any amendments to this protocol are required, the chief investigator will be responsible for the decision to amend the protocol and for deciding whether an amendment is substantial or nonsubstantial. Any substantial amendments will be submitted to the research ethics committee for approval before implementation. Informed consent from study participants will be obtained by the investigators through relevant forms. A dedicated website will be created for the study. This website will respect the General Data Protection Regulation policy. Every study team member will access the site with a personal and unique ID and password. The website will create two different databases to guarantee participants' privacy. The first database will record the fiscal code of the participant and will assign a unique ID. The second database will anonymously record the data from each participant using only the participant's ID. It is necessary to create two databases so that additional information on outcomes or other missing data will be recorded at a later time.

Patients will be asked for authorization to use their clinical data in an anonymous format, in accordance with the current privacy directives related to access to the ED. The informed consent model will be shown to participants who must be able to understand and sign it as an inclusion criterion to participate in the study. All collected informed consent forms will be stored at the ED of Policlinico Teaching Hospital of Catania. No financial or other incentives will be provided to the participants.

Data Collection

On arrival at the ED, each patient undergoes a triage phase. A nurse is usually responsible for evaluating the severity of the health condition and the priority for clinical assessment (unless the patient enters the ED by ambulance under a red code). The nurse usually performs this task by collecting vital signs and recording the patient's medical history. This information is then used to assign a color code representing the priority for further assessment. The patient then waits for the medical evaluation in a dedicated room where nurses can monitor the clinical condition of all attending patients. Participants who meet the inclusion criteria will be recruited during this phase and will be administered an electronic questionnaire (see Multimedia Appendix 1) about their smoking and nicotine product use habits and their medical history. This questionnaire serves to typify the patient's use phenotype and quantify exposure to each product.

In addition to the questionnaire, medical data recorded at the triage phase, such as the NEWS, heart rate, blood pressure, blood oxygen saturation, respiratory rate, temperature, and fraction of inspired oxygen, will be collected.

After the assessment and management of each patient in the ED, the final diagnosis, final disposition, and color code at discharge or admission to a ward will be recorded (see Table 1). To avoid compromising the health of patients with severe disease requiring urgent medical attention, potential participants who arrive at the ED under a red code (ie, with a severe acute illness) will be asked to participate only after they are stabilized (ie, the questionnaire, NEWS, and vital signs will be recorded later).

Based on the responses to the questionnaire, participants will be divided in the following 5 smoking subgroups to facilitate analysis: (1) current tobacco smoker, (2) former tobacco smoker, (3) former tobacco smoker now using e-cigarettes and HTPs (exclusive use), (4) current tobacco smoker also using e-cigarettes and HTPs (dual use), and (5) never smokers or e-cigarette/HTP users.

After 1 month, data in the electronic case report form (eCRF) will be extracted for the statistical analysis.

Since the ED is usually very crowded, four study team personnel will work on the study and will screen and recruit patients during the waiting period before the medical examination. The study team will interview potential participants in a dedicated room within the ED area to guarantee privacy. The initial survey will last approximately 5 minutes per patient. This is a reasonable time to collect product use information from each participant. After the medical visit and final disposition, compilation of the eCRF will be completed as provided by the study protocol, with each study member collecting all necessary information about the patients' outcome (discharge or admission to a ward) by the end of their shift. Some patients may stay in the ED beyond the length of a diurnal shift; in such a case, the data will be collected the day after their arrival. Some patients might access the ED

two or more times during the study. To avoid double entries, only the first visit will be included for analysis in the study. The eCRF database will reply with an error if we try to recruit a patient with the same fiscal code a second time (a fiscal code is a unique identifying code in Italy, and it is mandatory to be recorded for each patient during the triage phase in the ED).

Table 1. Data to record in the electronic case report form.

Data type	Value/units
NEWS[a] calculated at the patient's triage phase (conventionally, patients with an acute condition will be recorded as being at high risk, corresponding to NEWS>7)	0-17
Vital signs recorded during triage	
Heart rate	Beats per minute
Blood pressure	mmHg
Blood oxygen saturation	%
Respiratory rate	Breaths per minute
Body temperature	°C
Fraction of inspired oxygen	%
Smoking questionnaire	See Multimedia Appendix 1
Medical history and drug use history	Textual
Length of stay in the ED[b] or in the hospital (if admitted))	Hours and minutes, or days if admitted
Final diagnosis of discharged patients	Textual
Final disposition	Admitted/discharged
Final diagnosis of admitted patients	*ICD-9*[c] codes

[a]NEWS: National Early Warning Score.

[b]ED: emergency department.

[c]*ICD-9: International Classification of Diseases, 9th edition.*

Endpoint and Outcomes

The primary endpoint of the study is the association between the NEWS and product use phenotypes. Our hypothesis is that use of ENDS may be associated with a lower NEWS compared to cigarette smoking. If our hypothesis will be confirmed, the study will be replicated as a multicenter study to validate our findings.

Secondary outcomes will be hospital admissions (vs discharge) and length of stay in the ED and in the hospital (if admitted). Moreover, we will compare the prevalence of acute diseases known to be related to smoking between groups, specifically stroke, acute myocardial infarction, peripheral artery diseases, chronic obstructive pulmonary disease, asthma, and respiratory infections.

Statistical Analysis

Descriptive analysis will be performed by presenting numerical data as mean (SD) and categorical data as n (%). Patients will be classified according to product use as a current tobacco smoker, former tobacco smoker, former tobacco smoker now using e-cigarettes and HTPs (exclusive use), current tobacco smoker also using e-cigarettes and HTPs (dual use), and never smokers/never e-cigarette or HTP users.

Univariate comparisons will be performed using χ^2 tests for categorical variables and the Kruskal-Wallis H test for the NEWS. Regression analyses will be performed to examine the association between the use of different types of products and the NEWS as well as secondary outcomes. Demographics, including age, sex (male or female), and educational level, as well as past medical history will be included as independent variables. Since the majority of ENDS users report current or past smoking, the smoking status of these users will also be recorded along with those who do not report any ENDS use. Therefore, the analysis will be adjusted for the smoking status of ENDS users. Additionally, secondary analyses will be performed for never-smoking ENDS users, if a sufficient number of such participants will be available. All analyses will be performed using SPSS v.25 (IBM) and a P value <.05 will be considered statistically significant.

Dissemination

The intention of the authors is to disseminate the results of the study through articles in high-quality, peer-reviewed journals and through conference abstracts.

Results

In March 2024, we have enrolled a total of 901 participants (approximately 300 potential participants did not provide the informed consent to participate). The data will be analyzed by a statistician as soon as the database is completed. Full data will be published by December 2024.

Discussion

This protocol was designed to evaluate the impact of smoking and the use of other nicotine products on ED visits, including the respective clinical diagnoses and outcomes. Smoking is a leading preventable cause of morbidity and mortality. It is estimated that tobacco use accounts for 3%-6% of all ED visits and 5%-16% of total hospital expenses [28-30]. Smokers with preexisting diseases such as diabetes and asthma are more prone to ED visits than nonsmokers with similar conditions [23,31].

The smoking prevalence among patients at the ED surpasses that of the general population [16,18], indicating the ED as a key setting for managing smoking-related health issues. In recent years, there has been an intense debate about the harm reduction potential of ENDS. Some studies have shown their effectiveness in smoking cessation [32], yet there is scarce epidemiological evidence on the clinical impacts of noncombustible nicotine products. This study will be the first to explore the link between the use of various nicotine products and ED visits, as well as their association with urgent care needs for smoking-related disease.

Approximately one decade ago, our research group conducted the ECLAT study, which was the first randomized controlled trial that established the efficacy and the safety of e-cigarettes as smoking substitutes [33]. Since then, a newer generation of e-cigarettes, which are more efficient in nicotine delivery and more appealing, have shown encouraging results in clinical and real-world settings [34-41]. Therefore, they may represent a viable alternative for individuals unable or unwilling to quit smoking using approved methods. Nonetheless, it is important to thoroughly investigate and document the potential risk-reduction potential of these products in a clinical context.

Little epidemiological evidence exists on the harm reduction potential of ENDS. This study thus represents an opportunity to document epidemiological data on the link between the use of different nicotine products and disease severity during an ED visit, as well as clinical outcomes and associations with specific (ie, smoking-related) diseases. Besides further exploring the epidemiological impact of ENDS on diseases related to smoking, the implications of this study are also directly related to understanding the currently unknown burden of these products on emergency care resource use, particularly in the context of the well-known substantial effects of smoking on increasing ED visits. The systematic tracking of the impacts of nicotine use in this study will help to highlight the magnitude of tobacco and nicotine use in the community in relation to access to emergency health care services, and will enable those responsible for tobacco control policies, programs, research, and surveillance to assess the situation and inform decision-making.

This study, currently conducted in a single hospital, serves as a pilot phase, aiming to evaluate its feasibility and analyze the results. The ultimate objective is to expand this research to additional EDs within a national network.

Documenting the association between ENDS use and ED visits will provide insights on both local and central policy levels, especially when we consider that emergency and urgent care systems struggle with major challenges in developed countries with crowding, long waiting times, and, in general, increasing numbers of ED visits [42]. Therefore, it is important to examine factors associated with ED visits and adverse outcomes, and to assess if ENDS affect the ED burden in a different manner to smoking. At the same time, this study may document the need for routinely recording nicotine use habits for all patients accessing the ED instead of the current norm of recording smoking status only.

This study has several limitations. The brief period of recruitment and the use of only one study site may introduce sampling bias due to seasonality and locality. Therefore, this study may have limited generalizability to all Italian EDs. However, as mentioned above, this represents a pilot study with the purpose of further expanding the protocol to more regions and several EDs from other hospitals. While it is possible to verify exposure to tobacco smoke by measuring exhaled carbon monoxide and exposure to nicotine by measuring salivary cotinine, logistical and financial restrictions within the short duration of an ED presentation, as well as the urgent nature of attendance requested in the ED, preclude us from performing an objective assessment of the smoking status. Although self-report of smoking status has been shown to be accurate in the ED setting [17], a systematic review (despite including studies outside the ED setting) showed some discrepancy between self-report and objective assessment [43]. In addition, determining nicotine exposure would not help to distinguish between the use of tobacco cigarettes and noncombustible nicotine products. Moreover, the responses to questions on past smoking and nicotine use habits may be introducing recall bias. Finally, the exclusion of patients in a critical state who need urgent care will be compensated by a subsequent request to participate in the study once they are stabilized.

In conclusion, this study protocol addresses the need for additional epidemiological evidence on the effects of ENDS on health, with clinical endpoints. The ED setting represents an opportunity to record smoking and nicotine habits, assess the burden of different products, and provide guidance for interventions at both the personal and systematic level.

Acknowledgments

The publication cost of this paper has been supported by the Department of Clinical and Experimental Medicine of the University of Catania, Italy. DC is supported by a ministerial grant PON REACT-EU 2021 GREEN- Bando 3411/2021 of Ministero dell'Universita' e della Ricerca –Piano Nazionale di Ripresa e Resilienza (National Resilience Recovery Plan) EU Community.

Abstract

Background: Preeclampsia (PE) is one of the most common hypertensive diseases, affecting 2%-8% of all pregnancies. The high maternal and fetal mortality rates of PE are due to a lack of early identification of affected pregnant women that would have led to closer monitoring and care. Recent data suggest that misfolded proteins might be a promising biomarker for PE prediction, which can be detected in urine samples of pregnant women according to their congophilia (aggregated) characteristic.

Objective: The main purpose of this trial is to evaluate the value of the urine congophilia-based detection of misfolded proteins for the imminent prediction of PE in women presenting with suspected PE. The secondary objectives are to demonstrate that the presence of urine misfolded proteins correlates with PE-related maternal or neonatal adverse outcomes, and to establish an accurate PE prediction model by combining misfolded proteins with multiple indicators.

Methods: At least 300 pregnant women with clinical suspicion of PE will be enrolled in this prospective cohort study. Participants should meet the following inclusion criteria in addition to a suspicion of PE: ≥18 years old, gestational week between 20+0 and 33+6, and single pregnancy. Consecutive urine samples will be collected, blinded, and tested for misfolded proteins and other PE-related biomarkers at enrollment and at 4 follow-up visits. Clinical assessments of PE status and related complications for all participants will be performed at regular intervals using strict diagnostic criteria. Investigators and participants will remain blinded to the results. Follow-up will be performed until 42 days postpartum. Data from medical records, including maternal and fetal outcomes, will be collected. The performance of urine misfolded proteins alone and combined with other biomarkers or clinical variables for the prediction of PE will be statistically analyzed.

Results: Enrollment started in July 2023 and was still open upon manuscript submission. As of March 2024, a total of 251 eligible women have been enrolled in the study and enrollment is expected to continue until August 2024. Results analysis is scheduled to start after all participants reach the follow-up endpoint and complete clinical data are collected.

Conclusions: Upon completion of the study, we expect to derive an accurate PE prediction model, which will allow for proactive management of pregnant women with clinical suspicion of PE and possibly reduce the associated adverse pregnancy outcomes. The additional prognostic value of misfolded proteins is also expected to be confirmed.

Introduction

Background

Preeclampsia (PE) is one of the most common hypertensive diseases in pregnancy, characterized by elevated blood pressure accompanied by proteinuria or organ damage after 20 weeks of gestation [1]. The incidence of PE is approximately 2%-8% worldwide [2,3], and each year, an estimated 76,000 women and 500,000 fetuses die from PE and related complications [4]. Symptoms of PE are not specific, including headache, visual impairment, upper abdominal pain, and shortness of breath, among others. In severe cases, PE may develop into eclampsia, which involves seizures or coma [5-7]. PE may also lead to placental abruption; intrauterine growth restriction; hemolysis with a microangiopathic blood smear, elevated liver enzymes, and low platelets (ie, HELLP syndrome, a life-threatening liver and blood clotting disorder); and other serious health consequences for both the pregnant woman and fetus [8,9]. To date, the treatment of PE has mainly involved the use of antihypertensive medications such as methyldopa, labetalol, and hydralazine to lower blood pressure and prevent further maternal complications [10-12], and magnesium sulfate is also administered to prevent seizures in severe cases [13]. However, the only curative treatment of PE is to deliver the placenta. The current clinical strategy for PE is focused on the early screening and close monitoring of high-risk pregnancies, since low-dose aspirin therapy has proven to be effective in reducing the risk of developing PE by 62% [14]. Although potential biomarkers and ultrasonic techniques for detecting PE have been evaluated in recent decades, none has adequate positive or negative predictive value for the prediction of PE [15-17].

With increasing knowledge of the condition, six stages of PE have been proposed [6]. Defective placentation (stage 3) results in oxidative stress, and placental-derived products are released into the maternal blood (stage 4) before PE is diagnosed (stage 5). Recently, an increased level of misfolded proteins in the urine has been identified in patients with PE [18], suggesting that PE might share pathophysiologic features with recognized protein misfolding disorders such as Alzheimer disease. In patients with PE, misfolded proteins such as amyloid beta and transthyretin can accumulate in the circulation to exert neurotoxic effects and activate inflammatory cascades, leading to endothelial dysfunction and oxidative stress. Buhimschi et al [18] demonstrated that a dot test using Congo Red, a synthetic diazo dye with specific affinity for misfolded proteins, to visualize this aggregation feature (ie, congophilia) for detecting the presence of misfolded proteins in urine could serve as a promising diagnostic tool for PE. Li et al [19] subsequently developed a simple and rapid point-of-care testing (POCT) tool to detect the presence of misfolded proteins in urine based on visual observation, which achieved an overall sensitivity of 73.6% that reached up to 83% for severe PE cases.

The traditional approach for PE screening is to identify risk factors based on maternal demographic characteristics and medical history; however, this approach can only identify 35% of total PE cases and 40% of preterm PE cases, with a false-positive rate of approximately 10% [20,21]. A noninvasive laboratory method involving measurement of the ratio of soluble FMS-like tyrosine kinase 1 (sFLT-1) to placental growth factor (PlGF) in the urine proved to be effective in PE diagnosis, achieving a sensitivity of 70%-72.5% with a 5%-14% false-positive rate [22,23]. Thus, combining urine PlGF and sFLT-1 testing with other biomarkers may yield the best predictive performance.

In this trial, we will test a new congophilia-based detection method alone or combined with clinical variables and other urine biomarkers to predict the onset of PE before its clinical manifestation. This work can therefore help clinicians better identify PE earlier, enabling the proactive management and monitoring of pregnant women who exhibit signs or symptoms of PE but do not meet the current diagnostic criteria.

Objective

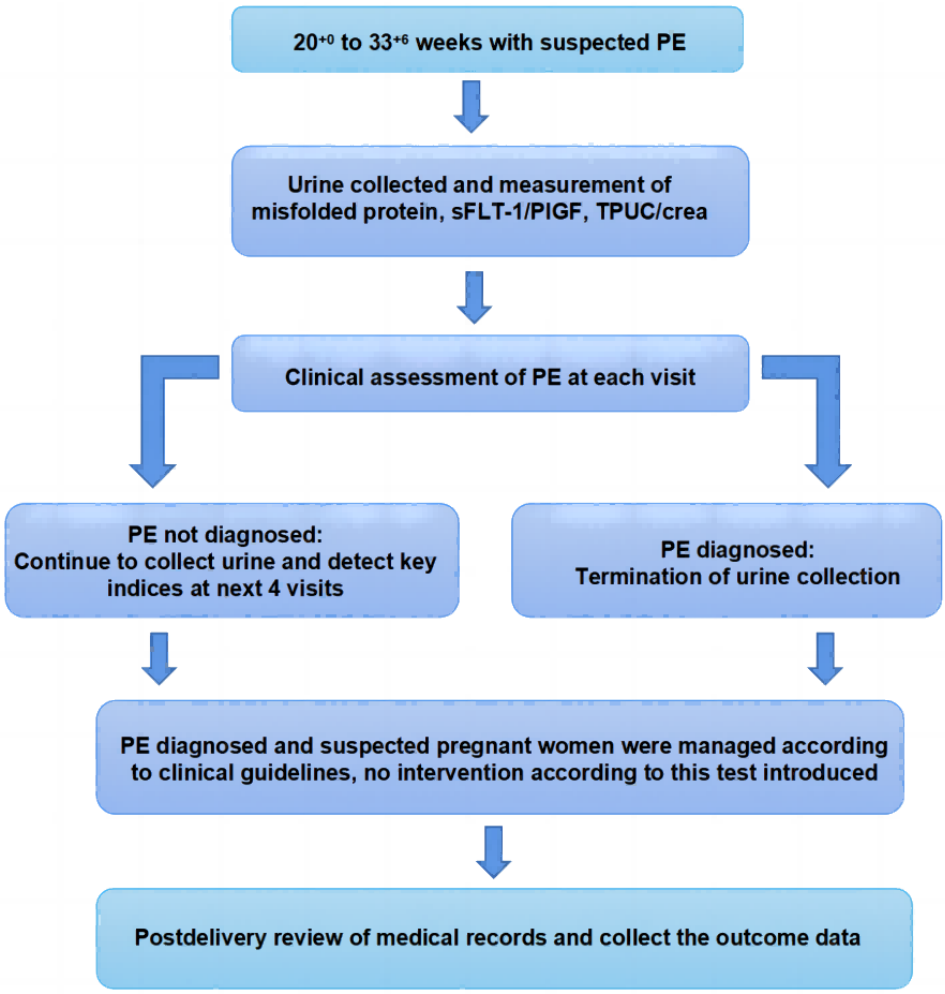
The primary objective of this study is to assess the short-term predictive potential of the new congophilia-based detection tool for PE onset in pregnant women with a clinical suspicion of PE. That is, we aim to confirm whether the urine misfolded protein level can be used to rule in or rule out PE in the short term. The secondary objectives are to evaluate whether the urine misfolded protein level correlates with PE-related maternal or neonatal adverse outcomes and to establish an accurate PE prediction model by combining misfolded protein values and multiple indicators.

Methods

Study Design

This is a prospective noninterventional clinical trial planned in accordance with the principles of evidence-based medicine using the PICO (patient, problem, or population; investigated condition; comparison; and outcome) criteria. The study procedure is outlined in Figure 1.

Figure 1. Flowchart of participants with suspected preeclampsia (PE) in the trial. Eligible pregnant women will be enrolled, and consecutive urine samples will be collected at each visit. Urine samples will be blinded and tested for misfolded proteins and other PE-related biomarkers. No intervention according to the test results will be introduced. Required clinical information will be collected from patients' medical records. crea: creatinine; PlGF: placental growth factor; sFLT-1: soluble FMS-like tyrosine kinase 1; TPUC: Total Protein in Urine.



Ethical Considerations

The trial is being conducted in accordance with ethical principles derived from the Declaration of Helsinki and is in line with Good Clinical Practice and applicable regulatory requirements. The clinical research ethics committee of Women's Hospital, School of Medicine, Zhejiang University has reviewed the trial protocol, and full ethical approval has been granted (IRB-20230198-K). Each woman identified as eligible for the study is required to give written informed consent, including but not limited to, for primary data collection and secondary analyses of research data prior to inclusion in the trial.

Apart from sample collection and required assessments during follow-up, the study does not involve any further impact on the patients' clinical procedures. The patients' PE status will be kept confidential from laboratory technicians, and neither the investigator nor the patient will know the detection results, which ensures that the clinical therapeutic scheme and pregnancy outcomes will not be affected.

Recruitment

Potential participants will be identified by the research team from the antenatal clinic at Women's Hospital, School of Medicine, Zhejiang University. Eligible women must meet all inclusion criteria without violating any of the exclusion criteria (Textbox 1) and will be provided with the participant information and consent form to sign. A research team member will provide a verbal explanation of the trial, including a description of the trial processes, the voluntary nature of the trial, and that a decision of whether or not to participate will not affect normal clinical care. No trial-related procedures will be performed on any individual without their prior written informed consent. All participants will be followed up until 42 days postpartum.

Textbox 1. Inclusion and exclusion criteria for determining trial eligibility.

Inclusion criteria

1. Aged ≥18 years.
2. Gestational week 20+0 to 33+6.
3. Signed written informed consent.
4. Single pregnancy.
5. Clinically suspected preeclampsia (PE), meeting one or more of the following criteria:

(i) new onset of elevated blood pressure (systolic ≥130 mmHg and/or diastolic ≥80 mmHg);

(ii) aggravation of preexisting hypertension (increase of more than 30 mmHg systolic/15 mmHg diastolic from the basic blood pressure in patients without hypertension, or a significant increasing trend or increase beyond the controlled level based on the original treatment for patients with hypertension);

(iii) new onset of proteinuria (no urinary tract infection);

(iv) one or more clinical symptoms indicate suspected PE (other possible causes have been ruled out): upper abdominal pain, headache with impaired vision, fetal growth restriction, thrombocytopenia (platelets count<100×10^9/L), liver function impairment (elevated blood concentrations of liver transaminases up to twice the normal concentration), and renal impairment (serum creatinine>1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease).

Exclusion criteria

1. Confirmed diagnosis of PE/chronic hypertension with PE (superimposed PE).
2. Confirmed diagnosis of eclampsia.
3. Confirmed diagnosis of hemolysis with a microangiopathic blood smear, elevated liver enzymes, and low platelets (HELLP syndrome).
4. Fetal chromosomal abnormalities.
5. Concomitant participation in another clinical study.
6. Received investigational intervention drugs in the past 3 months.
7. Visible hematuria.
8. Preexisting renal disease.

Sample Size

The target negative predictive value (NPV) is 99% and the target positive predictive value (PPV) is 54.0%. A positive test rate of 15% is assumed. The Type I error is set to .05. A sample size of 280 should be sufficient to detect NPV>90% and PPV>25% with 80% power. Therefore, at least 300 eligible participants will be included in this study considering a dropout rate of 6%. To avoid an overrepresentation of cases of late-onset PE, no more than 50% of the enrolled participants will be at 32 weeks gestation or above and no less than 20% of the enrolled participants will be at gestational week below 28+0 at inclusion.

Study Groups: Classification of Cases and Controls

Standard diagnostic criteria [24,25] for PE are new onset of hypertension (systolic blood pressure≥140 mmHg or diastolic blood pressure≥90 mmHg measured on two occasions at least 4 hours apart) and new-onset proteinuria (≥300 mg/day or protein/creatinine ratio ≥0.3 mg/dL) after 20 weeks of gestation. Diagnostic criteria in the absence of proteinuria include any of the following: (1) thrombocytopenia (platelets count<100×10^9/L); (2) liver function impairment (elevated blood concentrations of liver transaminases to twice the normal concentration); (3) renal insufficiency (serum creatinine>1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease); (4) pulmonary edema; and (5) central nervous system abnormalities or visual disturbances.

Cases are defined as patients who develop PE at any time between the first visit to 6 weeks (42 days) postpartum.

Controls are patients who do not develop PE throughout the pregnancy and up to 6 weeks (42 days) postpartum.

Outcome Measures

The primary outcome is the onset of PE after study inclusion. The secondary outcomes are the following maternal and fetal adverse outcomes: maternal death, pulmonary edema, acute renal failure, cerebral hemorrhage, cerebral thrombus, disseminated intravascular coagulation, eclampsia, HELLP syndrome, rupture of placenta, placental abruption, perinatal death, stillbirth, intrauterine growth restriction, small for gestational age, respiratory distress, necrotizing enteritis, intraventricular hemorrhage or subdural and cerebral hemorrhage, neonatal hypoxic encephalopathy, or periventricular leukomalacia. In addition, the date and mode of delivery, fetal weight, and Apgar score are important outcome measures.

Data Collection

Participant data for this study will be collected by investigators and input into an electronic case report form (eCRF). The data will be verified by the principal investigator when suspicious

data entries are noted. The data manager will check the completion of the data for final analysis. The study will include 6 visits plus a postpartum documentation. The first visit starts at enrollment, followed by 4 visits once a week when participants come for their routine prenatal examinations. There will be one visit at delivery as well as one postpartum documentation. On occurrence of pregnancy complications, further visits are possible. The clinical data to be collected during each visit are summarized in Table 1. The time interval between two consecutive visits could be 7±2 days, and adherence to the time schedule is crucial for incorporating participant data into the final analysis.

Table 1. Summary of the data collection procedure and timeline.

Sampling and Detection

Urine Sampling and Storage

All enrolled participants will be provided with a sterile cup to collect no less than 5 milliliters of midstream urine at each visit. The sampled urine tubes will be frozen and stored at –20 °C no later than 4 hours after collection. Samples will be shipped frozen to a local laboratory for further analysis.

Urine Coding

At enrollment, each participant will be assigned a specific study number to protect their anonymity. The leading principal investigators will ensure that the participants' anonymity is maintained in the trial database and during the whole research process. Samples collected from one participant at one time will be labeled with the same number to allow tracking and identification of any aliquot prepared from the original urine and for sample programming in laboratory analyzers. The test results will be held securely and separately from the eCRFs, ensuring that clinical decisions will not be influenced by the test results.

Laboratory Detection

Urine samples will be thawed at room temperature and centrifuged at 3000 rpm for 10 minutes. The supernatant will be used for detection.

Urine misfolded proteins will be detected by Pre-Eclampsia Detection Kit (CercaTest RED, Shuwen, China) since misfolded proteins can selectively bind to the Congo Red dye. When a mixture of the Congo Red and urine from a pregnant woman is loaded onto a chromatographic column mounted in a detection cuvette, the presence (positive) or absence (negative) of misfolded proteins can be determined based on the color of the eluent in the cuvette. The eluent will also be applied for quantitative measurement using the HACH DR1900 instrument by detecting the absorbance at a wavelength of 520-600 nanometers.

PlGF and sFLT-1 levels will be detected by the Elecsys PlGF and Elecsys sFlt-1 detection kits (Roche, Germany), respectively. The total urine protein/creatinine ratio will be detected by the Total Protein in Urine/CSF (TPUC) Kit and Creatinine Kit (Mindray, China), all according to the manufacturers' instructions.

Selection of Predictor Variables

According to the objective of this study, the misfolded protein level in urine will be considered as a predictor candidate for PE onset or adverse outcomes. Other preset variables include: (1) demographic factors, including high-risk factors of PE; (2) urine biomarkers reported in the literature; (3) medication; and (4) routine clinical variables or laboratory tests in daily practice (Textbox 2). The determination of valid variables will be based

on the statistical analysis results with a significance level of $P<.05$.

Textbox 2. Preset variable candidates for model development.

Demographic factors

- Age
- BMI
- Conception mode
- Parity
- Preexisting hypertension, diabetes, autoimmune diseases (systemic lupus erythematosus, antiphospholipid syndrome)

Urine biomarkers

- Misfolded proteins
- Placental growth factor
- Soluble FMS-like tyrosine kinase 1
- Total protein
- Creatinine

Medication

- Aspirin
- Antihypertensive drugs

Routine clinical variables or laboratory tests

- Blood pressure
- Aspartate aminotransferase
- Lactate dehydrogenase
- Serum creatinine
- Proteinuria (spot urine protein, 24-hour urine protein)
- Uterine artery pulse index

Statistical Analysis

All variables will be compared between case and control groups. Either parametric or nonparametric tests will be applied for continuous variables and χ^2 tests will be used for categorical variables. Receiver operating characteristic analysis will be used when applicable. Univariable or multivariable logistic regression will be applied to develop the prediction models. All *P* values will be two-tailed. The statistical analysis will be run on SPSS version 27 (IBM) statistical software.

Results

The study is currently in the patient recruitment phase. Study recruitment started in July 2023. As of March 2024, a total of 251 pregnant women with clinical suspicion of PE have been enrolled in the trial, who will be continuously followed up and monitored for their PE status until 42 days postpartum. Statistical analysis is scheduled to start after all participants reach the follow-up endpoint and complete clinical data are collected.

Discussion

Study Implications

Many potential PE biomarkers have been identified using samples from patients with a confirmed diagnosis of PE in comparison with samples obtained from normal pregnancies, which represents a convenient and pragmatic approach for biomarker identification. Although these studies have generated excellent candidate biomarkers for PE detection, there has been less focus on biomarkers that can be used in PE risk prediction. It is possible that biomarkers that are differentially expressed in patients with PE versus those without will fail in a predictive verification study. Thus, a prospective cohort with an uncertain subsequent PE status would provide the best avenue for exploring PE prediction models. To our best knowledge, this is the first prospective study to explore the predictive value of a congophilia-based detection tool in pregnant women with a clinical suspicion of PE in China. The study will be conducted in a high-quality tertiary hospital focused on women's health. Maternal age of 35 years or older; nulliparity; and preexisting hypertension, diabetes, and autoimmune diseases (eg, systemic lupus erythematosus and antiphospholipid syndrome) are the main high-risk factors for PE [25] and will be included as

predictive variables in our analysis. High-risk pregnant women are recommended to use low-dose aspirin to prevent PE; therefore, it is appropriate to consider medication with aspirin as a variable candidate. The crucial biomarkers of PE [22,23], such as PlGF, sFLT-1, and routine clinical variables or laboratory tests, are also under evaluation to build a prediction model. Another important feature of this study is the use of blinding, which ensures that the participants' laboratory data have no influence on the diagnosis of PE as well as the clinical decisions of treatment.

PE remains one of the most severe pregnancy complications associated with substantial maternal and perinatal morbidity. With current pregnancy trends of advancing age and obesity, the morbidity of PE might increase inevitably in the future. Since the only definitive treatment for PE is to terminate the pregnancy, early screening and continuous monitoring during pregnancy are particularly important for pregnant women with high risk of PE. No effective screening test for PE has been identified. The commonly used clinical screening methods are mostly based on blood samples with precise instruments [26-28], which limits the ability for home self-inspection and timely identification of the disease. Congophilia detection represents a promising new approach for the detection of PE by targeting the misfolded proteins in urine, providing a simple, rapid, and cost-effective method for early diagnosis of this complex condition. This method can be performed using small volumes of urine and no additional instrument is needed, making it suitable for use in resource-limited settings and even as a potential home self-test. Therefore, the affordable, noninvasive, and simple use of this POCT detection tool will enable its wide accessibility for bedside use in a central hospital, low-resource settings, and even at home, which would significantly reduce the serious socioeconomic burden attributed to PE.

Limitations

Although use of a prospective cohort in undiagnosed populations provides the best avenue for discovering predictive biomarkers, these markers or their combinations must be rigorously validated in internal/external cohorts to ensure their potential for PE prediction. The single-center nature of this study and prospective recruitment may imply the potential for selection bias. In addition, the enrollment was mainly conducted at prenatal clinics, and this might introduce selection bias regarding the severity of disease, as women with sudden onset of organ complications are more often seen at the emergency clinic. Therefore, future investigations with larger populations, along with assessment of the long-term outcomes of infants will be necessary to ensure the accuracy of the prediction model obtained in this trial and to establish the clinical utility of this tool for routine use in pregnancy care.

Conclusions

This study aims to provide comprehensive evidence on urine misfolded proteins alone or combined with other indicators as a short-term predictive tool for PE. Accurate prediction of PE will allow for proactive management of pregnant women with clinical high risks, and possibly reduce the adverse maternal and fetal outcomes and health care costs associated with hospitalization.

Acknowledgments

We are immensely grateful for the contributions of all investigators from the hospitals and local laboratories; their support is essential for conducting this study. In addition, all study participants are highly appreciated for their nonnegligible contribution to the research. This work is supported by Zhejiang Provincial Ten Thousand Plan for Technological Innovation Leading Talents (2020R52050), the Natural Science Foundation of Zhejiang Province (LQ19H040017), Zhejiang Province Health Innovative Talent Project (A0466), Key Projects of the Science and Technology Co-construction by National Administration of Traditional Chinese Medicine and Zhejiang Provincial Administration of Traditional Chinese Medicine (GZY-ZJ-KJ-23082), and International Cooperation Seed Program Project of Women's Hospital, Medical School of Zhejiang University (GH2024005).

Authors' Contributions

All authors contributed to the overall study design and specific methodologies. The main idea of this study was conceived by XL and XB in collaboration. They jointly take responsibility for the integrity of the data and the accuracy of the data analysis. MY and XY prepared the first draft of the manuscript with considerable input from HT, YT, and JF, and revised the manuscript based on the feedback of other authors. YW, YF, JS, YN, YY, YW, and PL will carry out the recruitment and data collection. All authors have critically reviewed, edited, and approved the final version of the manuscript.

Conflicts of Interest

XL, XY, and MY are employed by Shuwen Biotech. The other authors have no conflicts of interest to declare.

Abstract

Background: The ability to walk is a key issue for independent old age. Optimizing older peoples' opportunities for an autonomous and active life and reducing health disparities requires a better understanding of how to support independent mobility in older people. With increasing age, changes in gait parameters such as step length and cadence are common and have been shown to increase the risk of mobility decline. However, gait assessments are typically based on laboratory measures, even though walking in a laboratory environment may be significantly different from walking in outdoor environments.

Objective: This project will study alterations in biomechanical features of gait by comparing walking on a treadmill in a laboratory, level outdoor, and hilly outdoor environments. In addition, we will study the possible contribution of changes in gait between these environments to outdoor mobility among older people.

Methods: Participants of the study were recruited through senior organizations of Central Finland and the University of the Third Age, Jyväskylä. Inclusion criteria were community-dwelling, aged 70 years and older, able to walk at least 1 km without assistive devices, able to communicate, and living in central Finland. Exclusion criteria were the use of mobility devices, severe sensory deficit (vision and hearing), memory impairment (Mini-Mental State Examination ≤23), and neurological conditions (eg, stroke, Parkinson disease, and multiple sclerosis). The study protocol included 2 research visits. First, indoor measurements were conducted, including interviews (participation, health, and demographics), physical performance tests (short physical performance battery and Timed Up and Go), and motion analysis on a treadmill in the laboratory (3D Vicon and next-generation inertial measurement units [NGIMUs]). Second, outdoor walking tests were conducted, including walking on level (sports track) and hilly (uphill and downhill) terrain, while movement was monitored via NGIMUs, pressure insoles, heart rate, and video data.

Results: A total of 40 people (n=26, 65% women; mean age 76.3, SD 5.45 years) met the inclusion criteria and took part in the study. Data collection took place between May and September 2022. The first result is expected to be published in the spring of 2024.

Conclusions: This multidisciplinary study will provide new scientific knowledge about how gait biomechanics are altered in varied environments, and how this influences opportunities to participate in outdoor activities for older people.

Introduction

Overview

The ability to walk is a key issue in maintaining independence in old age. Walking difficulties hinder the ability to manage tasks of daily life and may lead to the need for help and an increased risk of disability and institutionalization [1,2]. With increasing age, changes in gait are common [3]. Walking speed declines with increasing age [4], due to changes in step or stride length, as well as slower cadence. Changes in ankle, knee, and hip motion and center of pressure are also common [4,5]. Gait variability, defined as fluctuations in spatiotemporal characteristics between steps increases with age [3,6] and is associated with increasing risk of developing mobility difficulties [7].

Spatiotemporal and kinematic parameters of gait provide important information, but outcomes are usually based on a treadmill or laboratory overground gait, which may be significantly different from walking outdoors. Only a few studies have examined differences in gait biomechanics between laboratory and outdoor circumstances among older people. In the studies of Schmitt et al [6] and Renggli et al [8] significant differences in several spatiotemporal parameters were found between outdoor walking and treadmill walking. On a treadmill, a decrease in walking speed, an increase in double support duration, shorter stride length, and decreased cadence were found compared to outdoor walking [6,8]. While these assessments provided knowledge about issues such as fall prediction [9] many uncertainties remain. For example, the environment where the activity takes place is typically not recorded, so it is not known whether changes in gait represent a response to some specific environmental demand or whether it is an expression of a person's usual performance. Taking into account environmental features, and using wearable sensors, such as inertial measurement units (IMUs) at the same time could add important information about walking speed and body orientation that is needed to understand how people move and adapt to challenges encountered in different environmental circumstances.

The ability to adapt gait to environmental demands may be crucial for preventing or reducing restrictions in participation on outdoor activities. The concept of life-space mobility gives us an idea about how well people are able to access different community amenities, attend different events, or be physically active, thus describing a person's opportunities for participation outside the home [10]. Life-space mobility refers to the spatial area in which a person moves in daily life, taking into account distance, frequency, and any assistance needed for movement. Restrictions in participating in out-of-home activities are known to correlate, for example, with functional limitations, pain, depression, and chronic conditions [11-13]. Previously it has also been shown that life-space mobility correlates with, for example, quality of life [14,15], physical functioning, and autonomy [16], and that restrictions on it may lead to cognitive decline [17,18], falls and fractures [19], nursing home admission [20], or even mortality [21]. However, research on the association between gait parameters and the impact on life-space mobility is scarce.

Study Objectives

The aim of the "Gait features in different environments contributing to participation in outdoor activities in old Age (GaitAge)" project is to study whether IMUs are valid for detecting traditional (gait cycle event timings) and novel (heading and torso angle) gait parameters among older people in laboratory and outdoor environments. We will focus on how gait parameters change when walking on a treadmill in a laboratory compared to an outdoor environment and in a hilly environment compared to walking in a level outdoor environment. Finally, we will study whether alterations in gait parameters in different environments are associated with outdoor participation (measured via life-space mobility and physical activity) in older people when health and demographics are taken into account.

Methods

Recruitment

Our target was to recruit a total of 40 participants for the study. First, we invited 15 participants from our pilot study conducted between May and June 2021 (not published), who had given their permission to contact them again. These participants were recruited through the University of the Third Age in Jyväskylä by advertising in a public lecture in May 2021. They were contacted again in April 2022 to enquire about their interest in taking part in this study. All of them were willing to take part in the study and met the inclusion criteria.

Additional recruitment to reach a total of 40 participants was done in June 2022 through 5 central Finland senior organizations. Leaders of these organizations were contacted via email and were asked to forward an information letter and invitation to all members of the organizations. Those members who were interested in taking part in the study were asked to contact researchers via email or by phone, after which a short phone interview was scheduled.

A researcher called potential participants and conducted a short telephone interview to screen their suitability and to confirm their willingness to participate. Inclusion criteria were community-dwelling, at least 70 years of age during the current year, able to walk at least 1 km without assistive devices, able

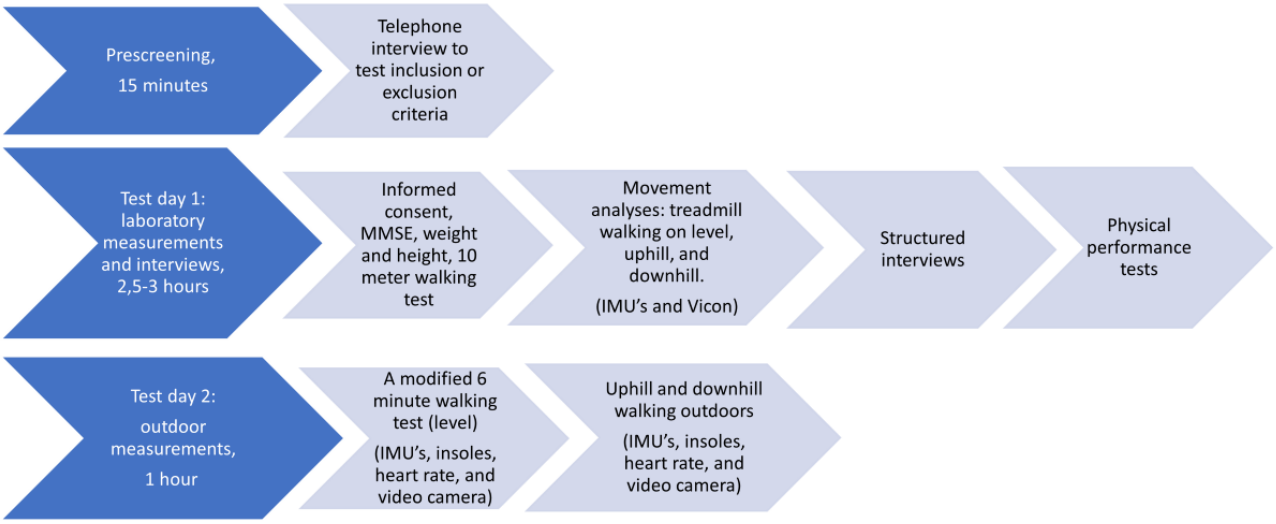
to communicate, and living in central Finland. Exclusion criteria were the use of mobility devices, severe sensory deficit (vision and hearing), neurological conditions (eg, stroke, Parkinson disease and multiple sclerosis), and memory impairment (Mini-Mental State Examination [MMSE]≤23) [22]. Memory impairment was assessed during the initial phone interview by asking about diagnosed memory illness and screened with an MMSE test during the first research visit to the laboratory.

Recruitment continued until 40 participants who met the inclusion criteria and were willing to participate were reached.

Data Collection

The data collection procedure is shown in Figure 1. Data collection took place between May 27, 2022, and September 28, 2022. The data collection protocol included two visits (1) indoor walking measurements and interviews that were conducted at the University of Jyväskylä sport and exercise laboratory and (2) approximately 4 days later, outdoor walking measurements were conducted at the local sports track and hilly terrain next to the sports track. For some participants, the time between indoor and outdoor walking measurements was longer than 3 days due to weather conditions, as it was not possible to perform outdoor measurements when it was raining. One participant was not able to participate in outdoor measurements because of a nonstudy-related injury after the laboratory measurements. All the measurements and interviews were conducted by research group members with help from research assistants trained for the task.

Figure 1. Data collection protocol of GaitAge project. IMU: Inertial measurement unit; MMSE: Mini-Mental State Examination.



Laboratory Measurements and Interviews

Overview

For the indoor research visit, participants were instructed to wear sneakers or running shoes and clothes that were suitable for physical activity, preferably as tight as possible to facilitate the attachment of reflective markers for 3D motion analysis. If the participant did not have shorts or tight leggings, they were provided with tight shorts. Participants were instructed to eat a light meal or breakfast and to avoid alcohol use 24 hours before the measurements.

At the start of the research visit, the MMSE test was conducted and written informed consent was obtained. Participants had the possibility to ask questions about the study and the study protocol was explained to them. After that, weight and height were measured.

10-Meter Walking Test

Indoor walking tests started with a 10-meter walking test to identify participants' walking speed. The time in seconds was measured using photocells placed 10 meters apart in a hallway. Participants were instructed to walk through the photocells at their usual walking speed, starting 2 meters before the first pair of photocells and stopping 2 meters after the second pair of photocells. The test was done once by each participant. Time was changed into walking speed (in m/s) and this information was used to determine the speed for the subsequent treadmill tests.

Next-Generation Inertial Measurement Units

After the 10-meter walking test, next-generation inertial measurement unit (NGIMU) devices (x-io Technologies Limited) were attached. NGIMU is an IMU sensor that includes a triple-axis accelerometer (±16 g; 400 Hz sample rate), triple-axis gyroscope (rotations ±2000°/s; 400 Hz sample rate), and triple-axis magnetometer (magnetic field ±1300 µT). NGIMUs also include analog inputs (8-channel; 0-3.1 V; 10-bit; 1 kHz sampling rate). One NGIMU including housing has dimensions of 56×39×18 mm and weighs 46 g. A total of 8 NGIMU devices were attached to participants with Velcro straps and leukoplast tape.

NGIMUs were placed on both legs above the third metatarsal, on the lateral mid shank, anterior thigh 5 cm above the knee joint, and to the middle of the spine just above the spina iliaca posterior superior and upper half of sternum.

VICON 3D Motion Analysis

3D motion capture (Vicon Motion Systems) was used to obtain ground truth values for indoor walking tests. A total of 16 Vicon Vero cameras were positioned around the space where treadmill walking took place. A total of 26 reflective markers were

attached to participants with 2-sided tape and secured with leukoplast tape and a self-adhesive bandage (Textbox 1). Data were sampled using Nexus software (Vicon Motion Systems).

Textbox 1. Placement (right and left legs and sides of the body) of the reflective markers for indoor 3D motion analysis.

- Hallux
  - Top of hallux nail
- Toe
  - Proximal head of second metatarsal
- Heel
  - Heel, at the same level as toe marker
- Ankle
  - Lateral malleoli
  - Medial malleoli (used only for calibration)
- Shank
  - Midway along the shank, laterally (left and right)
- Knee
  - Knee extension—flexion axis and lateral side
  - Knee extension—flexion axis and medial side
- Thigh
  - Midway between KNEE marker (lateral side) and spina iliaca anterior superios (SIAS)
- SIAS
- Spina iliaca posterior superior
- Thoracic vertebrae 10
- Cervical vertebrae 7 (C7)
- Sternum
  - Lowest part of the sternum
- Clavicula
  - Between the heads of clavicula

NGIMUs and Vicon data were synchronized with an analog trigger, which sent simultaneous pulses to the master NGIMU (400 Hz) and to Nexus software (1000 Hz).

Treadmill Walking Tests

Level Treadmill Walking

First, a safety harness was put on the participant. Second, the participant walked on the treadmill (Gymstick Walking Pad Pro 44 cm×120 cm) for 1-5 minutes for familiarization. Treadmill speed was gradually increased in increments of 0.5 km/h until the participant's walking speed from the 10-meter test was achieved or when the participant indicated that he or she did not wish to increase the speed. Participants were allowed to take support from the front and side rails if necessary for balance at any point during assessments, but they were not allowed to hold the rails during the full measurements.

After familiarization, the treadmill was stopped. The actual test started with 5 seconds of standing still in an anatomical posture. When starting, the speed was gradually increased toward the speed obtained from the 10-meter walking test and once achieved, the participant was asked to walk for 3 minutes at that speed. After 3 minutes, the treadmill was slowed down and the participant was asked to stand again for 5 seconds in an anatomical posture.

Uphill and Downhill Treadmill Walking

The treadmill was inclined or declined by 5° to correspond with the slope of the outdoor hilly walking tests. The order of test (incline or decline first) was randomly determined by a random number generator. The test speed was determined based on 1-5 minutes of walking at the new gradient, whereby participants were asked to indicate their self-selected speed for uphill or downhill walking. The actual test started with 5 seconds of

standing still in an anatomical posture. Then the speed of the treadmill was gradually increased to the test speed, and participants walked for 2 minutes at that speed. After 2 minutes, the treadmill was stopped, and participants again stood for 5 seconds in an anatomical posture.

Structured Interviews

Overview

Following the walking tests, interviews were conducted including structured questions and questionnaires.

Demographic Information

Demographic information included age, gender, perceived financial situation (from very poor to very good), highest educational status, living arrangements (living alone, with spouse, or with someone else), type of housing (apartment block, row house, semidetached, or detached house), and time of residence in the current house.

Health Condition

Health condition was determined via self-report (5-point scale from good to poor) [23] and by asking about illnesses diagnosed by a doctor from a list of chronic conditions, including different cardiovascular, respiratory, musculoskeletal, and eye diseases, hearing impairment, diabetes, cancer, and incontinence and an open-ended question about any other physician-diagnosed chronic conditions. In addition, participants were asked about whether they had artificial joints and if so, in what joint [23].

Functional Vision

Functional vision was assessed using a 7-item vision function questionnaire (VF-7) [24], which is a modified version of the 14-item vision function questionnaire (VF-14) [25]. The VF-7 comprises 7 activities dependent on functional vision and is validated for use in patients with cataracts. Patients are asked how much difficulty they have doing each activity, with or without glasses. The activities are reading small print; seeing steps, stairs, or curbs; reading traffic, street, or store signs; doing fine handwork; cooking; watching television; and driving in darkness. Each question is scored 4, 3, 2, or 1, respectively, if the participant has no, little, moderate, or a great deal of difficulty performing the activity, and 0 if the participant is unable to perform the activity due to poor vision. If a patient does not do an activity for reasons other than his or her vision, the item in question is not included in the scoring. The final score is obtained by averaging responses across all the relevant activities and multiplying by 25. Scores range from 0 (representing maximum impairment) to 100 (representing no impairment).

Trail-Making Test

Trail-making test (TMT) was used to measure executive functioning [26]. The TMT consists of 2 parts. Part A involves drawing connective lines between circles that are spread over a sheet of paper and are numbered from 1 to 25. Part B involves drawing connective lines between circles including numbers and letters in order (1-A-2-B-3-C-4-...etc). Participants are asked to draw the lines as fast as possible without lifting the pen from the paper. The researcher pointed out possible errors as they occurred and the participant continued doing the task. The time to complete the task was recorded. The maximum accepted time for part A was 100 seconds, and for part B 240 seconds or 4 mistakes.

Depressive Symptoms

Depressive symptoms were assessed with the Center for Epidemiologic Studies Depression scale (CES-D) [27] and balance confidence was assessed with the Activities-specific Balance Confidence scale [28]. History of falls during the previous 12 months was self-reported and separated into injurious and noninjurious falls [29].

Outdoor Mobility

Life-Space Mobility

Life-space mobility was assessed with the Finnish version of the University of Alabama at Birmingham Study of Aging Life-Space Assessment (LSA) [10,30]. The LSA establishes self-reported movement patterns according to specific life-space levels, ranging from within one's dwelling to beyond one's town during the 4 weeks preceding the assessment. For each level of life-space (bedroom, home, outside home, neighborhood, town, and beyond town), participants are asked how many days within a week they attained that level and whether they needed help from another person or used assistive devices. A life-space mobility score was calculated (range 0 to 120), reflecting distance, frequency, and independence of movement. Higher scores indicate a larger life-space.

Environmental Features

Environmental features near the participant's home were assessed using "Perceived environmental barriers for outdoor mobility" (PENBOM) questionnaire [31] and with self-evaluation of the home neighborhood environment, including questions about distances to services, closest grocery store, and walking and cycling routes [23].

Physical Activity

Self-reported level of physical activity was assessed with a 6-point scale [32] modified from Grimby [33] and Mattiasson-Nilo et al [34]. The levels varied from "1" hardly any activity and mostly sitting to "6" performing competitive sports.

Walking Ability and Walking Modifications

Walking ability and walking modifications were evaluated using a standardized questionnaire [35]. The participants were asked whether they had difficulties in walking 2 km with response options (1) able to manage without difficulty, (2) able to manage with some difficulty, (3) able to manage with a great deal of difficulty, (4) able to manage only with the help of another person, and (5) unable to manage even with help. Regarding walking modifications, participants were asked "Have you noticed any of the following changes in walking 2 km?" The response options (yes or no) concerned reduced walking frequency, having given up walking 2 km distances, walking more slowly, and resting while walking the 2 km distance.

Physical Performance Tests

Physical performance tests were performed after the interviews. Lower extremity performance was assessed using the short physical performance battery (SPPB) test following the guidelines of the Finnish Institute of Health and Welfare [36,37], which includes 3 subtests, static balance in 3 different positions, 4-meter walking time, and 5 repetitions of sit-to-stand. The balance test was performed without shoes. The walking test was performed at the usual speed and the sit-to-stand test was performed as fast as possible. Both these tests were performed with shoes on. The possible use of a walking aid during the test was also recorded. All subtest results were recorded in seconds and scored from 0 to 4 points, leading to a maximum of 12 points. Higher SPPB test scores indicate better lower extremity performance.

Functional Mobility

Functional mobility was assessed with the Timed Up and Go (TUG) test [38]. In the TUG test, the participant stands up from a chair, walks 3 meters, turns around, walks back, and sits on the chair. The TUG test was performed twice at the usual walking speed, with the shoes on. Time in seconds was measured using a stopwatch. Both results were recorded, and the best result (shorter time in seconds) was used. A lower TUG test time indicates better mobility.

Treadmill walking tests took approximately 1.5 hours including attachment of NGIMUs, instructions and walking tests with breaks, after which the participant had a 15-30 minute coffee break. Interviews and physical performance tests took approximately 45-60 minutes per participant. The total duration of the research visit to the sport and exercise laboratory was 2.5-3 hours.

Outdoor Measurements

Overview

Walking tests outdoors were performed approximately 4 days after the laboratory visit. Participants were instructed to wear good walking shoes (trainers, running shoes, etc) and clothes suitable for physical activity. Outdoor tests were conducted only on days with suitable weather conditions (no rain), thus for some participants the time between indoor and outdoor measures was longer than 4 days (range 2-20).

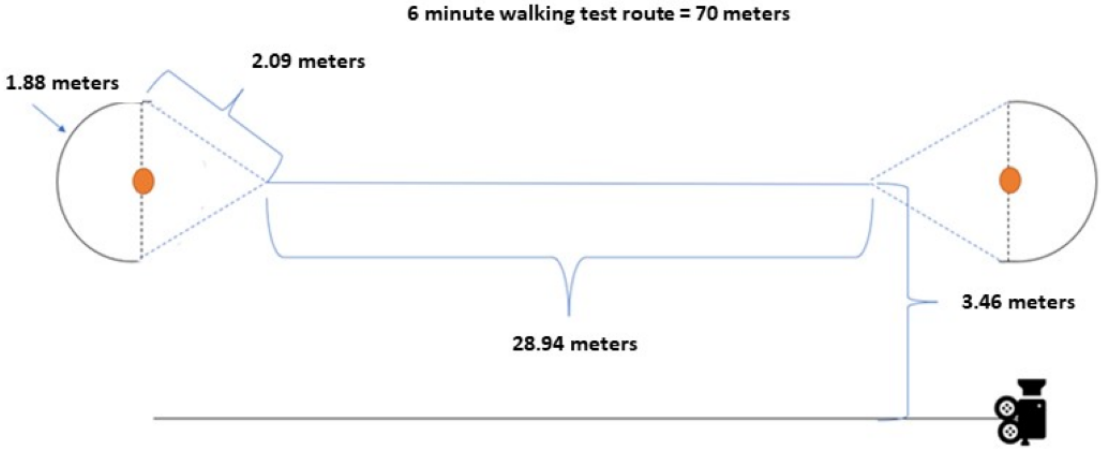
First, participants were equipped with NGIMUs, force-sensitive resistor (FSR)–insoles and a wrist-worn heart rate monitor (Polar Vantage M, Polar, Finland). The same set and placement of NGIMUs were used as in the treadmill walking tests. FSR-insoles were made with two FSRs (18 mm diameter and active area 12.7 mm), which were attached with tape to a thin insole (1-2 mm) and placed under the heel and ball of the foot. The size of the insole was modified according to each participant's feet and FSR-insoles were inserted in participants' shoes replacing the insoles they had in their own shoes. The participants reported that they did not notice having the insoles in their shoes, thus the insoles are not likely to affect the gait parameters. The FSRs were connected to a battery-powered open-source Internet of Things development board (M5StickC PLUS, Interlink Electronics) and force data were sampled at 200 Hz via the board's 12-bit analog-to-digital converter. Internal clocks of the development boards were synchronized before each measurement using an external button connected to the digital pins of the boards. FSR-insoles were connected to a custom mobile phone app via Bluetooth low-energy connection.

The heart rate monitor was placed on the participant's right wrist. The heart rate was measured to monitor exertion during the outdoor walking tests. A GoPro 9 Hero camera (120 Hz; GoPro Inc) was attached to a modified stroller which was pushed alongside the track. A second GoPro Hero camera was placed at the end of the walking track. NGIMUs and GoPro cameras were synchronized with a trigger device, which sent an analog signal to the master NGIMU and simultaneously turned on a light visible by both cameras. For camera calibration, a 5-second video was filmed of a checkerboard calibration matrix located at the same distance from the camera as the participant's walking route.

A Modified 6-Minute Walking Test

Participants walked along a 70 m long route (Figure 2) at the sports track (synthetic track surface) for 6 minutes at a self-selected speed. Rating of perceived exertion was assessed using the Borg scale (range 6-20; 6=no exertion, 20=completely exhausted) [39] at the beginning of the test, after 3 minutes and at the end of the test. A research assistant moved the camera and stroller alongside the participant at a distance of 3.46 meters from the midline of the participant's route. After 6 minutes of walking, the test was stopped and distance was measured to the nearest meter.

Figure 2. Route of a modified 6-minute walking test performed at a sports track.



Uphill and Downhill Walking Outdoors

A walking test in a hilly environment was performed next to the sports track. The steepness of the hill was 5°, and the ground surface was asphalt.

The participants walked at self-selected speed downhill for 20 meters and then after a short break (approximately 10 seconds) walked 20 meters uphill. Downhill and uphill trials were repeated 5 times, that is, 100 meters walking both ways. A research assistant moved the camera and stroller alongside the participant and a second researcher walked behind the participant for safety. Rating of perceived exertion was assessed after every 20 meters, and the heart rate was recorded with the heart rate monitor. Rest breaks were taken between trials as needed.

Data Analysis

Gait Parameters

Several gait parameters will be derived from IMU data. For example, step duration; step length; stance phase duration; swing phase duration; cadence; gait speed; variability of step, swing, or stance duration; and asymmetry of step, swing, or stance duration.

Step duration is defined as time and step length as the length between 2 consecutive contralateral heel strikes. Stride duration is defined as the time between 2 ipsilateral heel strikes. Swing duration is calculated as the time between consecutive toe-off and heel strike of the same foot, and stance duration as the time between consecutive heel strike and toe-off of the same foot. Cadence is defined as steps per minute and step velocity as step length divided by step duration. Variability in gait parameters (within-person differences in steps) is calculated as SD or coefficient of variation (SD divided by mean multiplied by 100%) of certain parameters per participant.

To calculate gait parameters from different IMUs we will use algorithms published in previous literature (eg, [40-43]). New algorithms are developed when necessary.

Vicon Data

Exported 3 dimension motion data are analyzed with open-source Mokka software (Motion kinematic & Kinetic analyzes, biomechanical tool kit, GitHub), where heel strikes and toe-offs are manually determined. In treadmill walking, heel strikes are set to the last frame before the heel marker starts to move backward in the image, that is, at the most anterior point. Toe-offs are set to the last frame before the hallux marker starts to move proximally, that is, at the most posterior point in the image. These analyses are performed by 2 researchers and similarity of identifications is ensured by checking agreement on data. In case of disagreements, event timings are discussed and agreed upon together. Events are then exported to Matlab (b2022; The MathWorks, Inc).

GoPro Camera Data

The GoPro camera data were used as a reference to validate the IMU's in the outdoor environment. From outdoor video data, heel strike and toe-off events and step length are digitized and identified manually. The heel strike is denoted as the first frame when the shoe touches the ground after the swing phase. Toe-off is determined as the last frame when the distal end of the shoe is still on the ground. These analyses are performed by 2 researchers and similarity of identifications is ensured by checking agreement on data. In case of disagreements, event timings are discussed and agreed upon together. ShotCut software (Meltytech, LLC) is used to mark event timings, which are copied to an Excel file (Microsoft Corporation). Timings are converted from frames to seconds using Matlab (MathWorks) and Excel.

Statistical Analyses

To test the validity of IMU sensors, we will use Bland-Altman plots and intra-class correlation coefficients. To compare gait parameters in different environments, we will use appropriate statistical methods depending on data properties, which may include *t* tests and repeated measures ANOVA and mixed effect models. Linear regression analyses are used to study associations with life-space mobility and physical activity. Other statistical testing will be performed where appropriate.

Data Management

All data are handled and registered according to the Finnish Personal Data Act and the European Union Data Protection Act. All data are recorded and analyzed without direct personal recognition information. The research material is carefully

maintained, documented, and stored in password-protected organizational servers.

Ethical Considerations

The study was conducted according to good scientific and clinical practices as laid down by the Declaration of Helsinki. All participants were informed carefully about the study, and they gave their written informed consent prior to any measurements. Data collection included no invasive or potentially physically or psychologically harmful elements beyond what one might experience in everyday life. Only people who were personally able to consent were recruited. Research assistants conducting the data collection were trained for study procedures and the safety of participants during the measurements was ensured. Participants had the possibility to withdraw from the research at any point without any consequences. The ethics committee of the JAMK University of Applied Sciences approved the study (JAMK/40/13.02/2021; January 11, 2021).

Results

The GaitAge data collection is completed. A total of 40 participants participated in indoor measurements and 39 of them in outdoor measurements. Participants were on average 76.3 (range 69-92, SD 5.45) years of age, 65% (n=26) of them were women, and all of them reported being able to walk 2 km without difficulties.

Gait data analyses are underway, and the first results reporting findings of the validation of NGIMUs is expected to be published in spring 2024.

Discussion

Principal Findings

Our project features several strengths. First, for example, a comparison of gait parameters in an outdoor environment and on a treadmill in a laboratory provides fundamental knowledge for studies aiming to use gait parameters to predict progressive neurological problems. We will report how older adults adapt their gait according to variable environmental demands. This study provides findings that can change our view of person-environment interaction processes by providing detailed information about changes in gait parameters in level, uphill, and downhill walking. Second, we will assess whether changes in gait biomechanics induced by environmental demands influence possibilities for general participation in outdoor activities of older people by combining information on gait parameters with life-space mobility. Third, we will explicitly focus on person-environment interaction at the individual level, which will create new study hypotheses and give new perspectives on research in environmental gerontology. Fourth, the study sample of 40 older adults with a comprehensive data set (several walking measures with IMUs, 3D motion analyses and video data, questionnaires, and physical performance tests) will have a multidisciplinary impact by providing information about objective and subjective aspects of gait and mobility in old age.

It should be noted that the study population included older adults without major mobility difficulties or neurological conditions, so the results cannot be generalized to clinical populations. There are also some limitations in the study protocol that will be taken into consideration in forthcoming analyses, for example, differences between measurement protocols for level treadmill walking (3 minutes) and outdoor walking (6 minutes). We will also need additional longitudinal studies to determine whether possible changes in gait in different environments are predictive of changes in mobility capacity.

Conclusions

This research will provide answers to major research questions about the role of the environment in outdoor mobility in old age. This research project could serve as a reference for future research on gait among different patient groups and will serve as a baseline for a longitudinal study, with the aim of exploring whether changes in gait parameters in different environments can be used as early signs of declining health and restricted participation in outdoor activities.

Acknowledgments

The GaitAge project was funded by the Research Council of Finland (330185 to MR). The financial sponsors had no role in the design, implementation, analyses, or reporting of the results. The authors would like to thank Sakari Vekki, Sailee Sansgiri, Olli-Pekka Mattila, and Timo Rantalainen for all the help with data collection and data processing. In addition, we would like to thank Lauri Halme, Mikko Kurkela, Elina Lius, and Marika Salminen for their valuable help with the data collection.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author (MR) upon reasonable request.

Authors' Contributions

MR, TF, and NC performed the concept and design. All authors took part in acquisition of data, drafting the paper, critical revision of the paper, and approved the final paper.

Conflicts of Interest

None declared.

Abstract

Background: Preventable harms from medications are significant threats to patient safety in community settings, especially among ambulatory older adults on multiple prescription medications. Patients may partner with primary care professionals by taking on active roles in decisions, learning the basics of medication self-management, and working with community resources.

Objective: This study aims to assess the impact of a set of patient partnership tools that redesign primary care encounters to encourage and empower patients to make more effective use of those encounters to improve medication safety.

Methods: The study is a nonrandomized, cross-sectional stepped wedge cluster-controlled trial with 1 private family medicine clinic and 2 public safety-net primary care clinics each composing their own cluster. There are 2 intervention sequences with 1 cluster per sequence and 1 control sequence with 1 cluster. Cross-sectional surveys will be taken immediately at the conclusion of visits to the clinics during 6 time periods of 6 weeks each, with a transition period of no data collection during intervention implementation. The number of visits to be surveyed will vary by period and cluster. We plan to recruit patients and professionals for surveys during 405 visits. In the experimental periods, visits will be conducted with two partnership tools and associated clinic

process changes: (1) a 1-page visit preparation guide given to relevant patients by clinic staff before seeing the provider, with the intention to improve communication and shared decision-making, and (2) a library of short educational videos that clinic staff encourage patients to watch on medication safety. In the control periods, visits will be conducted with usual care. The primary outcome will be patients' self-efficacy in medication use. The secondary outcomes are medication-related issues such as duplicate therapies identified by primary care providers and assessment of collaborative work during visits.

Results: The study was funded in September 2019. Data collection started in April 2023 and ended in December 2023. Data was collected for 405 primary care encounters during that period. As of February 15, 2024, initial descriptive statistics were calculated. Full data analysis is expected to be completed and published in the summer of 2024.

Conclusions: This study will assess the impact of patient partnership tools and associated process changes in primary care on medication use self-efficacy and medication-related issues. The study is powered to identify types of patients who may benefit most from patient engagement tools in primary care visits.

Introduction

Background

Health care encounters are opportunities for health care professionals (HCPs) to work productively with patients and families to address risks in medication use in ambulatory settings [1,2]. This study assesses a systematic redesign of time-limited primary care encounters to improve medication safety. Adverse drug events (ADEs) account for 6.1 emergency department visits per 1000 population each year in the United States and 38.6% of these visits require hospitalization [3]. Medication safety is recognized as a significant area for improvement by the World Health Organization ("Medication without Harm") [4]. The National Action Plan for ADE Prevention [5] highlighted ADEs associated with insulins, opioids, and anticoagulants, such as those from hypoglycemia, opioid misuse, injurious falls, and bleeding. Older adults are especially vulnerable to ADEs with nearly double the risk compared to younger populations [3]. Patients' roles (including families in this protocol) are critical to medication safety in ambulatory settings [6-8]. An analysis of insulin-related emergency department visits identified patient self-management as the most common precipitant to insulin-related hypoglycemia and errors—patients incorrectly managed their food intake and insulin products at home [9]. Leading contributors to benzodiazepine adverse events were nonmedical use (56%) and self-harm (30%) [10].

Major gaps have been identified in patient and family engagement in medication safety in ambulatory settings [11-15], including cultural barriers that disrupt engagement between HCPs, patients, and families; lack of patients' experience and skills in working with HCPs; and unclear expectations of patient roles in clinical encounters. Older adults often do not take advantage of existing systems for safe medication management practices at home, even for high-risk medications [16]. Patients often have an unvoiced agenda, especially related to concerns, side effects, and uncommunicated methods of managing their conditions [17]. Interventions to bridge these gaps in patient engagement include patient coaching prior to visits [18]; providing patients with instructional brochures, training videos, or prompts of questions to prepare for visits [19-21]; encouraging patients to bring medications and questions to visits [2]; and encouraging patients to ask questions [22-24]. One patient portal-based intervention focused on a dual approach of a previsit agenda-setting questionnaire followed by in-person coaching to prepare for encounters with HCPs [19].

This project uses the patient work system model [25]. The model, similar to those that study and improve the work performance of HCPs [26], focuses on the health-related work of patients and nonprofessionals. The concept of patient work systems broadens the scope for medication safety interventions to encompass patients' home environments [25], including setting expectations and clarifying the roles of patients and families [27], using community resources [28], and incorporating patient perspectives in medication safety improvement [29].

Although the inventions reported so far address several gaps in patient and family engagement, integrated approaches are lacking to systematically target key elements of the joint patient-professional collaborative work to achieve productive interactions. A redesign that acts on multiple aspects of collaborative work is needed to help patients and HCPs set expectations for their partnership appropriate to each patient, along with tools to support collaborative work, and skills training appropriate for the time and resource constraints typical in primary care encounters. Specific aspects of collaborative work are not usually recognized, such as psychological safety in the mostly hierarchical patient-HCP relationship, severe limitation of time, lack of training and knowledge of teamwork concepts, and limited tools for self-efficacy.

Objectives

The primary objective of this study is to assess the impact of a set of patient partnership tools that redesign primary care encounters to encourage and empower patients to make more effective use of those encounters to improve medication safety. Two notable features of the tools are (1) to encourage patients to tell, not just ask, primary care professionals (PCPs) about their medication use at home; and (2) to empower PCPs with tools to nudge patients to become active partners. The tools were developed to leverage the longitudinal relationship between patients and PCPs, instead of focusing on 1-time exposure to the tools. Comparison will be made between usual clinical processes as the control and redesigned clinic processes as the intervention.

Methods

Ethical Considerations

The human participant research protocol was approved by the University of Texas at Arlington Institutional Review Board under a reliance agreement for all study sites (protocol number and version UTA 2019-0439.25 approved on May 10, 2023; contact information: University of Texas at Arlington, Arlington, Texas, US, Angela Luna, IRB Specialist, Office of Regulatory Services, angela.luna@uta.edu). Documentation of patient consent was waived; verbal consent was sufficient and required for data collection (approved verbal consent scripts in Multimedia Appendix 1). The clinics determined that the interventions were part of their standard of care process once implemented. A data and safety monitoring board was appointed with one of the authors (RAY) as the lead to review any adverse events, protocol deviations, and issues with recruitment. The lead physician of each study site was included in the board. Quarterly reviews by the board will be conducted. The trial was registered with ClinicalTrials.gov (number NCT05880368 on May 26, 2023). The clinical leaders at each clinic will decide the types of primary care visits to be included in the interventions, such as annual wellness, disease management follow-up, or acute visits. The leaders will be asked to include all English- or Spanish-speaking patients who are at least 50 years old and have 5 or more medications listed in their electronic health records (EHRs). During each study period, requisite numbers of eligible patients will be recruited by a study coordinator to participate in data collection.

Study Design

The protocol was developed according to the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) statement (Multimedia Appendix 2) [30]. The study is a nonrandomized, cross-sectional stepped wedge cluster-controlled trial with 1 private family medicine clinic and 2 public safety-net primary care clinics each composing their own cluster (for a total of 3 clusters). There are 2 intervention sequences with 1 cluster per sequence and 1 control sequence with 1 cluster. We planned the study as a cluster trial because randomization of patients is not feasible when the clinical processes are changed for all patient visits once interventions are in place, not for individual visits. One control sequence is included in the clinic with no intervention planned.

Study Settings

The 3 clinics were in urban settings in a Southwest metropolitan area of the United States. All clinics predominantly serve patients with low socioeconomic status. One clinic is private with 1 family medicine physician. The other 2 clinics are public and part of a safety-net health system with family medicine residency training programs with approximately 15 primary care providers. The clinical and administrative leaders agreed to participate and to the timelines for data collection and implementation.

Interventions

Process redesign will be facilitated by two partnership tools: (1) a 1-page visit preparation guide given to relevant patients by clinic staff before seeing the provider, with the intention to improve communication and shared decision-making, and (2) a library of short educational videos that clinic staff encourage patients to watch on medication safety. The intervention design approach aimed to address multiple elements of collaborative work systems during primary care clinic visits to improve medication safety while minimizing the additional demands on busy PCPs and patients. The tools are expected to be used during typical patient wait times in the exam room and thus are expected to have minimal impact on throughputs. The following goals were considered during the design process: (1) to change collaborative work culture by clarifying patients' roles in contributing to medication use preferences, information accuracy, and in being prepared to participate in shared decision-making; (2) to explicitly recognize fear and reluctance in patient-professional communication by using concepts from the psychological safety literature in teamwork; (3) to set an expectation and to support learning the basics of medication use, such as the refill process and knowledge about tools to reduce unintentional errors; and (4) to encourage problem-solving in community settings, such as contacting pharmacists, who are generally more accessible than primary care providers, with medication-related questions. Participatory design methodologies [31,32] were used in the design and formative evaluation of the tools with older adults and PCPs. Iterative testing was conducted with users, both patients and PCPs. A qualified medical writer wrote the scripts for the videos. Health literacy and patient education experts edited the final versions of the visit prep guide and the scripts for the videos.

The visit preparation guide (Multimedia Appendix 3) contains three sections: ("ask") a list of question prompts for patients to consider about their medications, including one about deprescribing [33]; ("tell") a list of prompts for patients to communicate their medication management views, practices, and concerns; and ("expect") a set of behaviors to encourage collaborative work. The "ask" section had its origin in the approaches used in "Ask Me 3" [23] and EHR-based pre-encounter medication reconciliation [19], with a focus on barriers to self-efficacy in medication use. The "tell" section was designed to overcome communication barriers, such as fear of telling providers about nonadherence with medication regimens. The "expect" section is designed to provide means for providers to recognize and encourage patient collaborative actions, such as bringing medications to clinic visits [34].

The educational videos are less than 2 minutes each in length. The topics and learning objectives are based on interviews, focus groups, professional organization recommendations, and surveys with older adults and PCPs. The final set has 5 videos (length in min:sec): (1) working with your doctor (1:25); (2) taking medicine safely at home (1:33); (3) learning about your medicines (1:36); (4) working with your pharmacist (1:34); and (5) reading prescription labels (1:23). The videos are delivered in exam rooms on touchscreen tablets mounted to either the wall or portable stands.

There is no compensation to patients or clinicians for using the study tools. Participating clinics consider the interventions to be part of their standard of care once implemented, with no plans to compensate for any potential harm because of the trial.

Strategies to Improve Adherence to Interventions

Five points ("moments") of patient encounters during a typical office visit were identified to redesign clinical processes for enhanced patient partnership. The moments all present opportunities for PCPs to partner with patients to improve medication safety and were used to train PCPs on how to incorporate the interventions in the visit process. Two behavioral economics principles were used in developing sample scripts for PCPs: benefits appeal and psychological incentives [35].

1. Rooming, by medical assistants, sets the expectation for active partnership through benefits appeal and psychological incentives. Script examples include "This guide may help you be prepared. Check the items and give it to the doctor" and "I watched all these videos and I like them all. They are very short but will really help you."
2. Greeting, by providers, recognizes and encourages preparation in the patient work system with psychological incentives. Script examples include "Did you bring your meds? Great. I like it when you are prepared!" and "I see you are trying to be prepared. Very good."
3. Agenda setting, by providers, recognizes and encourages collaborative work through psychological incentives. Example scripts include "You used the prep guide. Thank you!" and "Thank you for telling me about your meds! I like it when we can work together better."
4. Closing, by providers, recognizes and encourages patient learning and engagement with psychological incentives. Example scripts include "Did you watch the videos here? Do you want to learn more?" and "That was a good visit – you are a 5-star patient today."
5. Discharge, by medical assistants or nurses, encourages learning through psychological incentives and group effects. Scripts examples include "It is great that you are trying to learn more about your meds" and "We can help you better by working together."

At the discretion of the clinics, gifts of token values are given to patients by staff or providers as part of psychological incentives. Examples of gifts are water bottles, band-aid holders, pill boxes, and medication bags, with a bulk purchase value of about US $1 per item. Staff and providers are informed that although they are encouraged, they are free to decide whether to use the tools and to adapt the suggested partnership enhancement scripts in their clinic encounters.

Outcomes

The primary outcome is self-efficacy in medication use in community settings. Self-efficacy will be measured by a validated tool: Medication Use and Self-Efficacy (MUSE) [36]. MUSE has eight items with a 5-point Likert scale, ranging from "1 – strongly disagree" to "5 – strongly agree": (1) It is easy for me to take my medicine on time; (2) It is easy to remember to take all my medicines; (3) It is easy for me to set a schedule to take my medicines each day; (4) It is easy for me to take my medicines each day; (5) It is easy for me to ask my doctor questions about my medicine; (6) It is easy for me to understand my doctor's instructions for my medicine; (7) It is easy for me to understand instructions on medicine bottles; and (8) It is easy for me to get all the information I need about my medicine. We replaced the word "pharmacist" with "doctor" given that our focus is on interventions in primary care settings. The MUSE score is the sum of the individual responses to the 8 items and ranges between 8 and 40, with 40 indicating "strongly agree" for all 8 items.

Secondary outcomes are a combination of patients' and PCPs' views on communication, collaborative work, and medication reviews. For patients, we will assess their views on collaborative work with seven items selected from five previously published instruments: (1) I know what each of my prescribed medications does (from Patient Activation Measure [37]); (2) I worry about drug interactions between the medications I take (from Medication-Related Problems [38]); (3) During the visit, I was asked to talk about any problems with my medicines or their effects (from Patient Assessment of Chronic Illness Care [39]); (4) During the visit, I was asked questions, either directly or on a survey, about my medicine habits (from Patient Assessment of Chronic Illness Care); (5) I understand what my doctor expects of me regarding my medicines (Psychological Safety Measure [40]); (6) If I make a mistake with my medicines, my doctor does not hold that against me (from Psychological Safety Measure); and (7) My doctor knows the vitamins and supplements I take (from Home Medication Experience Questionnaire [41]).

For providers, we will record the results of medication reviews in a medication review form and capture collaborative work during the visit. The medication review form was adapted from a toolkit published by the Agency for Health Care Research and Quality [42]. The medication review form measures regimen issues (contraindications, drug-drug interactions, and duplications); patient self-management issues (taking expired medications, taking incorrectly, failure to refill, and missed follow-up visits or lab testing); making changes without communicating with the primary care provider (making changes in medications, stopping a prescription, and stopping a supplement); and discrepancies in the medication record (taking medications not in the record, taking medications different from the record, medications active in the patient's record but not taking, or incorrect dose information). For each issue identified, we asked the providers whether they believed it presented a risk to medication safety (no risk, minor risk, or major risk). The collaborative work activities captured are medication changes made in the visit (removal of expired medications, updating prescriptions, replacing prescriptions, prescribing new

medications, regimen simplification, deprescribing, and changes in total number of medications); whether a caregiver is present, and if not, if a caregiver would be helpful; whether the patient brought their prescription and nonprescription medications to the visit; whether the patient knows why and how to take their medications; practices in engaging patients (agenda setting, creating or updating medication list with patients, and using teach-back techniques); and issues impeding the collaborative work (health literacy, language barriers, cognitive impairment, lack of a caregiver, not enough time, patient not knowing their medications).

All outcomes will be assessed immediately after the conclusion of a clinic visit. A research coordinator will survey consenting patients and give a paper form to the provider to collect data on primary and secondary outcomes. Implementation-related measures will be collected in terms of monthly use of the visit preparation guide and access logs of the video library. Protocol deviations will be reported and addressed per University of Texas at Arlington policies.

Study Timeline

Cross-sectional measurements will be taken at 6 time periods of 6 weeks each and will include a transition period of no data collection for intervention clinics (Table 1). Sample sizes will vary by period and cluster. We powered the trial according to the stepped wedge design (clinics A and B only) so that the additional data from the control clinic would add to the power as a supplement. The control clinic is in the same health system as one of the intervention clinics and shares a similar patient population and staff. Using a stepped wedge design allows for the implementation of the intervention at different time points in each clinic, thus providing logistical advantages (like maximizing resources for implementation) and controlling for biases from trends in patient care [43].

Table 1. Design of the nonrandomized, cross-sectional stepped wedge cluster-controlled trial with the schedule of enrollment, interventions, and assessments.

[d]N/A: not applicable (transition period for implementation; no data collected).

[e]INT: intervention.

Sample Size

The study is a superiority trial, on the hypothesis that interventions will improve patients' self-efficacy in medication use. We powered the trial to detect a difference of 3.8 units on the MUSE scale from pre to postintervention, with a pooled SD of 4.7 (standardized effect size of 0.79) based on a validation study on MUSE [36] using a 2-tailed significance level of 0.05. Power analysis was computed using the R package (version 4.1.0; University of Washington) swCRTdesign [44] via a web-based tool [45]. The transition period was excluded from the sample size calculations. We used 0.07 for intracluster correction and 0.9 for cluster autocorrelation based on study design recommendations [46,47]. With power set at 80%, the

requisite numbers of visits to collect data for each period are in Table 2, with a total sample size of 405.

Table 2. Sample size calculation. Sample size is the number of visits, not the number of patients, using a cross-sectional design.

	Period 1	Period 2	Period 3	Period 4	Period 5	Period 6
Clinic A	15	N/A[a]	35	20	15	15
Clinic B	30	50	N/A	45	30	30
Clinic C	20	20	20	20	20	20

[a]N/A: not applicable (transition period with no data collection efforts).

Recruitment

During each 6-week data collection period, study coordinators will work with study clinics to select recruitment days and identify up to 4 eligible visits per provider on those days. Only 2 visits per provider per shift will be enrolled to avoid disrupting care. Providers will be recruited and consented, informed of identified visits on selected data collection days, and asked to obtain verbal consent from the patients in identified visits to be approached by the study coordinator. The coordinator will then recruit and consent the patient. Patient and clinician participants will be compensated US $10 and US $25, respectively, for each data collection encounter.

Assignment of Interventions and Blinding

Because of the nature of the assessed interventions, we consider blinding not possible for patients or PCPs. Research coordinators who collect data are not blinded to the interventions as they may see interventions, but they are instructed to conduct data collection in consistent procedures regardless of intervention status.

Data Management and Confidentiality

All primary and secondary data collected will be entered into Research Electronic Data Capture (REDCap; Vanderbilt). A quarterly data review will be carried out to assess potential issues with data collection, including missing data and duplicate records. No personal identifying data will be collected.

Statistical Methods for Primary and Secondary Outcomes

Hierarchical models will be used to assess the impact of the interventions on primary and secondary outcomes. Hierarchical models, including linear mixed models, have been described and recommended for use in testing for intervention effects in cross-sectional stepped wedge designs [48,49]. The effect of the intervention is subject to confounding with time due to the staggered entry in stepped wedge designs, and thus the hierarchical modeling structure captures time trends and accounts for the effects of clustering within clinics. Should there be ceiling or floor effects with the total MUSE scores, responses to individual items will be explored. No interim analysis will be conducted. Social determinants of health will be evaluated, including sex, age, race, ethnicity, preferred language, educational level attained, self-reported health literacy, insurance status, and study clinics (private vs public). Associations of these variables with primary outcomes will be assessed, as we anticipate social determinants of health may affect the impact of the interventions. Selected social determinants of health will be assessed through subgroup analyses and model adjustment.

Descriptive statistics, such as medians, IQRs, and proportions, will be tabulated, overall and within clinics, to understand the distribution of the study population. Potential confounding variables were specified prior to data collection and include patient demographics, social determinants of health, time, and clinician. Confounding variables will be evaluated and controlled for in the analysis primarily through model adjustment or stratification. Because the intervention is confounded by time, the model will account for time period as a covariate in the statistical model, following recommendations on mixed models for stepped wedge trials by Li et al [48]. In addition, we included an extra clinic as a control group to assess changes over time in the absence of the intervention.

The study protocol is publicly registered and fully available. Participant level-data will not be made available. Statistical code will be made available upon request.

Dissemination Plan

A writing group will lead publication efforts in peer-reviewed journals and professional conferences. Reports will follow the CONSORT (Consolidated Standards of Reporting Trials) statement and its extensions (for both cluster randomized trials and nonpharmacological interventions) and follow journal authorship guidelines. We will also report implementation-related findings such as uptake patterns of tools over time and qualitative feedback from clinicians and patients at the study sites.

Results

The study was funded in September 2019. The trial started on April 10, 2023, and continued until December 15, 2023. The 3 study sites were in urban settings in a Southwest metropolitan area of the United States. All clinics predominantly serve patients with low socioeconomic status. One clinic is private with 1 family medicine physician. The other 2 clinics are public and part of a safety-net health system with family medicine residency training programs with approximately 15 primary care providers. As of February 15, 2024, we enrolled 405 patients. Data analysis is currently underway and the first results are expected to be submitted for publication in 2024.

Discussion

The trial aims to assess the impact of a set of patient partnership tools that redesign primary care encounters on patient

self-efficacy in medication use in community settings. Secondarily, the trial will provide information on the systematic approach to patient partnership enhancement in collaborative work during primary care visits, from both the patients' and providers' perspectives. We expect the tools and associated process changes in primary care clinics to improve several components of the collaborative work system in terms of self-efficacy, tools, and skills. The intervention is unique compared with prior approaches, such as generic videos on open communication between patients and HCPs or EHR-based tools to help agenda setting [19,22]. If adoption proves successful and MUSE scores rise, the trial will support the innovative approach to improve medication safety in ambulatory settings by improving the value of primary care through collaborative work and partnership. The trial will be carried out in clinics serving vulnerable populations with poor indicators for social determinants of health. The combination of a private family medicine clinic and a primary care clinic in a public safety-net hospital system will provide evidence about the applicability of the approach in a wide range of clinical settings. In addition to the visit prep guide and videos, the trial will also generate other tools for implementation, such as training for PCPs to engage the patient work system and thus improve self-efficacy and ultimately medication safety.

Both the intervention and the assessment approaches are based on collaborative work concepts not previously used to increase patient engagement. Psychological safety in the hierarchical relationship between patients and providers and the clarification of roles and responsibilities have been absent in prior interventions. Although prescribing decisions are important aspects of medication safety, the intervention targets barriers to successful self-management in the patient work system, including patients' home environments.

The trial design has several strengths. The assessment collects data to illuminate both the patient's and PCP's perspectives immediately after an office visit. The data include both patient-centered safety outcomes such as self-efficacy and clinical outcomes such as risks posed by issues identified during medication review. The data also include process measures on collaborative work like psychological safety. The studied patient population is on 5 or more chronic medications and thus is a high-risk group.

The trial has several limitations. Data on ADEs are not collected. Future studies are needed to assess the longer-term impact. The trial is limited in time and thus longitudinal data are not collected on the potential long-term impact of the partnership tools (ie, the impact of repeated exposure over years). The modality of tools (paper visit preparation guides and exam room videos on tablets) is limited and does not leverage consumer and EHR technology in communication and in learning. The number of study clinics is small. However, with stepped wedge design, we expect to control some of the confounding variables, such as seasonality.

Acknowledgments

This trial is supported by a grant from the US Agency for Health Care Quality and Safety (grant number HS027277). The content is solely the responsibility of the authors and does not necessarily represent the official views of the sponsor and funder. The sponsor and funder have no roles in study design; collection, management, analysis, and interpretation of data; writing of the report; and the decision to submit the report for publication, with no ultimate authority over any of the above activities other than regulatory authority. The authors thank the following for their contributions: Laura Townsend, Yan Lang, Emily Reeve, Cheryl DeLeon, Monica Patton, Genevieve Walker, Isaac Watemberg, Mai Nguyen, Nicole Hickman, Eva Bustos, Nihita Shah, and Rashmi Rode.

Data Availability

The data sets generated and analyzed during this study are not publicly available to protect patient confidentiality but may be available from the corresponding author upon reasonable request. The assessment instruments and intervention tools are available for noncommercial use.

Authors' Contributions

YX was responsible for writing the protocol, acquiring funding, and planning the study. ZNH, KMD, KGF, APG, RAY, and SB participated in cowriting the protocol. ZNH coordinated data collection procedures across study sites. KMD, KYC, YZ, LK, JW, KGF, AME, APG, SIP, AIA, RAY, and DS were involved in codeveloping intervention tools. JLR, KMS, SIP, AIA, and MAC participated in codeveloping assessment concepts. KGF, APG, RAY, DS, and MJ played a role in coplanning for the study. KGF and SB were responsible for designing the study. KGF, AME, and RAY were involved in recruiting study sites.

Conflicts of Interest

KYC has a potential research conflict of interest due to a financial interest with companies Hewlett-Packard Enterprise, Boostr and DecisionNext. A management plan has been created to preserve objectivity in research in accordance with UTA policy. The authors have no further interests to declare.

Abstract

Background: Family and community nurses (FCNs) play a crucial role in delivering primary care to patients within their homes and communities. A key aspect of their role involves various health interventions, which are influenced by their unique competencies, such as health promotion, advanced clinical knowledge, and strong interpersonal skills. However, it is essential to understand which specific health outcomes these interventions impact to better understand the relationship between FCNs' skills and the health results.

Objective: This study aims to outline the steps we will take to develop a set of core outcomes. These outcomes will be particularly sensitive to the health interventions carried out by FCNs, providing a clearer picture of their practice's impact.

Methods: A Delphi survey will be used for this research, conducted from January to December 2024. The process will involve 5 steps and input from 3 stakeholder categories. These stakeholders will help identify a preliminary list of outcomes that will form the basis of our core outcome set (COS).

Results: This guideline will be beneficial for a wide range of stakeholders involved in COS development, including COS developers, trialists, systematic reviewers, journal editors, policy makers, and patient groups. As of January 2024, we have successfully completed the first stage of the study, with the stakeholder group approving the reported outcomes and assigning participant lists for each stakeholder group.

Conclusions: This study will provide a roadmap for identifying the key health outcomes influenced by the interventions of FCNs. The multistakeholder, multiphase approach will ensure a comprehensive and inclusive process. Ultimately, the findings will enhance our understanding of FCNs' impact on health outcomes, leading to more effective primary care strategies and policies.

KEYWORDS

clinical knowledge; core outcomes set; Delphi survey; family and community nurse; health interventions; health promotion; primary care; stakeholder engagement

Introduction

Family and community nurses (FCNs) provide primary care services to patients within their homes and communities [1]. Their core activities span a broad spectrum of primary services, including health promotion and primary, secondary, and tertiary prevention, focusing on the health and well-being of communities and populations [2]. These specialized professionals are crucial as they deliver accessible and comprehensive primary care services to individuals and communities, particularly in underserved areas and communities with high rates of chronic diseases [3]. Hence, they play a pivotal role in promoting health, preventing disease, and managing chronic conditions by fostering close collaborations with other health care providers to ensure comprehensive patient care. Although various outcomes linked to the activities of FCNs have been described in recent literature [4-8], a formal core outcome set (COS) is yet to be established [9].

Even though FCNs are primarily employed in primary care settings, they have been recognized as key connectors between the various levels of care and health care providers involved in primary, secondary, and tertiary care levels [10]. Primary care is the first level of contact between a patient and the health care system, focusing on illness prevention, health promotion, and the diagnosis and treatment of common conditions [11]. Secondary care involves specialized medical care provided by health care professionals such as specialists, nurses, and technologists, involving more complex medical procedures and treatments in health care facilities [12]. Tertiary care refers to specialized and complex medical and surgical treatments provided by specialized health care providers in specialized centers. In this intricate scenario, FCNs facilitate a smooth transition of care between the various levels of care in a typical patient journey, addressing the challenges of chronic diseases by providing preventive care, health education, and referrals to specialists when necessary [13,14]. This ability to provide comprehensive care and coordinate with other health care providers enables FCNs to ensure that patients receive seamless and effective care across different health care system levels [15].

The curricular competencies of FCNs, as described in recent literature through the ENhANCE project [16], are primarily based on health promotion, high relational competencies, skills, and advanced clinical knowledge. These competencies define the health domain of FCNs as a specific FCN health intervention. According to Caruso and colleagues [16], to frame an integrated view of the complex relationship between curricular competencies and health outcomes, it is necessary to clarify which specific health outcomes are susceptible to the domains described in defining the role of FCNs.

In essence, aligning a specific domain with a health outcome is crucial for 2 main reasons. First, it allows health care providers and policy makers to determine the effectiveness of the FCN role [17]. Second, linking specific domains to specific health outcomes enables the measurement and comparison of the impact of different domains, thereby informing decisions about which domains are most effective for improving health outcomes [18]. Moreover, matching interventions to outcomes helps ensure that resources are used effectively and efficiently [19]. Health care providers and policy makers can prioritize resource allocation and improve health outcomes for the greatest number of people by focusing on domains that impact health outcomes. Lastly, matching domains to outcomes also promotes accountability and transparency in health care [18]. By clearly documenting the impact of domains on health outcomes, health care providers and policy makers can demonstrate their commitment to improving health and provide evidence of their progress toward this goal. However, even though the nature and classification of the health domain provided by FCNs are clearly recognized in the literature (eg, ENhANCE Project - European Curriculum for Family and Community Nurses) [15], the health outcomes that are susceptible to those interventions remain largely undefined and poorly described, and no COS has been defined in relation to the FCNs [9].

A COS is a standardized and agreed-upon set of outcomes that should be measured and reported in all studies of a particular condition or intervention [20]. A COS helps ensure that the most important and relevant outcomes are measured and reported consistently across studies, allowing for meaningful comparison and synthesis of results [20]. Developing a COS involves a systematic and collaborative process involving stakeholders such as patients, health care providers, researchers, and policy makers. The goal is to identify the most important outcomes, starting from a defined framework and developed from the perspective of patients, ensuring that these outcomes are relevant and meaningful to all stakeholders [20,21].

A COS can improve the quality and comparability of research by standardizing the measured and reported outcomes, informing clinical decision-making, and supporting evidence-based health care. It can also help to reduce the risk of selective reporting of outcomes and publication bias, leading to a more comprehensive understanding of the impact of a domain on health outcomes [20,21]. This COS is therefore labeled as the Family and Community Nursing Core Outcomes Set (FCN-COS), using the approach proposed by Moher and colleagues [22]. This protocol will develop FCN-COS sensitive to the health interventions that characterize the practice of FCNs. The objectives of the study are to (1) determine a consensus with a Delphi survey regarding an FCN-COS and (2) develop an FCN-COS sensitive to the health domains that characterize the practice of FCNs involving stakeholders such as patients, health care providers, researchers, and policy makers.

Methods

Design

This protocol is designed to incorporate a multimethod and multiphase approach from January to December 2024. It adheres to the recommendations of the "Core Outcome Measures in Effectiveness Trials" (COMET) Handbook (version 1.0) [23] and the Guidance on Conducting and Reporting Delphi Studies (CREDES). The development of the FCN-COS guideline will commence in January 2024 and will be carried out in 5 stages.

- Stage 1: compilation of a preliminary, evidence-based list of reviewed outcomes for consideration in the FCN-COS.
- Stage 2: execution of a web-based Delphi survey to validate the classification and work toward a reporting guideline for FCN-COS.
- Stage 3: conducting a final web-based consensus meeting to identify the definitive outcomes for inclusion in the FCN-COS reporting guideline.
- Stage 4: development of a high-quality reporting guideline and a detailed explanatory document, transforming final FCN outcomes into definitive outcomes and domains.
- Stage 5: Postdevelopment activities, including pilot-testing and dissemination of the results.

The process will involve 3 categories of stakeholders: health care professionals, methodological experts, and service users. These stakeholders will contribute to identifying the preliminary list of proposed outcomes, participate in the Delphi survey rounds, contribute to the consensus meeting, and review the materials produced for disseminating the results.

Stage 1

Preliminary List of Outcomes

The practice of FCNs has significantly contributed to the development of comprehensive health interventions. The preliminary list of proposed outcomes is based on the Classification Clinical Care Classification System (CCC, version 2.5), which provides standard terminology for outcomes and domains, facilitating the documentation of nursing assessments in home care settings. This classification comprises 176 nursing diagnoses, including 60 primary outcomes and 116 diagnostic subcategories. The outcomes included in the preliminary list are defined using existing taxonomies [24], supplemented by a summary of outcomes from a recent systematic review [9] (Multimedia Appendix 1 [5,8,13,25-36]). Additionally, the literature review that will serve as a foundation for developing a preliminary list of outcomes [9] will be updated with specific searches in MEDLINE, CINAHL (EBSCO), Global Health (Ovid), Scopus, and Web of Science. The steering committee will approve the final list of outcomes. The Delphi survey will present the outcomes within each domain to participants in a random order.

Preliminary Consensus Meeting

A preliminary consensus meeting has been arranged to define specific methodological aspects of the Delphi survey among the authors of the study protocol. Specifically, an initial web-based consensus meeting was held to define domains. The preliminary outcomes are based on the CCC (version 2.5) taxonomy [24], serving as an evidence-based classification to initiate the preliminary FCN-COS. These preliminary outcomes, developed in the home care setting, have been identified as a crucial starting point [24].

Moreover, a web-based meeting was held in the designing phase of the protocol to discuss strategies for mitigating the risk associated with a low response rate to the Delphi survey. Before starting with the Delphi survey, a brief video will be disseminated among the participants to familiarize them with the project, particularly focusing on the timeline and rounds of discussion.

Stage 2

Delphi Surveys

A web-based Delphi survey will be started to generate consensus regarding the preliminary list of outcomes. We will use the Delphi technique to obtain consensus from the panel of participants through 2 rounds of discussions. Therefore, the first round of discussion will take place from the outcomes identified in the previous stage, inviting participants to add further outcomes not included in the preliminary outcomes. Outcomes identified during the first round will be included in the second round of the Delphi process outcome item. The second round of discussion will take place to provide feedback and identify further outcomes from participants. More precisely, participants will reevaluate their original rating from the first round by including the other participants' overall rating for each outcome. An outcome will be included in the final FCN-COS with a consensus equal to or greater than 80% in all stakeholder groups rating the outcome as critically important.

Participants: Panel Composition

We plan to involve various stakeholder groups, each contributing a balanced mix of skills and competencies. These groups include health care professionals in primary care, health care researchers, nurses actively involved in nursing regulatory authority boards, and service users. The first group will consist of individuals who have experienced primary nursing care within the past 2 years. The second group will focus on research methods to provide robust support for the Delphi survey methodology. Service users will offer feedback based on their experiences in primary care.

Recruitment Process

Potential participants will receive personal emails explaining the project and its objectives. Before initiating the survey, we will organize a web-based meeting to help participants better understand the project's aim. We will then ask them to complete the first round of the Delphi survey within a 2-week time frame. Participation in the survey is optional, and informed consent will be obtained from those who choose to participate. Each participant will be assigned a unique identification number for the 2 rounds of the Delphi survey. We will request the contact authors from each FCN-COS developer stakeholder group to invite their coauthors to provide feedback. This approach ensures that we gather opinions from both clinical and methodological experts in FCN-COS development. At the end of the 2-week

period, we will send reminders to participants to complete the survey.

We will collect demographic data, including age, profession, years of experience, educational background, and previous experiences with COS development. Each stakeholder who completes the first round of the Delphi survey will be invited to participate in the second round. We will obtain their name and informed consent to be recognized as a member of the Delphi group in the publication resulting from this research.

Delphi Scoring and Software

The reporting guideline outcomes listed will use a 9-point scale, with 1-3 labeled as not important for inclusion in the COS, 4-6 labeled as important but not critical for inclusion in the COS, and 7-9 labeled as critical for inclusion in the COS [37]. Participants will also be allowed to score "maybe" if they are unable to offer an opinion as to whether the reporting guideline outcome is important or not. An electronic survey format called "web-based" will be used for managing the Delphi surveys [23].

Data Analysis

Descriptive statistics will be used for each survey round to determine the overall scores for each stakeholder group, considering the 3 categories (not important, important but not critical, and critical) to determine whether outcomes are critical for the FCN-COS. Only responses from participants who will rate at least 50% of the outcomes will be included in the analysis. By comparing the distribution of the mean overall scores from the second Delphi round between participants who attended the consensus meeting and those who did not, selection bias between the Delphi procedure and the consensus meeting (see Stage 3 section) will be evaluated. Data analysis will be performed using SPSS Statistics for Windows (version 28; IBM Corp).

Stage 3

Consensus Meeting

The stakeholder group of 100 people will be included in a web-based interactive consensus meeting. The consensus meeting will be represented through a short study overview as outcomes reported by each stakeholder group. The outcomes where the consensus meeting is reached will be considered first to ratify those results. If a consensus meeting is reached for other outcomes, they will be considered according to the stakeholder groups. An opportunity to discuss each outcome will be given to all participants, defined by an anonymous scoring method, between the ones defined at the consensus meeting. Stakeholders will define the final outcomes based on the review of the responses from Delphi participants. The consensus meeting will be fundamental to identifying the outcomes included in the reporting guideline for FCN-COS development. If 70% of the consensus meeting participants favor the outcome's inclusion, it will be considered consensus. The best form of communication in the consensus meeting will be determined by comprising methods of feedback (eg, track changes) and ensuring disagreements' resolution. In the end, a written report after the consensus meeting will be circulated for comment.

Delphi Round 1

Each outcome will be presented to reflect the outcomes' clarity or ambiguity [23]. Every participant will be asked to score each outcome, and after that, they could add any other outcomes they believed to be added to develop FCN-COS. The research group will revise the entire reporting list of outcomes. Each outcome will have a summarized view, including the scored outcome and its distribution. All outcomes will be carried forward to round 2. The response rate of participants as all the participants completed the survey compared to the sent email invitations. The incomplete answers will also be monitored.

Delphi Round 2

In the second round, each participant who participated in the first round will be shown the number of respondents and the distribution of scores for each outcome. They will be asked to rescore the outcome of the other Delphi participants and to justify any reason for an eventual change (eg, if a participant changed their score from "not critical" to "critical" in the second round). For each outcome, the number of participants who have scored it and the distribution of scores will be summarized. When the second round is completed, the attrition bias will be considered by comparing 2 groups of the first and second rounds. A comparison will be developed between participants who completed the second round and those who completed only the first one. Changes in participants' scores will also be examined, and the reasons for changes between the 2 rounds will be summarized.

Consensus Definition

A consensus will be defined and obtained before participants take part in the Delphi survey, as previously recommended. Reporting outcomes will only be prioritized if they reach 80% of the support from participants scoring "critical" (ie, score 7-9) [23].

Stage 4 (Development of Reporting Guideline and Explanatory Document and Procedure)

The aim of the explanatory document is to provide the background, rationale, and justification for the FCN-COS. This document will be developed concurrently with the reporting guidelines.

In stage 4, stakeholders will concentrate on the development of the reporting guideline for studies developing COS and the accompanying explanatory document. Additionally, a draft recommendation will be created to explain the origin of the outcome (whether from stakeholders or the Delphi survey), the level of consensus achieved (through the Delphi survey and consensus meeting), and a brief rationale for inclusion. The expert panel will review the document and provide feedback on the guideline and explanatory document as needed. The FCN-COS guideline will undergo several revisions until the final draft is deemed complete.

Stage 5 (Pilot-Testing of the FNC-COS)

In the end, in stage 5, we will test the draft completed in the previous stage. Authors will be invited to test the FNC-COS, and the more experienced COS developers will review the

guidelines to improve it. Their feedback will be reached through an anonymous survey incorporated into the final COS guideline.

Ethical Considerations

The University of Pavia Review Board has been consulted and confirmed ethical approval for this study (number 02/int/2023/CdS).

Results

In this study, a comprehensive FCN-COS will be developed through a rigorous multiphase approach. COS developers, trialists, systematic reviewers, journal editors, policy makers, and patient groups will benefit from the COS development, as it will aim to improve the quality and comparability of future research by standardizing, through 5 distinct stages, the measurement and reporting of outcomes in the field of family and community nursing. As the first stage of the study will be successfully completed, with the stakeholder group expected to approve the reported outcomes and assign participant lists for each stakeholder group, this significant milestone will signify the initial step toward establishing a standardized framework for measuring and reporting outcomes in family and community nursing research, which will inform future clinical decision-making and enhance research quality and comparability in this vital domain. The Delphi survey approach will be a sound method for soliciting input from a wide range of stakeholders, including health care professionals, researchers, and service users. The surveys will aim to establish consensus on the importance of various outcomes. This iterative process will be instrumental in refining the list of outcomes and ensuring that the most critical outcomes are identified. The consensus meeting will mark a critical juncture in the development of the FCN-COS. Bringing together a diverse group of stakeholders for an interactive discussion will ensure that the final outcomes selected truly reflect a collective consensus, as well as the development of the reporting guideline and explanatory document. The involvement of an expert panel in reviewing and revising these documents will ensure their quality and clarity. The pilot-testing stage will represent a valuable step in validating the FCN-COS. Inviting authors and experienced COS developers to test the guideline and provide feedback will be a practical approach to identifying any potential issues or areas for improvement. Their insights will contribute to the refinement and usability of the FCN-COS.

Discussion

Overview

To date, no FCN-COS has been developed, and its development could aid in organizing and understanding various interventions within the family and community context [9]. The establishment of FCN-COS will enhance the organization and improvement of FCN interventions, shedding light on the impact of the FCN on health outcomes within a broader family and community context.

This proposed protocol for developing and the future FCN-COS is essential to comprehend how nursing domains are defined by FCN interventions. An example is the “role relationship,” such as parenting skills to ensure child protection. Multidisciplinarity in the health care setting is a priority to ensure continuity of care, involving various health care professionals to better guarantee community health. This can be better illuminated through the FNC-COS, starting from the preliminary version of FCN-COS. The preliminary version of FCN-COS is a crucial starting point. This classification is vital to prioritize the most relevant interventions for FCNs in practice and guide the development of a consensus-based set of core interventions using a Delphi survey approach [24]. This can help ensure that nurses are equipped with the most relevant and evidence-based interventions to provide high-quality care to families and communities.

FCNs provide primary care services to patients in families and communities [1]. Their core activities cover a wide range of primary services, from health promotion to primary, secondary, and tertiary prevention, focusing on the health and well-being of communities and populations [2]. These specialized professionals are important because they provide accessible and comprehensive primary care services to individuals and communities, particularly in underserved areas and communities with high rates of chronic diseases [3]. The FCN is a key role that can bridge the gap between home care settings and hospitals, with autonomy as a self-regulated profession [15]. For this reason, this Delphi process aims to develop a standardized classification of FCN interventions emerging from the unique needs and contexts of FCN practice. In particular, as the FCN’s clinical practice develops in primary, secondary, and tertiary care, defining FCN-COS is a priority that has not yet been developed [9].

The FCN-COS derived from stage 1 is based on the national and international literature [9], and it will need to be adapted for country-specific use in Italy. This will be developed by engaging with a panel of participants in Italy, using a Delphi approach, to define the classification and identification of any outcomes that may be more or less relevant to FCN practice in Italy. In other words, this proposal will be developed as the result of the implementation of the next phases of the protocol to ensure that the FCN is relevant and applicable to the unique needs and contexts of FCN practice in Italy.

Expected Results From the Delphi Study

Having an FCN-COS is highly relevant to sustaining health promotion and salutogenic interventions in the family and community context [2]. FCN-COS is fundamental to try to fill the gaps about the current unavailability of FCN-COS in the Italian context [9]. This protocol, even if developed in Italy, will be fundamental for the international context. In particular, we focused on the international literature review to define the preliminary outcomes of the FCN-COS [9]. After the preliminary outcomes, stage 1 of the study will follow. A standardized scheme of classification and a precise hierarchical classification of interventions are fundamental to facilitate assessments [21].

Furthermore, the social recognition of the FCN could be strengthened by the definition of a COS shared between health care professionals, even internationally [9,24]. The Delphi survey allows the illumination of experts’ opinions through a

series of iterative questionnaires to reach a consensus on defining FCN-COS. The Delphi survey will be conducted ensuring the anonymity of the panel of participants. This is fundamental to reduce the impact of dominant personalities in the debate and decreasing peer pressure [38]. In this sense, every answer will be equally weighted, and the feedback process allows experts to develop a precise idea between one round and another, letting them know the previous ratings of the survey [39].

Limitations

The methodology used is the main limitation in defining FCN-COS. This approach limited the possibility of elaborating on in-depth views of the panel composition about the FCN-COS. However, a web-based system should help researchers optimize the response rate. Despite this, developing the best possible FCN-COS could be possible through future further validation studies to verify the defined FCN-COS in relation to measurable patient-level outcomes and to the previously developed FCN-COS.

Conclusion

The Delphi survey is fundamental to developing a COS sensitive to the health interventions that characterize the practice of FCNs. The FCN-COS will be developed as the main turning point, which can determine a greater quality and comparability of research, inform clinical decision-making, and support evidence-based health care. Furthermore, FCN-COS will be fundamental to define FCN as an emerging health care professional in the field of nursing.

Acknowledgments

This study was partially supported by the University of Pavia (no specific grant) and the Ricerca Corrente funding from the Italian Ministry of Health to IRCCS Policlinico San Donato.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

SR, CA, and RC conceptualized the study. All authors developed the first draft of the manuscript and are involved in the data collection. All authors contributed to the development of the study protocol and approved the final draft of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Uncomplicated urinary tract infections (UTIs) in women are among the most common bacterial infections in primary care. Given the health threats related to the overuse of antibiotics, alternative options are of increasing importance. Patient-reported outcome measures are valuable tools for including the patients' perspective when evaluating the efficacy of these strategies. Aiming to identify a suitable instrument to measure the severity and bothersomeness of UTI symptoms in women, we performed a systematic review of the literature and identified the Holm and Cordoba Urinary Tract Infection Score (HCUTI), which measures the severity, bothersomeness, and impact of uncomplicated UTIs on daily activities. This instrument showed sufficient content validity but needs translation and further validation before it can be used in German research.

Objective: For use in the German setting, we aim (1) to perform translation and linguistic validation of the HCUTI and (2) to evaluate content validity and psychometric properties of the German version of the HCUTI in a population of women with uncomplicated UTIs.

Methods: The HCUTI will be translated and linguistically validated using the dual-panel method. This process involves a bilingual translation panel and a lay panel to check the comprehensibility of the translation. Content validity of the translated questionnaire will be assessed using cognitive interviews according to the criteria for good content validity as recommended by the COSMIN (Consensus-based Standards for the selection of health Measurement Instruments) group involving women with uncomplicated UTIs and health care professionals. Subsequent psychometric validation of the German version of the HCUTI in a population of women with uncomplicated UTIs will include the assessment of structural validity, internal consistency, test-retest reliability, construct validity, responsiveness, and interpretability.

Results: Results of the translation and linguistic validation process and the results of the content validity study were obtained in September 2023 and will be published separately. Data on the psychometric properties of the German version of the HCUTI are anticipated in mid-2024.

Conclusions: We expect that data from the content validity study will provide important suggestions for potential modifications of the HCUTI for use in the German setting. The final version of the questionnaire will be used for the assessment of its psychometric properties in a large population of women with uncomplicated UTIs.

Introduction

Background

Patient-reported outcome measures (PROMs) are increasingly used in medical research and patient care since researchers, clinicians, and decisions makers are becoming increasingly aware that the patients' perspective is crucial when evaluating the efficacy of treatments and the quality of health services [1]. PROMs are standardized questionnaires for the assessment of information on health outcomes directly from the patient, including symptoms, physical, emotional, and social functioning, or multidimensional constructs such as health-related quality of life (HRQoL). Initially developed for use in research, the application of PROMs has expanded involving various domains of patient care including clinical decision-making and the evaluation of treatment strategies [1].

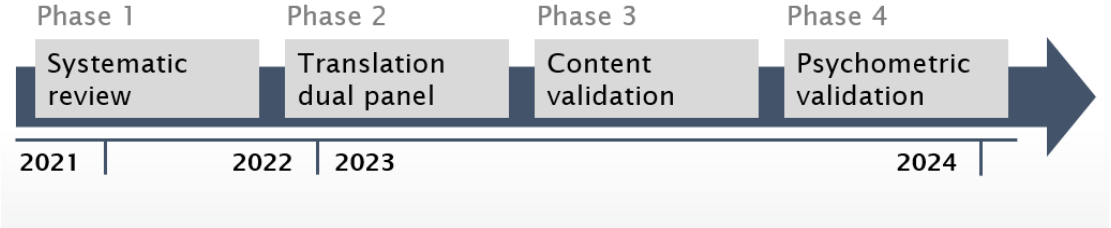
In primary care, uncomplicated urinary tract infections (UTIs) are among the most common bacterial infections in women and an important public health problem [2,3]. UTIs are generally self-limiting but commonly treated with antibiotics since they are bothersome, and antibiotic treatment leads to a more rapid resolution of symptoms [4,5]. Given the health threats related to conservative antibiotic treatment, the development of alternative treatment options is of increasing importance, and evaluating these strategies by considering the patients' perspective is a high priority. For this purpose, PROMs are valuable tools. For uncomplicated UTIs, several disease-specific instruments have been developed and validated, assessing symptom burden [6,7], the impairment of daily activities [6,8], and HRQoL [6]. The selection of a PROM is guided by content-related considerations, including the construct to be measured and the target population, but it is also essential to consider the quality of the measurement properties of available instruments. Aiming to facilitate the selection of high-quality PROMs for research and patient care, the COSMIN (Consensus-based Standards for the selection of health Measurement Instruments) initiative has suggested a methodology for conducting systematic reviews of PROMs [9]. This includes the assessment of the methodological quality of single studies on measurement properties of PROMs using the COSMIN risk of bias checklist [10] and the evaluation of the quality of measurement properties of the PROMs themselves.

A systematic review of the quality of measurement properties of available PROMs for uncomplicated UTIs using the COSMIN methodology was performed [11]. Among the identified PROMs measuring symptom severity and bothersomeness, the Acute Cystitis Symptom Score (ACSS) [6] and the Urinary Tract Infection-Symptom and Impairment Questionnaire (UTI-SIQ-8) [7] can be recommended for use (COSMIN category A). Capturing the broadest spectrum of outcomes, the assessment revealed that the Holm and Cordoba Urinary Tract Infection Score (HCUTI) [12] is a promising tool that warrants further validation (COSMIN category B). The HCUTI comprises 43 items on 3 subscales measuring the following aspects over a 7-day period: symptom severity (18 items), bothersomeness (18 items), and impact on daily activities (7 items). All items are rated on a 4-point Likert scale ranging from 1=none to 4=a lot. The instrument is available in Danish and has sufficient content validity. Data on other important measurement properties, for example, structural validity, are not yet available, indicating the need for further validation studies before the instrument can be used.

Objectives

The objective of this work is to perform translation and linguistic validation of the HCUTI for use in the German setting and to evaluate content validity and psychometric properties of the German version of the HCUTI in a population of women with uncomplicated UTIs. The protocol aims (1) to describe the translation process of the HCUTI from Danish into German language and the linguistic validation, (2) to describe the content validation of the translated HCUTI, and (3) to describe the psychometric validation of the German version of the HCUTI. The timeline is presented in Figure 1.

Figure 1. Study schedule.



Methods

Translation and Linguistic Validation

The HCUTI will be translated from Danish into German language using the dual-panel method [13]. A bilingual translation panel consisting of 4 nonprofessional persons fluently speaking Danish and German will perform the translation in a web-based meeting. A bilingual person with a medical background will moderate the session under the guidance of the study team, and discussion points and decisions about the wording of the single items will be protocolized. To ensure that the original meaning of the items is maintained, the developer of the HCUTI will participate in the translation process. Based on the translations of the single members of the panel, consensus will be sought about the wording during the session. Subsequently, a lay panel involving 4 German native-speaking women who have experienced uncomplicated UTI in their lifetime will review the translation regarding comprehensibility of the instructions, items, and response options, also in a web-based meeting. Changes in wording will be documented in minutes, and the session will be additionally audio recorded for later analysis. Two members of the research team will adapt the questionnaire according to the results of the lay panel. This procedure will result in the German version of the HCUTI, for which content validity and psychometric properties will be assessed.

Assessment of Content Validity

Overview

Following a qualitative approach, the content validity of the German version of the HCUTI will be assessed in cognitive interviews with affected women and interdisciplinary experts.

Recruitment of Participants

Women with uncomplicated UTIs will be recruited through the study team's network. Women being at least 18 years of age who have been diagnosed with uncomplicated UTI in the past 3 years will be included. Experts from relevant disciplines including family practice, urology, gynecology, nursing, health sciences, and psychosomatic medicine will be also recruited through the study team's network.

Procedure

Content validity will be assessed in accordance with the COSMIN criteria [10]. These criteria were developed in 2016 in a Delphi study among 159 experts from 21 countries including participants with expertise in qualitative research, development and evaluation of PROMs, and different professional backgrounds such as clinicians [14]. COSMIN provides a detailed, standardized, and transparent methodology, thereby promoting the selection and use of high-quality PROMs in research.

In individual semistructured interviews, women with uncomplicated UTIs (n=7) and health care professionals (n=7) will complete the questionnaire. The aim is to assess the relevance, comprehensiveness, and comprehensibility of the instructions, items, response options, and recall period from the women's and experts' perspectives. Two trained interviewers will conduct the interviews in a web-based meeting or in-person session following a standardized interview topic guide (Multimedia Appendix 1). The results will be documented for each item using a Microsoft Excel (Microsoft Corp) sheet. All interviews will be recorded and transcribed verbatim. Two researchers will perform data analyses using thematic analyses to identify problems related to relevance, comprehensiveness, and comprehensibility. Single items will be modified if at least 3 interviewees make a specific comment on that item. If required, the questionnaire will be adapted based on the results of the interviews, and all items will be tested in their final form in further qualitative interviews with women with uncomplicated UTIs.

Assessment of Psychometric Properties

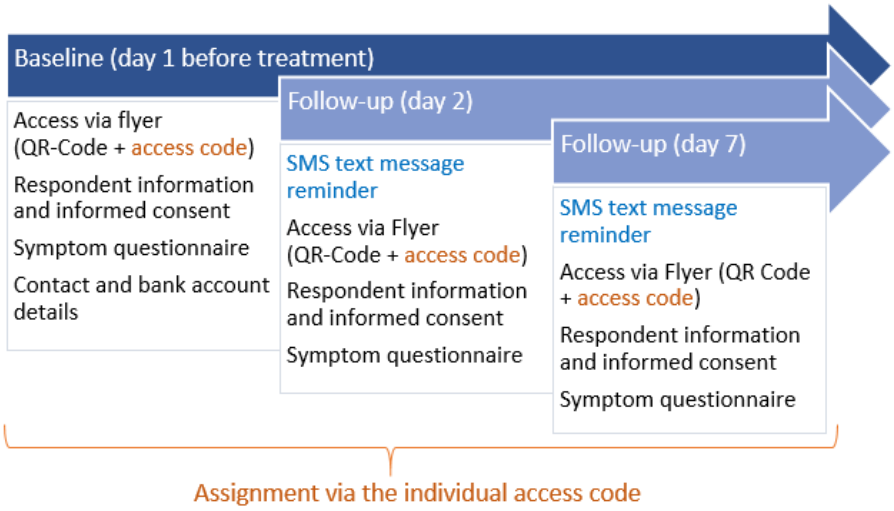
Overview

Once the content validation has been carried out and the final version of the HCUTI has been accepted by the interviewees and experts in terms of relevance, comprehensiveness, and comprehensibility, the psychometric validation study will be carried out in a quantitative web-based survey. For this purpose, the final HCUTI will be used in the target population, and the measurement properties will be analyzed using the survey data set.

Recruitment of Participants

A web-based survey targeting a sample size of >200 will be carried out. The study procedure is displayed in Figure 2. Women with uncomplicated UTIs will be recruited in practices for family medicine, urology, and gynecology. Women being at least 18 years of age with a confirmed diagnosis of acute cystitis or uncomplicated UTI (*International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* [*ICD-10*] codes N30.0, N30.9, and N39.0) will be included. Women with complicated UTI and women with insufficient German language skills will be excluded. Participating women will complete the survey at 3 measurement points: baseline (day 1, before treatment), follow-up 1 (day 2), and follow-up 2 (day 5). Subsequent data analyses on psychometric properties will include the assessment of structural validity, internal consistency, test-retest reliability, construct validity, responsiveness, and interpretability. All analyses will be performed in accordance with the criteria of the COSMIN group [9].

Figure 2. Procedure of the psychometric validation study.



Data Analyses

Structural Validity

Structural validity is defined as the degree to which the scores of an instrument are an adequate reflection of the dimensionality of the construct to be measured [15]. Unidimensionality refers to whether the items in a scale or subscale measure a single construct and is an assumption for internal consistency. The HCUTI is hypothesized to measure symptom severity, bothersomeness, and impact on daily activities, suggesting the unidimensionality of the 3 subscales. Structural validity will be assessed using item response theory and Rasch analysis. Confirmatory factor analyses will be performed to test the unidimensionality of the 3 subscales. The assessed parameters according to the criteria for good measurement properties as recommended by the COSMIN group are depicted in Textbox 1.

Using Rasch analysis, the resulting dimensions will be tested for differential item functioning, which is a method for analyzing measurement equivalence. Differential item functioning of an item is present if the item response differs across groups (eg, sex and race), controlling for an estimate of the construct being measured [16].

Textbox 1. Parameters and criteria for the assessment of structural validity.

- Unidimensionality: Comparative fit index or Tucker-Lewis index or comparable measure >0.95 or root mean square error of approximation <0.06 or standardized root mean square residual <0.08
- Local independency: Residual correlations among the items after controlling for the dominant factor <0.20 or Q3's<0.37
- Monotonicity: Item characteristic curves will be generated for each item; adequate-looking graphs are required or item scalability >0.30
- Model fit: Item response theory: χ^2>0.01 and Rasch: infit and outfit mean squares ≥0.5 and ≤1.5 or *Z* - standardized values >–2 and <2

Internal Consistency

Internal consistency is defined as the extent to which items within an instrument measure various aspects of the same characteristic or construct and is commonly evaluated using Cronbach α [17]. Given unidimensionality, we will analyze Cronbach α for the 3 subscales of the HCUTI. Cronbach α≥.70 is considered sufficient.

Test-Retest Reliability

Test-retest reliability is the degree to which test scores remain unchanged when measuring a stable individual characteristic on different occasions [18]. For the assessment of test-retest reliability, patients will complete the HCUTI before treatment (baseline) and at days 2 and 5 after baseline assessment. To define stable patients, an anchor question from the ACSS [6] on change in symptom severity will be included. Patients are asked if they have perceived any changes in their symptoms. This item is rated on a 5-point Likert scale as follows: 0=now I feel back to normal (all symptoms have gone away), 1=now I feel much better (majority of symptoms has gone away), 2=now I feel only somewhat better (majority of symptoms is still present), 3=no changes, now I feel about the same (no changes in my symptoms), and 4=now I feel worse (my condition is worse).

Based on the rating, participants are categorized into 3 groups as improved, unchanged, or worsened. Test-retest reliability will be assessed for patients whose symptom severity has not changed. The degree of agreement will be assessed using intraclass correlation coefficients. An intraclass correlation coefficient >0.70 is considered sufficient.

Construct Validity

Overview

Construct validity is the degree to which a measurement instrument assesses the intended construct and involves the evaluation of the relationship between the instrument and comparator instruments measuring the same, similar, or dissimilar constructs [10]. To determine construct validity,

hypotheses are formulated a priori, and these hypotheses concern comparisons with other outcome measurement instruments and differences in scores between "known" groups.

Comparison With Other Outcome Measurement Instruments

To determine the convergent validity of the HCUTI, the following comparator instruments will be administered:

The UTI-SIQ-8 is a self-administered questionnaire designed to assess symptom severity and bothersomeness of uncomplicated UTIs with 4 items each. The symptom severity scale is rated on a 5-point Likert scale ranging from 1=not at all to 5=very strong, and the bothersomeness scale is rated on a 5-point Likert scale ranging from 1=not at all to 5=very severe.

The ACSS comprises 4 domains assessing typical symptoms, differential diagnosis, quality of life, and additional symptoms. We will use 2 items of the quality-of-life subscale assessing the impact of UTI symptoms on daily activities and social activities. These items are rated on a 4-point Likert scale ranging from not 0=affected at all to 3=extremely affected.

The EQ-5D-5L is a generic instrument for the measurement of self-reported health status and HRQoL [19]. The EQ-5D-5L descriptive system comprises the following 5 dimensions: mobility, self-care, usual activities, pain or discomfort, and anxiety or depression. Each dimension has five response levels: 1=no problems, 2=slight problems, 3=moderate problems, 4=severe problems, and 5=unable to or extreme problems. The EQ-5D-5L further includes a vertical EQ visual analog scale capturing the respondents' overall assessment of their health on a scale ranging from 0=worst possible health you can imagine to 100=best possible health you can imagine).

Correlations of the subscales of the HCUTI with the comparator instruments will be examined. A priori formulated hypotheses are tested using Spearman rank correlation coefficients. Following the recommendations of the COSMIN group, correlations with instruments measuring similar constructs should be ≥0.5 (high). Correlations with instruments measuring related but dissimilar constructs should be between 0.3 and 0.5 (moderate). Correlations with instruments measuring unrelated constructs should be <0.3 (low). The hypothesized associations are depicted in Table 1.

Table 1. Hypothesized associations between the subscales of the HCUTI[a] and the comparator instruments.

Comparator instruments	HCUTI subscales		
	Symptom severity	Bothersomeness	Impact on daily activities
UTI-SIQ-8[b] symptom severity	High	Moderate	Moderate
UTI-SIQ-8 bothersomeness	Moderate	High	Moderate
ACSS[c] daily activities item	Moderate	Moderate	High
ACSS social activities item	Moderate	Moderate	High
EQ-5D-5L			
Index: quality of life	Moderate	Moderate	High
Mobility	Moderate	Moderate	Moderate
Self-care	Moderate	Moderate	Moderate
Usual activities	Moderate	Moderate	Moderate
Pain or discomfort	High	Moderate	Moderate
Anxiety or depression	Low	Low	Low
EQ VAS[d]: health status	Moderate	Moderate	Moderate

[a]HCUTI: Holm and Cordoba Urinary Tract Infection Score.

[b]UTI-SIQ-8: Urinary Tract Infection-Symptom and Impairment Questionnaire.

[c]ACSS: Acute Cystitis Symptom Score.

[d]VAS: visual analog scale.

Comparison Between Subgroups (Known-Groups Validity)

Since no clinical ratings or controls will be available due to the design of the study, known-groups validity of the HCUTI will be examined using Kruskal-Wallis test to compare the symptom severity score at baseline assessment between different age groups. We hypothesize no significant differences in symptom severity across age groups.

Responsiveness

Responsiveness to change is defined as the ability of an instrument to detect change over time in the construct to be measured [20,21]. For the assessment of responsiveness, external criteria such as patient reports are needed to determine whether the patient's condition has improved, worsened, or not changed. For symptom severity, the anchor question from the ACSS will be used. We will further include a global rating of change item, which is rated on a 7-point Likert scale as –3=much worse, –2=moderately worse, –1=a little worse, 0=no change, +1=a

little better, +2=moderately better, or +3=much better. This item will be also used to assess changes in bothersomeness and changes in impact on daily activities. Based on the rating of the anchor questions, participants are categorized into 3 groups as improved, unchanged, or worsened. Analyses on responsiveness will be performed at days 2 and 5 after the baseline assessment.

First, we will examine the sensitivity of the HCUTI to changes in patients whose severity of illness has changed. Spearman rank correlations between change scores in the anchor questions and change scores in the subscales of the HCUTI will be calculated to examine if the anchors can be considered as appropriate (>0.3) [22]. Second, receiver operating characteristic curves will be used to assess the ability of the HCUTI subscales to distinguish between patients who have experienced different changes in their condition severity. For this analysis, patients will be grouped based on the anchor question as follows: participants with improvement in symptom severity, bothersomeness, and impact on daily activities ("a little better," "moderately better," or "much better") versus participants with no change or worsening in symptom severity, bothersomeness, and impact on daily activities ("no change," "a little worse," "moderately worse," or "much worse"). Area under the curve values >0.70 indicate sufficient discrimination between groups [9]. The points on the curve maximizing sensitivity and specificity are considered the optimal cutoff value for differentiating between responders and nonresponders. Third, following the construct approach, we hypothesize that improvement in the symptom severity scores of the HCUTI from baseline assessment to days 2 and 5 is related to improvements in the impact on daily activities and social activities as measured with the ACSS. We further hypothesize that improvement in the symptom severity scores of the HCUTI from baseline assessment to days 2 and 5 is related to improvements in the EQ-5D-5L index score and the EuroQol visual analog scale score. Spearman correlation coefficients will be calculated to assess the degree of association between the measures of change. We expect correlations ranging from 0.30 to 0.50.

Interpretability

Interpretability refers to the ease of deriving meaning from an instrument's scores. Interpretability is not considered a measurement property but is an important characteristic for the clinical application of an instrument. Data on the interpretation of changes in the scores are based on the minimal important difference (MID), which denotes the smallest score or change in score that would likely be important from the patient's or clinician's perspective [22]. We will estimate the MID for the 3 subscales of the HCUTI between baseline assessment and days 2 and 5 using an anchor-based approach, a distribution-based approach, and an integrated approach.

Using the anchor-based approach, the MID will be calculated by selecting patients who reported that they felt "a little worse" and "a little better" on the anchor questions. The mean change in scores of the HCUTI subscales in these groups will be calculated.

Applying the distribution-based approach, the MID is estimated based on the distribution of observed scores in the study population at baseline using 2 criteria: half SD and SE of measurement (SEM) [22]. According to these criteria, a change of more than one-half of the outcome score's SD is considered a MID [23]. The SEM is calculated as follows: $SEM=\sigma x\sqrt{(1-rel)}$, where σx=SD of the scale or subscale and rel=reliability of the subscale (internal consistency). A value of 1 SEM is used as a cutoff value for determining the MID [24].

The integrated approach combines the anchor-based approach and the distribution-based approach, taking into account the advantage of both an external criterion and a measure of variability [25]. To determine the MID, the upper bound of a 1-tail 95% CI for the mean score change in the "no change" group is used. The following formula will be used: mean score change in the patient group that did not change+1.645×SE. Patients will be equally grouped as using the classical anchor-based approach.

Ethical Considerations

The study has been approved by the Ethics Committee of the University of Magdeburg, Germany (19/23) and conforms to the principles of the Declaration of Helsinki. Written informed consent is obtained from all participants. The copyright holders gave permission to use the HCUTI for translation and validation. Data collected in the translation process; the content; and the psychometric validation study, including meeting minutes, transcripts, audio records, and survey data are stored in a pseudonymized way. An independent trusted third party at the Medical Faculty of the University of Magdeburg manages data containing personally identifiable information (consent forms and personal data required to pay incentives) and stores these data separately from the study data. A financial incentive is paid to all participants as follows: 50$ for participation in the dual panel or content validity study; 40$ for patients participating in the psychometric validation study; 100$ for physicians participating in the psychometric validation study + 10$ for each included patient.

Results

Results of the translation and linguistic validation process and the results of the content validity study were obtained in September 2023 and will be published separately. Data on the psychometric properties of the German version of the HCUTI are anticipated in mid-2024.

Discussion

Expected Results

The increasing research activities in the development of alternative approaches to conventional antibiotic treatment of uncomplicated UTIs indicate the need for high-quality PROMs to evaluate the efficacy of these strategies. This study will provide data on the content validity and psychometric properties of the German version of the HCUTI. We expect that the German version of the HCUTI is a valid and reliable PROM for the assessment of the symptom severity, bothersomeness, and impact of uncomplicated UTIs on daily activities in women. A tool with sufficient measurement properties that can be used

for the evaluation of novel therapeutic strategies in the German setting will be available.

Challenges

For participation in the web-based survey for the psychometric validation of the HCUTI, strict inclusion criteria in terms of physician-diagnosed cystitis or uncomplicated UTIs according to the respective *ICD-10* codes are applied. This requires collaboration with physicians and is time-consuming. For the recruitment of participating practices, a comprehensive approach is planned, including personal contacts of the study team, personal invitation letters, contact with professional associations, conferences of local physicians, and publications in local medical journals. An incentive will be paid to all participating physicians. To keep the effort for the physicians during data collection as low as possible, they will be asked to confirm the diagnosis on a prepared form and to hand the study information out to the eligible women. The study information includes all data required for study participation, and the women can participate in the survey independently.

In view of the planned analysis, in particular regarding structural validity, responsiveness, and interpretability, a sufficient sample size must be obtained. To maximize the participation rate and minimize the dropout rate, an incentive will be paid to the participating women. For the follow-up assessment, a reminder will be sent via SMS text message to enable prompt completion of the questionnaire using a mobile device. The study procedure will be pretested to evaluate the feasibility of the procedure and the implementation of the survey in LimeSurvey (LimeSurvey GmbH).

To draw attention to our research activities, information on our study, possibilities for participation, and current results will be published on a regular basis at the Institute of Social Medicine and Health Systems Research's website, X (formerly known as Twitter) account, and other social media platforms.

Acknowledgments

This work is funded by Bionorica SE, Germany. The study sponsor has no role in the design of the study, data collection, data management, data analysis, data interpretation, and issues regarding the publication of results.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

CA, KP, and SN contributed to the conceptualization of the study. KP designed the study protocol and drafted the paper. All authors were involved in revising the draft.

Conflicts of Interest

CA received institutional funding for the submitted work and consultancy fees from the Dr Wolff Group, Bionorica SE, Sanofi, Incyte Biosciences, RHEACELL, and LEO Pharma.

Abstract

Background: Podcasts have proven to be a successful alternative source of educational material for students. Given the ability to listen to podcasts 24/7 and while on the go, this technology has the potential to provide informative and educational material to a large number of people at any given time. Podcasts are usually freely available on commonly used mobile devices, such as smartphones, laptops, and tablets.

Objective: This paper describes the impact of health-related podcasts as an intervention tool to support the knowledge and awareness of nursing students on a given topic.

Methods: Pre- and postpodcast questionnaires will gather data regarding the participants' knowledge and awareness of two topics—gestational diabetes and mental health. This intervention will be tested on general nursing undergraduate students. The total number of students (N=2395) from the participating universities are broken down as follows: (1) University College Cork (n=850) and the University of Galway (n=450) in Ireland, (2) Mzuzu University in Malawi (n=719), and (3) University of Fort Hare in South Africa (n=376).

Results: The study received ethical approval from the University College Cork Ethics Committee (2022-027A1). The approval obtained from University College Cork sufficed as ethics coverage for the University of Galway in Ireland. Ethics approval was also received from the Mzuzu University Research Ethics Committee (ID MZUNIREC/DOR/23/28) and the Inter-Faculty Research Ethics Committee of the University of Fort Hare (ID CIL002-21). Data collection is currently underway and will continue until the end of February 2024. The quantitative and qualitative data are expected to be analyzed in March 2024.

Conclusions: Results from this study will allow for an investigation into the impact of podcasts in different settings: a high-income country (Ireland), an upper-middle–income country (South Africa), and a low-to-middle–income country (Malawi). The data gathered from this feasibility study will provide more clarity on the potential utility of podcasts as an intervention tool. We will gather data regarding listener demographics (eg, country of residence, age, gender, and year of study).

KEYWORDS

podcasting; podcast; nursing student; gestational diabetes; mental health; health; knowledge

Introduction

Overview

The term “podcast” has been used since approximately 2004. It originally stemmed from 2 terms “iPod” and “broadcast” [1]. The groundbreaking iPod device from Apple pioneered the mobility of digital audio information. Although the iPod has never been the only device used for podcast listening, it swiftly grew into one of the most prominent listening devices [2]. A podcast can be listened to on any digital audio listening device, including a computer that supports audio file playing. Therefore, podcasts can be listened to 24/7 and while on the go. These combined attributes have dramatically increased the use of podcasts over the last 20 years [3]. During this period, podcasts have been regarded as effective medical educational instruments [4,5]. Thus, the accessibility and open access of podcasts may be hugely attractive to higher education institutes as a method of teaching and learning.

Chin et al [6] (2017) showed that after listening to the extracurricular audio podcasts on health-related topics, students who completed the study experienced a significant and probably educationally relevant improvement in their knowledge. This aligns with the results of Mitchell et al [7] (2021), which showed an overall increase of 11.54% in knowledge attainment in undergraduate nursing students after listening to a podcast on delirium [7]. Overall, these studies demonstrate the impact of podcasting on knowledge attainment in third-level education.

A study of the literature in 2017 further highlights that podcasts are a popular source of educational material for a wide range of health care professionals, including junior doctors, nurses, and medical students [4]. In particular, third-level nursing education is an area of health care that calls for sophisticated critical thinking abilities and decision-making processes, which may likely influence clinical competency. University staff members can find themselves searching for new and creative ways to present material in an engaging fashion as the demands on their time and the availability of innovative tools for use in nursing education expand. The implementation of podcasting in nursing education is one strategy to enhance learning, as discussed in the literature. Recent research conducted in Northern Ireland on podcasting to improve undergraduate nursing students’ awareness of Parkinson Disease found that “podcasting as an educational resource for undergraduate student nurses is a successful way of developing knowledge for PD [Parkinson disease]” [8].

There has been a rise in research being conducted on podcasting in nursing education [9]. Despite this, there is limited research being undertaken on the use of podcasts in Africa, even though podcasting is a great topic of conversation among interested African communities. Surveys completed by the Reuters Digital News Report that included 2 African countries highlighted that 33% of participants were considered regular podcast users [10]. Notably, 50% believed that podcasts are more informative in terms of providing a better understanding of issues compared to traditional media platforms [10].

This research will allow for an investigation into the impact of podcasts on knowledge and awareness in different settings—a high-income country (Ireland), an upper-middle–income country (South Africa), and a low-to-middle–income country (Malawi).

Knowledge and awareness have often been used synonymously, but in this study, a distinction between these 2 interchangeable words is set. Knowledge has been described as “the fact or condition of knowing something with familiarity gained through experience or association,” the “acquaintance with or understanding of a science, art, or technique,” and “the range of one's information or understanding” [11]. Awareness has been described as “knowledge and understanding that something is happening or exists” [12]. In our study, awareness will be defined as having heard of a term or topic, while knowledge will be defined as a deeper understanding of the area.

The podcast topics are as follows:

Pregnancy

According to the World Health Organization (WHO), approximately 800 women died every day from pregnancy and childbirth-related avoidable causes in 2020 [13]. Of note, nearly 95% of these maternal deaths took place in low- and low-to-middle–income countries, such as Malawi [13]. This highlights the need to raise awareness of pregnancy risk factors, complications, and services available for women to access the care they need.

Gestational Diabetes

The WHO describes gestational diabetes as “hyperglycemia with blood glucose values above normal but below those diagnostic of diabetes,” which occurs during pregnancy [14]. Worldwide, 21.3 million pregnancies are linked to hyperglycemia, and of these, 18.4 million pregnancies are linked to gestational diabetes mellitus [15]. Furthermore, it is estimated that more than 90% of hyperglycemia cases in pregnancy occur in low- and middle-income countries [16]. Gestational diabetes can impact both the fetus and the mother. Long-term

implications for children include an increased risk of obesity and metabolic disruption [17]. Furthermore, women who experience gestational diabetes are at risk for developing type 2 diabetes later in life [17]. This demonstrates that gestational diabetes a potentially preventable condition can have a huge societal burden and devastating long-term outcomes.

HIV/AIDS

The WHO figures highlight how HIV infection remains a significant global health concern with 40.1 million deaths occurring to date [18]. Approximately, 650,000 persons died in 2021 as a result of HIV-related causes, and by the end of 2021, an estimated 38.4 million people were living with HIV [18]. Nearly 60% of new HIV infections worldwide occur in the WHO African Region [18]. The HIV infection is incurable. However, owing to accessibility to effective HIV prevention, diagnosis, treatment, and care, especially for opportunistic infections, HIV infection has evolved into a manageable chronic health disease, allowing those who have it to live long and healthy lives. Unfortunately, the disease continues to take many lives despite the availability of treatment and hence it is an important podcast topic to discuss to increase knowledge and awareness.

Cervical Cancer

According to global estimates, there were 604,000 new cases and 342,000 deaths from cervical cancer in women worldwide in 2020 [19]. New cases of cervical cancer and deaths from cervical cancer that occurred in low- and middle-income countries accounted for around 90% of the global total deaths in 2020 [20]. Nearly 50% of high-grade cervical precancers are caused by 2 human papillomavirus types (16 and 18) [20]. This is an important topic to discuss as cervical cancer is curable if detected early and treated effectively. Preventing cervical cancer is more affordable with the human papillomavirus vaccine, precancer lesions screening, and treatment.

Malnutrition

The WHO defines malnutrition as “undernutrition (wasting, stunting, underweight), inadequate vitamins or minerals, overweight, obesity, and resulting diet-related noncommunicable diseases” [21]. A total of 462 million adults are underweight, compared to 1.9 billion who are overweight or obese [21]. Undernutrition is a contributing factor in about 45% of deaths in children younger than 5 years and mostly takes place in low- and middle-income countries [21]. The prevalence of childhood obesity and overweight is also rising in these same nations. The global burden of malnutrition has substantial and long-lasting effects on people and their families as well as on communities, nations, and the economy; therefore, greater conversation around this area is imperative.

Mental Health

As evidenced by the inclusion of mental health in the United Nations Sustainable Development Goals [22], there has been growing recognition of the crucial role mental health plays in achieving global development goals in recent years [23]. According to Arias et al [24] (2022), 418 million disability-adjusted life years or 16% of all disability-adjusted life years worldwide could be attributed to mental diseases in 2019. Overall, this confirms that the need for action on mental health topics is paramount.

Objective of the Feasibility Study

This paper explores the impact of health-related podcasts as an intervention tool to support the knowledge and awareness of nursing students on a given topic. To address this objective, we aim to answer the following questions:

1. Can podcasts support listeners' knowledge of global health topics?
2. Is knowledge attainment from podcasts different across Ireland, South Africa, and Malawi?
3. Is podcasting effective for supporting awareness in nursing students on global health diseases and issues?

Methods

Research Design

This pre- and postpodcast intervention is a feasibility study. Feasibility studies facilitate researchers’ evaluation of whether an intervention is suitable to undergo additional investigation or whether the concepts and conclusions can be applicable and sustainable to the population [25]. A feasibility method was chosen for this study due to the lack of previously published studies on this specific intervention.

Type of Study and Setting

This study mainly involves quantitative data, but qualitative data will be synthesized for the 1 open-ended question on the survey tool. These questionnaires will be created and managed using Google Forms, as it is compliant with the General Data Protection Regulation. Microsoft Excel will be used to capture qualitative and quantitative data and to execute descriptive statistics in the form of percentages and frequencies [26]. This study will be carried out from March 2023 until March 2024.

The selected podcast topics revolve around global health concerns that exhibit significant variations in understanding and practices across different countries. This is intended to enable in-depth podcast discussions and survey questions that can yield insights into how nursing students use the podcasts. These podcast topics have been chosen to encompass a diversity of health-related topics affecting both high- and low-income countries.

To date, the recordings of the podcasts have been conducted. Video and audio files for 2 out of the 6 podcasts will be available for the study participants. Despite only 2 podcasts being chosen for research purposes, all 6 podcasts will be disseminated on platforms including but not limited to YouTube and Spotify. The podcasts’ duration ranges from approximately 30 to 60 minutes each. Each podcast discusses the risk factors, symptoms, and treatment or management of the global health topic.

Each podcast was created with a panel of international experts along with a chair (AD and BC). The 2 podcasts selected for the study are the gestational diabetes podcast and the mental health podcast. As this is a voluntary feasibility project, we only have the resources to examine 2 of the podcasts. Upon completion of this research, we will determine if podcasting is

an effective method of increasing knowledge and awareness attainment. If the results are positive, we will conduct a broader survey, which will include members of the public and not just nursing students, and will release more podcasts. In addition, mental health and gestational diabetes are widespread issues normally taught in depth in nursing schools and are not confined by geographical locations or socioeconomic status. Likewise, these podcasts had the best audio quality, conversation flow, and in-depth discussion, as decided by the research team. It is evident from the literature that gestational diabetes is a global phenomenon that can impact people from Ireland, South Africa, and Malawi and have potentially long-term preventable implications [16,17]. Similarly, mental health is a global health concern that is gaining increasing attention due to the addition of mental health in the Sustainable Development Goals and the disability-adjusted life years that are attributable to mental disease [23,24]. The selected global health topics are on the list of the top 10 global public health challenges to track in 2023 [27].

Measurement Tools

For the gestational diabetes podcast, a 5-item "Yes-No-I don't know" awareness questionnaire and a 27-item "Yes-No-I don't know" knowledge questionnaire were developed by the researchers. For the mental health podcast, a 4-item "Yes-No-I don't Know" awareness questionnaire and a 26-item "Yes-No-I don't know" knowledge questionnaire were developed by the researchers. The gestational diabetes podcast has 1 additional survey question on awareness and knowledge compared to the mental health podcast, as the podcast discussion on gestational diabetes covered additional items beyond those initially prepared in the semistructured podcast guide.

The knowledge questionnaires for each of these podcasts will address 3 key themes: risk factors, symptoms, and services or treatments. Examples of the questions asked can be found in Table 1.

The only qualitative question asked at the end of each podcast is the following:

"Do you have any further comments on the podcast (duration or formatting), questions asked, or recommendations for future podcasts?"

Table 1. Example of questions asked on knowledge and awareness.

Topic	Area being assessed	Examples of question asked before and after the podcast
Gestational diabetes	Knowledge	Is obesity or BMI a risk factor for gestational diabetes mellitus?
Gestational diabetes	Awareness	Have you heard of metformin?
Mental health	Knowledge	Is a history of mental illness in a blood relative family member a risk factors for mental illness?
Mental health	Awareness	Are you aware of risk factors for mental health problems?

Study Population

The study will collect data from undergraduate general nursing students from 4 universities located across Ireland, South Africa, and Malawi.

Sampling and Sample Sizes

The sample will consist of a cohort of undergraduate nursing students from University College Cork (UCC) and the University of Galway (Ireland), the University of Fort Hare (South Africa), and Mzuzu University (Malawi). These students will be recruited through invitation via the university they are attending. Entry into the study will be entirely voluntary.

The main aim is to compare the pre- and postpodcast scores on knowledge and awareness differences with a paired 2-tailed *t* test. The inputs that will be used are the expected mean (SD) of the paired differences. As this is a feasibility study, a formal sample size calculation is not required [28].

Inclusion and Exclusion Criteria

Exclusion criteria include those who are unable to complete the web-based questionnaires due to a lack of internet connection. These surveys are solely available via Google Forms and are thus inaccessible without an internet connection. Participants will be excluded if they are not a current resident and a registered undergraduate general nursing student of Ireland, South Africa, or Malawi and do not agree to consent to the study. As this is a feasibility study, we are targeting a small cohort of individuals who are convenient to the research team. Inclusion criteria encompass those aged 18 years and older.

Data Collection and Management

Questionnaires will be made using Google Forms, which are stored on UCC's Microsoft OneDrive. The questionnaires will include closed-ended questions using a point scale, with points given to the tick-the-box answers of "Yes", "No," or "I don't know." These questionnaires will be distributed to UCC (Ireland), University of Galway (Ireland), University of Fort Hare (South Africa), and Mzuzu University (Malawi). Regarding the data collection, the investigators will not seek names or emails from the participants, and the data will be fully anonymized. Fully anonymized data are achievable in this study, as participants are not required to complete two different surveys. The pre- and postpodcast questions are on a single Google Form, separated only by the embedded podcast file (not 2 separate survey forms), allowing a direct comparison of survey responses without requiring participant contact details. Once the survey is submitted, the option to withdraw will no longer be available. Answers to our survey (questionnaires) will be stored on UCC-supplied Google Forms and uploaded to OneDrive. Data on knowledge and awareness will be collected from both pre- and postpodcast surveys. Information on gender,

age, year of study, and the university the student is attending will also be stored, along with the consent forms. The UCC-supplied OneDrive will also be used during data collection and data analyses due to the ability to store data generated on the cloud automatically. Data will be stored for a minimum of 10 years. The data will be controlled by the UCC study members. General Data Protection Regulation will be observed at all times with all information anonymized.

Data collection tools will be structured according to the research themes outlined as follows:

Podcast Knowledge

Participants will be asked about their knowledge of the global health topic by assessing knowledge of symptoms, risk factors, and treatment options associated with the disease. The Google Forms will present an individual question on symptoms, risk factors, and treatments and ask respondents to indicate whether they are symptoms, risk factors, and treatment options of the condition with response options "Yes," "No," or "I Don't know." For the prompted symptoms items, "No" and "I Don't Know" responses will be combined and scored 0, and "Yes" responses will be scored 1. Total scores for prompted awareness of warning signs and risk factors as well as knowledge of symptoms, risk factors, treatment options, government policies, or screening programs will be calculated by adding the recorded responses together.

Podcast Awareness

To achieve this objective, terms on awareness will focus on whether participants have previously heard of terminology associated with the specific podcast and are aware of services available for that health topic or whether they have heard of the condition or disease. With regard to awareness assessment, a scoring system will be implemented. For each question item, "No," and "I Don't Know" responses will be combined and scored 0, and "Yes" responses will be scored 1.

Data Analysis

Microsoft Excel and Google Forms will be used to capture raw quantitative data and to execute the descriptive statistics in the form of percentages and frequencies. Descriptive statistics, including percentages, means, and standard deviations will be calculated for participants' survey responses. For the pre- and posttest analysis, a paired 2-tailed *t* test analysis for the questions that assess medical knowledge will be performed. The means of both the pre and posttests will be calculated. The pretest will act as the control, and therefore, *P* values will be determined to identify if the results are statistically significant. This analysis will enable the observation of whether the podcasts were an effective intervention tool by examining a higher posttest mean score. Significance will be defined as $P<.05$.

This is an international feasibility study, and it would be of great interest to analyze participants' country of residence in conjunction with the level of knowledge and awareness gained from the podcast to give us an insight into which country would benefit most from this form of audio learning. To conduct this, we will perform a subgroup analysis in SPSS. Furthermore, men and women have been shown to learn differently, with women preferentially being auditory learners [29]. Therefore, a subgroup analysis on gender will be carried out on SPSS. This research will help to clarify whether podcasting is a useful educational resource that is of benefit to both sexes as an alternative source of learning [30].

For this study, we only have 1 open-ended question, which is "Do you have any further comments on the podcast (duration or formatting), questions asked, or recommendations for future podcasts?" We will conduct a thematic analysis of the responses to open-ended questions [31]. To analyze and describe the comments, a coding frame will be developed. If responses contain 2 or more different statements, these statements or sentences will be coded separately or line by line.

Ethical Considerations

The study received ethical approval from the UCC's Social Research Ethics Committee (ID 2022-027A1). The approval obtained from UCC sufficed as ethics coverage for the University of Galway in Ireland. Ethics approval was also received by the Mzuzu University Research Ethics Committee (ID MZUNIREC/DOR/23/28) and by the Inter-Faculty Research Ethics Committee at the University of Fort Hare (ID CIL002-21) in South Africa. The study will conform with the precepts of the Declaration of Helsinki on Human Rights of 1975. This research will involve participation through remotely answering survey questions and listening to podcasts. The survey is available in the English language only, as it is the official language in Ireland, Malawi, and South Africa. Participation in this research is not likely to cause any harm or pose a risk to the study participants' well-being.

Informed consent will be explicitly sought from the study participants at the beginning of the survey, and participants are required to be 18 years of age and older. Only undergraduate nurses can take part in this research. Participate confidentiality will be upheld throughout the study process. To maintain confidentiality, no emails, names, or contact information will be required.

The study data will be stored on a password-protected laptop to which only the research team will have access. Participation in this study is entirely voluntary, and participants retain the right to withdraw their participation and data at any time while filling out the survey. However, once the survey is submitted, participants cannot withdraw because the survey is anonymous, and we can therefore not identify who completed the survey. Participants will not receive remuneration or compensation for taking part in the study.

Results

Data collection is currently being conducted and will be carried out until February 2024. The quantitative and qualitative data are expected to be analyzed by March 2024.

Discussion

Comparison With Prior Work

This study, to the best of our knowledge, is the first podcast intervention study to compare the impact of podcasting on

nursing education internationally. This is extremely pertinent considering the changing landscape of third-level education, the impact of web learning, and the shift away from conventional approaches [32]. This study may highlight the idea that the next generation may be keener on using this technology, as they have grown up with e-learning and internet-based content.

The implementation of podcasting in nursing education is a strategy that has been considered in previous literature. O'Connor et al [33] (2020) identified that the next generation of nursing students has grown up with technology and thus are mostly learners with diverse digital literacy abilities and perhaps a need for interactive, learner-centred courses. Fortunately, podcasting is emerging as a viable educational option. Abate [34] (2013) demonstrated that when undergraduate nursing students listened to a segmented podcast, they had increased scores on multiple choice exams and case study tests, compared to face-to-face lectures and unsegmented podcasts. Likewise, Burke and Cody [35] (2014) reported that 86% of undergraduate nursing students felt that podcasts enriched their learning, and an astonishing 94% of these students would recommend podcasting for other courses.

Expected Findings

This study will investigate the impact of informational podcasts on the attainment of knowledge and awareness in undergraduate nursing students. It will provide valuable insights into the impact of podcasts in education settings across different countries. We anticipate that results from this study could illuminate whether educational podcasts serve as an impactful learning resource for undergraduate nursing students.

Future Research

Other populations apart from undergraduate general nursing students should be included in further studies to determine the appropriateness of this intervention across third-level education. If the results are positive, this feasibility study will be used to inform future research on podcasting in third-level education.

Strengths and Limitations

The role of social media platforms as a medium to deliver education has been under development for several years. This research will provide a clear contribution focusing on the impact of one such platform—YouTube—for undergraduate nursing students in the areas of knowledge and awareness on a set of given topics. This research is international and will enable a greater understanding of the usefulness of podcasts in a high-income country (Ireland) compared to middle-to-low-income countries (South Africa and Malawi). Nonresponse is one of the limitations of this study. Pre- and postpodcast questionnaires are planned to be administered before and after listening to a podcast recording. This may cause participants to become mentally fatigued and not fill out the questionnaire following the podcast, resulting in a reduced response rate. Another limitation of this study is selection bias. For this study, only general undergraduate nursing students will be used to gather information, and thus, they could skew the results due to the level of knowledge they should already have from their undergraduate studies. The generalisability of the study may be limited by the cohort only being composed of nursing students.

Conclusions

Results from this study will allow for an investigation into the impact of podcasts in different settings, a high-income country (Ireland), an upper-middle–income country (South Africa), and a low-to-middle–income country (Malawi). The data gathered from this feasibility study will provide more clarity on the potential utility of podcasts as an intervention tool. We will gather data regarding listener demographics (ie, country of residence, age, gender, and year of study) to ascertain the outreach of the podcasts, which could shape future studies on podcasts as an educational tool. If the results of our study are positive in terms of an increase in knowledge and awareness, we hope to identify other populations that might benefit from this sort of educational resource.

Acknowledgments

We would like to thank all the wonderful speakers who have contributed their time and knowledge to the creation of these podcasts.

This research received no specific grants from any funding agency in the public, commercial, or not-for-profit sectors. STR was partially funded by a grant from the Wellcome Trust’s Institutional Strategic Support Fund (ISSF) at Imperial College London.

Data Availability

The media data that support the methodology of this study are openly available on Figshare [36]. This is covered by the Creative Commons Attribution license (CC BY 4.0 license).

Authors' Contributions

AD, BC, JOD, and GBC contributed to the design and development of podcasts. LC, GBC, AD, BC, and COM assisted with study recruitment and advertisement. RB, STR, AD, BC, JOD, GBC, COM, and LC edited and reviewed the manuscript. All members of the research team approved the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Maternal pushing during the second stage of labor could influence labor progress and maternal-neonatal outcomes. Although the image of health care providers directing the laboring women to push during the second stage of labor could be commonly observed globally, this practice is not sufficiently researched and is questioned regarding its effectiveness and outcomes on the mother and baby. Meanwhile, a strategy referred to as "spontaneous pushing," which supports women to push by following their bodily urges, has been evaluated in several trials. However, in China, spontaneous pushing is not common practice. Notwithstanding the evaluation of spontaneous pushing, there is a lack of high-quality evidence to support either strategies of directed pushing or spontaneous pushing.

Objective: This study aims to test the feasibility of a future randomized controlled trial to compare the effects of spontaneous pushing and directed pushing during the second stage of labor for maternal and neonatal outcomes in China.

Methods: A nonrandomized, single-group, noninferiority feasibility study will be conducted in a public hospital in Hebei Province, China. In total, 105 women meeting the selection criteria will be recruited to receive the intervention (spontaneous pushing), while 105 sets of medical notes from women who received routine care (directed pushing) will be identified and reviewed to compare outcomes for both cohorts. A mixed methods approach will be used to assess primary outcomes (feasibility and acceptability) and secondary outcomes (effectiveness).

Results: Data collection took place between May and October 2023. A total of 110 women were invited to participate in the intervention of spontaneous pushing. Midwives' interviews were conducted and will be transcribed for analysis in March 2024. The data analysis is planned to be completed by May 2024.

Conclusions: This feasibility study will provide important information by conducting a full-scale clinical trial in the future as well as the potential facilitators and barriers of it. A future randomized controlled trial is likely to have considerable policy and funding impacts regarding pushing management during the second stage of labor and improvement in women's childbirth experience.

Introduction

Background

To achieve physiological childbirth, it is acknowledged that sound maternity practice should aim primarily at giving every woman an opportunity to achieve normality if that is what women choose [1]. More recently, a clinical practice that supports a woman to follow their bodily desire to push during the second stage of labor has been evaluated in several clinical trials [2-5]. This practice is called "spontaneous pushing." However, this is not a new practice; rather, it is a return to previous practice because it is believed that women in the past gave birth unaided. During spontaneous pushing, a woman takes several breaths in between pushes and is encouraged to give several short pushes throughout the duration of 1 uterine contraction [6]. This could occur with open and closed glottis, depending on women's preference [6]. Evidence from a systematic review confirmed that spontaneous pushing did not necessarily lead to a longer duration of the second stage of labor [7]. In addition, women in the spontaneous pushing group are less likely to experience an extended episiotomy and cesarean birth during labor [8].

Meanwhile, in most hospital settings around the world, directing a woman to push during labor is commonly observed [7]. This is usually called "directed pushing." In this context, women are required to follow specific instructions from health care providers and to push in the Valsalva maneuver, involving taking deep breaths and pushing long and hard with closed glottis [7]. At the beginning of the last century in resource-rich countries, promoters of natural birth introduced and advocated this way of directed pushing [9]. They believed that directed pushing could expedite the second stage of labor and avoid the use of forceps, which was commonly used at that time [10]. However, subsequent findings revealed that directed pushing unfavorably alters maternal physiology and contributes to adverse fetal outcomes [11], including poor fetal acid-base balance [12], fetal heart rate increase or decrease [13], low umbilical cord pH and partial pressure of oxygen levels [14], low Apgar scores at 1 and 5 minutes [12], and decreased cerebral oxygenation [15].

Effective spontaneous pushing during the second stage of labor contributes to satisfactory labor progress and improved maternal and neonatal outcomes. The World Health Organization [16] recommends that women in the expulsive phase of the second stage of labor should be encouraged and supported to push spontaneously. Both the Association of Women's Health, Obstetric and Neonatal Nurses and the American College of Nurse-Midwives advocate the use of spontaneous pushing as best practice, which is consistent with physiological birth practices and evidence improved outcomes [17,18]. In a Chinese context, spontaneous pushing has been recommended by a national guideline by the China Maternal and Child Health Association titled *Clinical Practice Guideline for Normal Birth*. The guideline recommends that "women are 'allowed' to push (spontaneously) during a uterine contraction" [19]. Despite the guideline, the routine practice of directed pushing remains in China. Spontaneous pushing is only conducted in an extremely small proportion of hospitals [20]. More evidence is needed to narrow down the gaps between practice guidelines with clinical routine practice. Consequently, high-quality original trials are required to further explore the evidence on pushing management and outcomes in the Chinese context.

Aims

As this study will involve a change of practice in the Chinese context, it is ethically required to conduct a feasibility study before a full-scale randomized controlled trial (RCT) can be performed. Additionally, this study will be conducted as part of a PhD candidature; hence, there are time constraints. This study aims to test the feasibility of a future RCT to compare the effects of spontaneous pushing and directed pushing during the second stage of labor for maternal and neonatal outcomes.

This study will include (1) the preparation program for midwives and (2) the implementation of spontaneous pushing during the second stage of labor for women and a comparison with normal standard care (directed pushing).

Objectives

The primary objective is to test the feasibility of a future RCT to compare the effects of spontaneous pushing and directed pushing for maternal and neonatal outcomes. The secondary objective is to explore the effectiveness of spontaneous pushing and directed pushing for women without an epidural during the second stage of labor.

Methods

Study Design

This feasibility study is a nonrandomized, single-group, noninferiority trial. All participants will receive the intervention (spontaneous pushing). A mixed methods approach will be used to assess the primary and secondary outcomes. This protocol adheres to the SPIRIT (Standard Protocol Items: Recommendations for Intervention Trials) guidelines (Multimedia Appendix 1) [21].

Table 1 illustrates the objectives, outcomes, and the corresponding study design. Tables 2 and 3 illustrate the chart of the study designs, visits, and assessments for both women

and midwives. The flow diagram (Multimedia Appendix 2) demonstrates the enrollment, allocation, follow-up, and assessment process for women to compare the effectiveness of the intervention.

Table 1. Objectives, outcomes, and study design.

Objectives and outcomes	Study design
Primary objective: To test the feasibility of a future RCT[a] to compare the effects of spontaneous pushing and directed pushing for maternal and neonatal outcomes	
Feasibility: recruitment rates, retention rates, and attendance rates of participants	Quantitative study design
Acceptability: women's and midwives' perspectives and acceptability of the intervention	Quantitative study design (survey for women) and qualitative design (interviews for midwives)
Secondary objective: To explore the effectiveness of spontaneous pushing and directed pushing for women without an epidural during the second stage of labor	
Maternal and neonatal outcomes	Quantitative study design

[a]RCT: randomized controlled trial.

Sample Size Determination

One of the objectives of the feasibility study is to gain estimates for a sample size calculation in a future RCT [22]. Although a formal sample size calculation is not necessarily needed in a feasibility study, the sample size was calculated based on the duration of the second stage of labor as a parameter outcome in previous studies. Statistical power analysis was used to estimate sample size in PASS (version 15.0; NCSS LLC, USA) software with statistical power at 90%, α at .05, and dropout rate at 20%. The sample size was calculated to be 105 in each group. Based on clinical judgment and the number of laboring women eligible in the site-specific hospital, a sample size of 105 is set for each group.

To cover all 4 shifts of the roster, a total of 6 midwives will be recruited to deliver the intervention. All the midwives recruited to the study will be interviewed at the end of the study to assess midwives' acceptability and experience participating in the study.

Setting

This study will be conducted in a single Birth Centre in the Fourth Hospital of Shijiazhuang, Hebei Province, China. The economic status of the population and the medical resources of Hebei Province is at the average level among all the provinces in China [23], with an annual live birth rate of 762,376 in 2019 [24]. The chosen hospital has one of the largest numbers of annual birth rates in Hebei Province with around 15,600 births in 2022. The default pushing strategy at this hospital is directed pushing, which also aligns with most other hospitals in China.

Participants

All participants will be recruited from the Fourth Hospital of Shijiazhuang, Hebei Province, China. In total, 105 women will be recruited to receive the intervention. At the same time, 105 sets of medical notes will be identified, and relevant information will be extracted to compare health outcomes between the 2 cohorts. These medical notes will be from women who received standard care, that is, "directed pushing" during the second stage and met the same selection criteria as the women in the spontaneous pushing group. The women whose notes will be reviewed will not be recruited into this study, but permission has been obtained from the site-specific hospital to examine the deidentified medical notes. The demographic data, that is, age and the parity and labor care section of the medical notes will be reviewed and examined and parity in 2 cohorts will be matched for further comparison.

Six midwives will be recruited to support spontaneous pushing. They will be rostered to cover all 4 shifts of the roster to ensure that every recruited woman will be supported to push spontaneously by a recruited and trained midwife. All recruited midwives will be interviewed for the qualitative study part.

Eligibility Criteria

The eligibility criteria for women and midwives are presented in Textboxes 1 and 2. The medical note audit will include women who received directed pushing during the second stage of labor and met the same eligibility criteria as the women in the spontaneous pushing group.

Textbox 1. Eligibility criteria for women.

Inclusion criteria

- Older than 18 years of age
- Gestation 37+ weeks at birth
- Single, healthy fetus in cephalic presentation
- No complications during labor

Exclusion criteria

- Administered epidural analgesia
- Any medical or obstetric complication affecting second-stage management
- Unable to comply with guidance
- Undergo cesarean birth during labor

Textbox 2. Eligibility criteria for midwives.

Inclusion criteria

- Qualified with a certificate in maternal and neonatal care by the Ministry of Health, People's Republic of China
- Employed at the Birth Centre of the Fourth Hospital of Shijiazhuang, Hebei Province, China
- Providing care at the birth site
- Willing to participate (not allocated by a manager)
- Have at least 1 year of postregistration practice

Exclusion criteria

- Unwilling to participate
- Allocated by a manager to participate
- Doula or other nonregistered lay birth support person

Recruitment

Recruitment of Women

The researcher (JY) will approach and recruit women into the study during their third trimester of pregnancy. This will allow the women to have enough time to read the information leaflet for the study, ask any questions, and make an informed decision about participating in the study without any undue pressure.

The study will be advertised using posters and information leaflets in the antenatal services of the hospital. The researcher (JY) will approach women while they are in the waiting room awaiting their appointment and will talk to them about the study assessing their willingness to receive further information about the study. Verbal information and a written information sheet outlining the study will be provided to the women to take home and review again before their next visit. At the women's subsequent visit, the researcher (JY) will meet women who are willing to participate, provide them with an opportunity to ask any further questions about the research, and seek their consent to participate in the study by asking them to sign a consent form.

Recruitment of Midwives

Study information will be shared at one of the midwives' regular meetings or workshops and written information will be provided. Midwives will be encouraged to take the information sheet home to review, and those interested in participating in the study will be encouraged to contact the research team.

Upon permission, recruited midwives will be recruited to participate in a preparation program, which will be in a workshop format. The workshop will help to prepare them to provide care to women in the spontaneous pushing group. At the end of the study, the midwives will all be invited to attend a focus group interview to gain their views and thoughts about the implementation of the study, the intervention, and their experience of participating in the study. Midwives will not be rewarded for participating in the study. With permission from the birth center manager, the participation of midwives will occur during their normal working hours.

Patient and Public Involvement

Patients and the public were not directly involved in the development of this protocol. However, the development of the research question and the preparation program content are in accordance with the previously published studies on laboring women's and midwives' experiences and priorities.

Ethical Considerations

Ethics Approval

All the methods will be performed in accordance with the relevant guidelines and regulations. The protocol is approved by 2 ethical committees, the University of Technology Sydney Medical Research Ethics Committee (ETH22-7072) and the Health Research Committee from The Fourth Hospital of Shijiazhuang, Hebei Province, China (20230064). All participants will be provided with informed written consent prior to their enrollment in the study. Deidentified findings of this study will be shared locally via staff forums and education sessions in China; shared through peer-reviewed journal publications, international conferences, and seminar presentations; and included as part of the first author's (JY) PhD thesis.

Informed Consent

Informed consent from both women and midwives will be obtained. A member of the research team (JY) will discuss the study with the women and midwives and provide them with details about the study and obtain written consent. All participants will not receive any type of compensation from the study.

All women participating in the study will be given a study code number, and this will be documented in their medical records and all study documents. A sticker with the logo of this study will be tagged in the top right corner of the participant's medical notes. This will help midwives identify the recruited women when they arrive at the birth center in labor.

Participants' Safety and Withdrawal

A participant (including laboring women or midwives) may choose to withdraw from the study at any time. With consent, data before participant withdrawal will be retained and used in data analysis. Participant withdrawal may happen for several reasons, including but not limited to the following: (1) participant decision, (2) inability to comply with study procedures, and (3) the occurrence of what the participant perceives as an intolerable adverse effect.

In addition, the chief researcher (KB) will exclude a participant if it is considered necessary for any reason, including but not limited to (1) clinical decision, (2) ineligibility (either arising during the study or retrospectively having been overlooked at screening), (3) significant protocol deviation, and (4) significant noncompliance with intervention.

The nature and reason for the withdrawal or discontinuation will be recorded.

Intervention

Preparation Program for Midwives

Before the commencing of the study, a preparation program will be provided to the recruited 6 midwives. The program was developed and informed by the research team's midwifery experience, engagement with the literature and a systematic review [8].

The aim of the midwifery preparation program is to provide midwives with comprehensive and evidence-based practice information on the management of pushing in particular the management of spontaneous pushing during the second stage of labor. This will ensure that midwives feel confident to support women with spontaneous pushing during the second stage of labor. The program will run over 3 weeks and will include 6 sessions, and 5 hours in total over 3 weeks. The training plan is displayed in Table 4.

Table 4. Preparation program for midwives.

Week and session	Topic	Details	Duration (min)
Week 1			
Session 1	Induction	• Introduction of the project and the research team • Midwives to introduce themselves and discuss their expectations of the program, allowing the researcher to answer any questions they may have • The procedure of the feasibility study • The role of the midwife in the feasibility study • Time for question and answers	50
Session 2	Review of the current evidence	• Pushing during the second stage of labor: a scoping review • Directed pushing vs spontaneous pushing: meta-analysis • Discussion	40
Week 2			
Session 3	How to support spontaneous pushing	• Standard procedures of directed pushing management • Strategies to support spontaneous pushing • Comparison of spontaneous pushing and directed pushing • Simulation in pairs • Time for question and answers	90
Session 4	Q&A: Expectations or questions on pushing management	• This session will be conducted digitally using the social media app Tencent meeting • In this session, midwives will be encouraged to share their expectations or questions on managing the second stage of labor • Questions about the process of the study will be answered by the researcher	30
Week 3			
Session 5	Further discussion of the research and participant withdrawal options	• A brief recap of the research and refresh of the training content (highlight the items that directly relate to midwives) • Safety and distress protocol will be explained to midwives • Withdrawal options and their procedures will be explained to midwives	30
Session 6	Scenario-based learning and practice	• Scenario-based learning • Time for question and answers	50 minutes

Strategies to Support Spontaneous Pushing During Labor

Spontaneous pushing encourages a woman to push following her bodily instincts. A standardized step-by-step procedure may not be suitable for every laboring woman. The following strategies are shown to facilitate the spontaneous pushing during labor: (1) encourage woman to select the most comfortable position for her during pushing [7]; (2) offer information about progress of her labor and about any sensations she may feel [25]; (3) affirm to the woman how well her body is working and encourage her to work with and listen to her body urges [25]; (4) support the woman to wait for pushing urges, instead of coaching her to push immediately when the contraction begins [25]; (5) support the woman to push with open glottis, including sighing, moaning, or even crying [26]; and support and encourage the woman to give several short pushes (usually 4 to 6 s) instead of 1 long push (8 to 10 s or even longer) [27].

Outcomes

Overview

The outcomes measured will include 3 domains: feasibility, acceptability, and effectiveness.

Primary Outcomes

The primary outcomes will include (1) feasibility (recruitment rates, retention rates, and attendance rates of participants) and (2) acceptability (women's and midwives' perspectives and acceptability of the intervention).

Secondary Outcomes

Secondary outcomes will include the duration of the second stage of labor, maternal pushing position, mode of birth, rates of cesarean birth, perineal laceration, the rates of episiotomy, newborn Apgar scores, rates of newborn resuscitation, and rates of transfer to the neonatal intensive care unit. Table 5 illustrates the primary and secondary objectives, outcomes, criteria for success, methods for analysis, and measurement tools.

Table 5. Primary and secondary outcome criteria, analysis, and measurement.

Objectives, outcomes, and criteria for success	Methods of analysis	Measurement or tool
Primary objectives: To test the feasibility of a future RCT[a] to compare the effects of spontaneous pushing and directed pushing for maternal and neonatal outcomes		
Recruitment		
Complete recruitment within 6 months	Descriptive	Researcher work log
Women recruited/women accessed×100% > 10%	Descriptive	Researcher work log
Number of women recruited/number of women who bring Information Sheet home×100% > 30%	Descriptive	Researcher work log
Retention		
Loss of follow-up under 30%	Descriptive	Researcher work log
Number of women who completed spontaneous pushing during labor/number of women recruited×100% > 30%	Descriptive	Researcher work log
Number of women who completed the postnatal questionnaire/number of women who completed spontaneous pushing during labor×100% > 80%	Descriptive	Researcher work log
Attendance of participant		
Percentage of completion of all sessions of midwives' preparation program (midwives) > 80%	Descriptive	Researcher work log
Acceptability of the "intervention"		
Overall score of the questionnaire survey above 4 out of 5 (Childbirth Experience Questionnaire above 3 out of 4)	Descriptive	Questionnaire survey
Midwives' focus group	Framework analysis method	Qualitative data
Secondary objectives: To explore the effectiveness of spontaneous pushing and directed pushing for women without an epidural during the second stage of labor		
Duration of the second stage of labor		
From full cervical dilation to the birth of the baby	Mean (SD) or medians for continuous variables	Case report forms
Mode of birth		
Normal vaginal birth, forceps extraction, vacuum extraction, breech delivery, and cesarean birth	n (%) for categorical variables	Case report forms
Perineal laceration		
Intact, I degree, II degree, III degree, and IV degree	n (%) for categorical variables	Case report forms
Episiotomy		
Mediolateral episiotomy, midline episiotomy, and intradermal suture	Mean (SD) or medians for continuous variables	Case report forms
Apgar score		
Apgar scores in 1 minute, 5 minutes, and 10 minutes after birth	Mean (SD) or medians for continuous variables	Case report forms
Admission to neonatal intensive care unit		
Newborn transferred to the neonatal intensive care unit because of any emergency	Mean (SD) or medians for continuous variables	Case report forms
Neonatal resuscitation		
Resuscitation strategies following China Neonatal Resuscitation Guideline	Mean (SD) or medians for continuous variables	Case report forms

[a]RCT: randomized controlled trial.

Data Collection

Overview

The primary and secondary outcomes will be measured using a combination of qualitative and quantitative methods. Three data collection tools will be used during this process.

Case Report Form

A self-designed case report form (CRF) will be used by the researcher (JY) to extract the effectiveness outcomes from a woman's medical notes. These will include the duration of the second stage of labor, maternal pushing position, mode of birth, rates of cesarean birth, perineal laceration, rates of episiotomy, newborn Apgar scores, rates of newborn resuscitation, and rates of transfer to the neonatal intensive care unit. The researcher (JY) will also record on the work log the name of the midwife who supported the recruited woman with spontaneous pushing. As the maternal pushing position is not routinely recorded in medical notes, the researcher (JY) will ask the midwife about a woman's pushing position during labor and will record it on the CRF. Midwives will also be advised to record the maternal pushing position in the labor notes during the preparation sessions.

Survey for Women

A questionnaire with closed-ended and open-ended questions will be used to explore women's satisfaction with pushing, their childbirth experience, and their experience in joining the study. The researcher (JY) will access women during their stay in the postnatal ward for the completion of the survey. In case women withdraw from the study, for personal or medical reasons, a withdrawal note will be recorded in their CRF.

Focus Group With Midwives

The focus group with the midwives will form the qualitative part of the study. At the end of the intervention phase of the study, midwives will be invited to attend a face-to-face focus group to share their experience of supporting women with spontaneous pushing and their experiences of being part of the study. The discussion will be moderated by a senior researcher (HL) from the research team and will be guided by several open-ended questions.

As the primary objective of this study is to explore the feasibility of a future RCT, it is important to fully understand how midwives and women feel about the intervention, the procedure, and the enablers and barriers. The questions in the surveys for women and interviews for midwives will focus on the perceptions of both the women and midwives during the pushing phase of labor as well as their experience of being part of the study.

After a lengthy literature search, it was evident that there was no validated survey tool available that would meet the aims of this study. Therefore, the survey for women was developed based on the principles and domains advocated by Bowen et al [28], Section B "Childbirth Experience Questionnaire" in the survey for women is a freely available tool, which has been published in English and validated in Chinese by Zhu et al [29].

Data Analysis

The data in this study include both quantitative and qualitative data. For quantitative data, "intention-to-treat" analysis will be used. Statistical description will be conducted by the description of mean value, SD, number of cases, and percentage. Pearson chi-square test will be conducted for categorical variables. Independent group 2-tailed *t* test will be conducted for continuous variables. The threshold for statistical significance will be set at .05. For qualitative data, a framework method will be used, which is commonly applied for the thematic analysis of interview transcripts [30]. After a verbatim transcription of the audio recording, the framework method will help to create and apply an analytic framework in the data analysis process in 5 steps (data familiarization, framework identification, indexing, charting, mapping, and interpretation) [31]. The quantitative and qualitative data will be combined in order to compile recommendations from the feasibility in order to conduct a future RCT.

Results

This study will provide both quantitative and qualitative data on the feasibility of a future RCT, including the rate of and ease of recruitment, retention, and attendance of participants during the process. Qualitative results from midwives' focus group interviews will be presented to illustrate midwives' acceptability of the intervention. In addition, a series of labor and birth outcomes will be compared to explore the effectiveness of the intervention.

Data collection took place between May and October 2023. A total of 110 women were invited to participate in the intervention of spontaneous pushing. Midwives' interviews were conducted and will be transcribed for analysis in March 2024. The study is expected to conclude in May 2024.

Discussion

Principal Findings

This is a protocol for a study assessing the feasibility, acceptability, and effectiveness of spontaneous pushing during the second stage of labor among Chinese women without epidural analgesia.

A challenge for this study may likely be the recruitment of laboring women. One of the exclusion criteria for women in this study is "administered epidural analgesia" (Table 3). A large proportion of recruited women may be excluded due to the use of epidural analgesia during labor. The epidural analgesia rate varies from one hospital to another in China [32]. However, the most recently noted rate within the study hospital was around 65% for primiparous women. Despite the anticipated high loss rate of laboring women, this exclusion criterion is set based on the underpinning midwifery philosophy that labor and birth under the use of epidural analgesia is not considered a physiological process. The International Confederation of

Midwives [33] states that "Normal birth is where the woman commences, continues and completes labour with the infant being born spontaneously, in the vertex position at term, without any surgical, medical, or pharmaceutical intervention." The use of epidural analgesia inhibits nerve conduction by blocking painful impulses from the nerves [34]. Although epidural analgesia is considered to be an effective way of pain relief in labor and birth [35], blocking of pain impulses also blocks other impulses conducted by the nerves, including pushing or bearing down urges. At the same time, the "intervention" in this study, spontaneous pushing, encourages laboring woman to feel their bodily urges and push in their most effective way. From this perspective, women who used epidural analgesia during labor may have difficulty feeling their pushing instinct, and hence, they are excluded from this study. The criteria of excluding women who used epidural during labor does not mean to influence women's choices for their pain relief methods. The reasons for this criteria item will be explained beforehand to women to avoid their potential shame of the use of epidural analgesia during labor.

Strengths and Limitations

A strength of this study is the mixed methods that will be used to measure outcome assessment, including quantitative data for effectiveness outcomes and focus group data for acceptability and feasibility outcomes. Another strength of the protocol is that a detailed preparation program for midwives is developed to support spontaneous pushing during labor. A potential limitation of the study is that participants will be both primiparous and multiparous women as we assume that a larger proportion of primiparous women will use epidural analgesia during labor, which will exclude them during the study. Another limitation of the study will be the risk that crossover in clinical context may occur where midwives may facilitate spontaneous pushing when taking care of women from routine practice groups.

Conclusions

This feasibility study will be used to evaluate the feasibility of conducting a full-scale RCT in the future as well as providing an opportunity to explore the potential facilitators and barriers of implementing an RCT. A future RCT will aim to compare the maternal and newborn outcomes between directed pushing and spontaneous pushing in women without epidural analgesia during the second stage of labor. The findings in this study are likely to have considerable policy and funding impacts regarding pushing management during the second stage of labor in line with the World Health Organization's recommendation to improve normality during labor and improve a woman's childbirth experience.

Acknowledgments

The first author (JY) would like to acknowledge the scholarship supported by the China Scholarship Council. This proposed research is being undertaken as a PhD degree and the candidate and supervisors all contributed to the research.

Data Availability

Data sharing is not applicable to this paper currently as no data sets were generated or analyzed during this study.

Authors' Contributions

JY drafted the manuscript protocol. KB and H Roth contributed to the study design and editing. DA and HL helped with the study design. H Rong was a major contributor in assessing the study protocol in hospital settings. All authors read and approved the final manuscript.

Abstract

Background: Exercise rehabilitation is a promising strategy for reducing cardiovascular disease risk among patients with breast cancer. However, the evidence is primarily derived from programs based at exercise centers with in-person supervised delivery. Conversely, most patients report a preference for home-based rehabilitation. As such, there is a clear need to explore strategies that can provide real-time supervision and coaching while addressing consumer preferences. Evidence from cardiac rehabilitation has demonstrated the noninferiority of a smartphone-based telerehabilitation approach (REMOTE-CR) to improve cardiorespiratory fitness in people with cardiovascular disease compared to a center-based program.

Objective: This study aims to assess the feasibility, safety, and preliminary efficacy of the REMOTE-CR program adapted for patients with breast cancer at risk of cardiotoxicity (REMOTE-COR-B). We will also assess the satisfaction and usability of REMOTE-COR-B.

Methods: We will conduct a single-arm feasibility study of the REMOTE-COR-B program among patients with stage I-III breast cancer who are at risk of cardiotoxicity (taking treatment type and dose, as well as other common cardiovascular disease risk factors into account) and who are within 24 months of completing primary definitive treatment. Participants (target sample size of 40) will receive an 8-week smartphone-based telerehabilitation exercise program involving remotely delivered real-time supervision and behavior change support. The platform comprises a smartphone and wearable heart rate monitor, as well as a

custom-built smartphone app and web application. Participants will be able to attend remotely monitored exercise sessions during set operating hours each week, scheduled in both the morning and evening. Adherence is the primary outcome of the trial, assessed through the number of remotely monitored exercise sessions attended compared to the trial target (ie, 3 sessions per week). Secondary outcomes include additional trial feasibility indicators (eg, recruitment and retention), safety, satisfaction, and usability, and objective and patient-reported efficacy outcomes (cardiovascular fitness, quality of life, fatigue, self-reported exercise, self-efficacy, habit strength, and motivation). Adherence, feasibility, and safety outcomes will be assessed during the intervention period; intervention satisfaction and usability will be assessed post intervention; and objective and patient-reported efficacy outcomes will be assessed at baseline, post intervention (2-month postbaseline assessment), and at follow-up (5-month postbaseline assessment).

Results: Recruitment for this trial commenced in March 2023, and 7 participants had been recruited as of the submission of the manuscript. The estimated completion date for the project is October 2024, with results expected to be published in mid-2025.

Conclusions: The REMOTE-COR-B intervention is a novel and promising approach to providing exercise therapy to patients with breast cancer at risk of cardiotoxicity who have unique needs and heightened safety risks. This project will provide important information on the extent to which this approach is satisfactory to patients with breast cancer, safe, and potentially effective, which is necessary before larger-scale research or clinical projects.

Introduction

With increased rates of breast cancer survival, especially beyond 5 years, there is now an increased need to focus on the late adverse effects of cancer treatment [1,2]. The adverse impact of cancer treatment on cardiovascular health is one such late effect [3]. Cardiovascular disease (a group of heart and blood vessel disorders [4]) is now a leading cause of death among survivors of breast cancer, and survivors of breast cancer have a higher risk compared to the general population [3,5]. In addition to the overlapping risk factors of cancer and cardiovascular disease, including obesity and physical inactivity [6], the cardiotoxic nature of common breast cancer treatments (including chemotherapy, radiotherapy, and human epidermal growth factor receptor [HER]–targeted therapy) is a contributing factor to this increased risk [3]. Anthracycline-based chemotherapy and trastuzumab are of particular concern, being associated with a 5-fold increase in the risk of heart failure compared to treatment without these agents [7].

Exercise rehabilitation focused on increasing cardiorespiratory fitness is a promising strategy for reducing cardiovascular disease risk among survivors of breast cancer [8]. Lower fitness is associated with an increased risk of cardiovascular disease and all-cause mortality in the general population [9], and fitness declines have been observed during cancer treatment. Following breast cancer, major cardiovascular events tend to emerge initially around 4 years after adjuvant treatments, with a second peak around 10 years post treatment [10]. A recent study in over 4000 women, 12 years after a diagnosis of breast cancer, found that increased physical activity (equivalent to approximately 3 hours of brisk walking per week or ≥9 metabolic equivalent task hours [MET-hrs]) was associated with a 56% reduced risk of cardiovascular events (including heart failure, myocardial infarction, angina, coronary revascularization, peripheral arterial disease, carotid artery disease, transient ischemic attack, stroke, and cardiovascular death) when compared to women who exercised less (<9 MET-hrs per week) [11]. To date, over a dozen randomized controlled trials have demonstrated that exercise rehabilitation can effectively increase cardiorespiratory fitness among survivors of breast cancer [8]. Alongside consistent evidence from randomized controlled trials that exercise also improves quality of life and physical functioning [12], this evidence has led to exercise being recommended in guidelines as a routine part of cancer management [13,14].

While the evidence for exercise rehabilitation improving fitness among survivors of breast cancer is strong, it has primarily been derived from center-based exercise rehabilitation programs, where participants receive real-time in-person supervision. However, reliance on center-based delivery is likely to limit accessibility and uptake [12], as many survivors of breast cancer report a preference for home-based rehabilitation [15]. Even with this preference, it is important to ensure participant safety as well as the suitability and individualization of exercise prescriptions. Particularly because exercise trials typically recruit more “well” survivors of cancer, who are generally younger, less likely to be obese, and who are more physically active (ie, rarely include those most at-risk of cardiovascular disease) [16]. As such, there is a clear need to explore noncenter-based delivery models that can provide real-time supervision and coaching to optimize safety, particularly for high-risk patients with breast cancer (eg, those at high risk of cardiovascular disease). Evidence from the cardiac rehabilitation setting suggests that the use of sensors and mobile technologies is a promising strategy for reducing cardiovascular disease risk

among survivors of breast cancer, warranting investigation [17,18].

Maddison et al [19] developed a smartphone-based exercise telerehabilitation program (REMOTE-CR) that allowed participants to receive real-time remote exercise supervision and coaching from an exercise professional. A noninferiority, randomized trial (n=162) compared REMOTE-CR to a 12-week center-based exercise cardiac rehabilitation program in people with cardiovascular disease [19]. At the 12-week follow-up, REMOTE-CR was shown to be noninferior to center-based exercise cardiac rehabilitation on maximum oxygen uptake (VO_2max; adjusted mean difference [AMD] 0.51, 95% CI 0.97-1.98 mL/kg/minute). At longer-term follow-up (24 weeks), participants allocated to REMOTE-CR were also more likely to be participating in physical activity than those allocated to the center-based program (ie, less sedentary time: AMD –62, 95% CI –118 to –5 minutes/day) [19]. Importantly, per capita costs for delivering REMOTE-CR were 70% lower than center-based exercise cardiac rehabilitation, and although more adverse events were self-reported by the REMOTE-CR group during the intervention period, none were severe, and the majority (42/50, 84%) were not related to program participation. The same approach could be adapted for use in a cardio-oncology setting. However, the extent to which it would be feasible, safe, and effective (ie, positively impact fitness outcomes) for survivors of breast cancer at risk of cardiotoxicity, given their unique needs and risk profile, is unknown.

The overall aim of this study is to determine the feasibility of the REMOTE-COR-B program, a smartphone-based telerehabilitation exercise program for survivors of breast cancer at risk of cardiotoxicity. The secondary objectives of this trial are to determine satisfaction with and usability of REMOTE-COR-B, as well as potential effects on cardiovascular fitness that can be used to inform future, adequately powered trials.

Methods

Ethical Considerations

Ethics clearance was obtained by the Peter MacCallum Cancer Centre Ethics Committee (HREC/60412/PMCC-2020). Informed consent will be obtained from all participants involved in the trial. Participants will be assigned a study ID number. All study materials will be coded with the ID number only. Only the research team will have access to the study database, which contains the information needed to link ID numbers with identifiable information. Participants will be provided with an AUD $25 (US $16.32) gift card at the end of each assessment as an incentive to complete outcome assessments and in acknowledgement of their time. Participants will also be reimbursed for travel expenses or parking costs for attendance at each appointment.

Trial Design

A single-arm feasibility study will be conducted to determine the feasibility, safety, and preliminary efficacy of REMOTE-COR-B (protocol version 7; date August 24, 2023). The trial has been prospectively registered on the Australian New Zealand Clinical Trials Registry (ACTRN12621001557820). The study protocol is reported in accordance with the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) guidelines [20], and the intervention is described according to the Consensus on Exercise Reporting Template (CERT) [21]. Study materials are available on the Open Science Framework [22].

Eligibility and Recruitment

The inclusion and exclusion criteria are provided in Textbox 1. Eligibility will be confirmed using medical data and patient interviews, as appropriate.

Textbox 1. The inclusion and exclusion criteria for the study.

Inclusion criteria

- A diagnosis of stage I-III breast cancer.
- At risk of cardiotoxicity according to predetermined criteria (taking treatment type and dose as well as other common cardiovascular disease risk factors into account, including age, obesity, and the presence of other comorbidities; Figure S1 in Multimedia Appendix 1 [3,6,23-27]).
- Completion of primary definitive anticancer therapy within the last 24 months (which may be surgery, radiotherapy, or chemotherapy depending on the treatment pathway; participants who received both adjuvant and neoadjuvant treatment are eligible).
- Generally participating in less than the REMOTE-COR-B exercise target (ie, <150 minutes of moderate to vigorous intensity aerobic activity per week over <3 sessions per week) [13,14,28].
- An Eastern Cooperative Oncology Group (ECOG) performance status of 0-2 [28]
- Having sufficient reading and writing English skills is required for understanding the participant information sheet and study participation instructions.

Exclusion criteria

- Participants who have been diagnosed with metastatic (stage IV) or recurrent breast cancer.
- Those who have a medical condition where exercise or cardiopulmonary exercise testing is contraindicated (eg, unstable angina, uncontrolled heart failure, or asthma) [21].
- Having an implanted cardiac device [21].
- Being unable to provide informed consent.
- Being unable to fully participate in study assessments due to cognitive or physical impairment.
- Participating in another exercise study or exercise program with similar goals.
- Participating in a clinical trial that presents safety or contamination issues for either trial (to be assessed by the Steering Committee).

Eligible participants will be identified by the breast cancer clinical and research staff at the Peter MacCallum Cancer Centre and the Royal Melbourne Hospital. Potentially eligible patients will receive an email through the REDCap (Research Electronic Data Capture [29,30]) platform and will be provided with an information pack (including a study flyer and participant information and consent form). Patients can indicate their interest in the trial through the REDCap platform or by direct contact with the research team. Trial staff will contact interested patients to provide a verbal explanation of the project and its procedures, answer patients' questions, and complete the eligibility screening. Following confirmation of eligibility, trial staff will obtain informed consent to participate in the study through REDCap, and the baseline assessment will be scheduled. Participants can withdraw from the study at any time without reason or consequence. In addition, the investigator may discontinue a patient from the study at any time if the investigator considers it necessary for any reason.

Adapting the REMOTE-CR Intervention

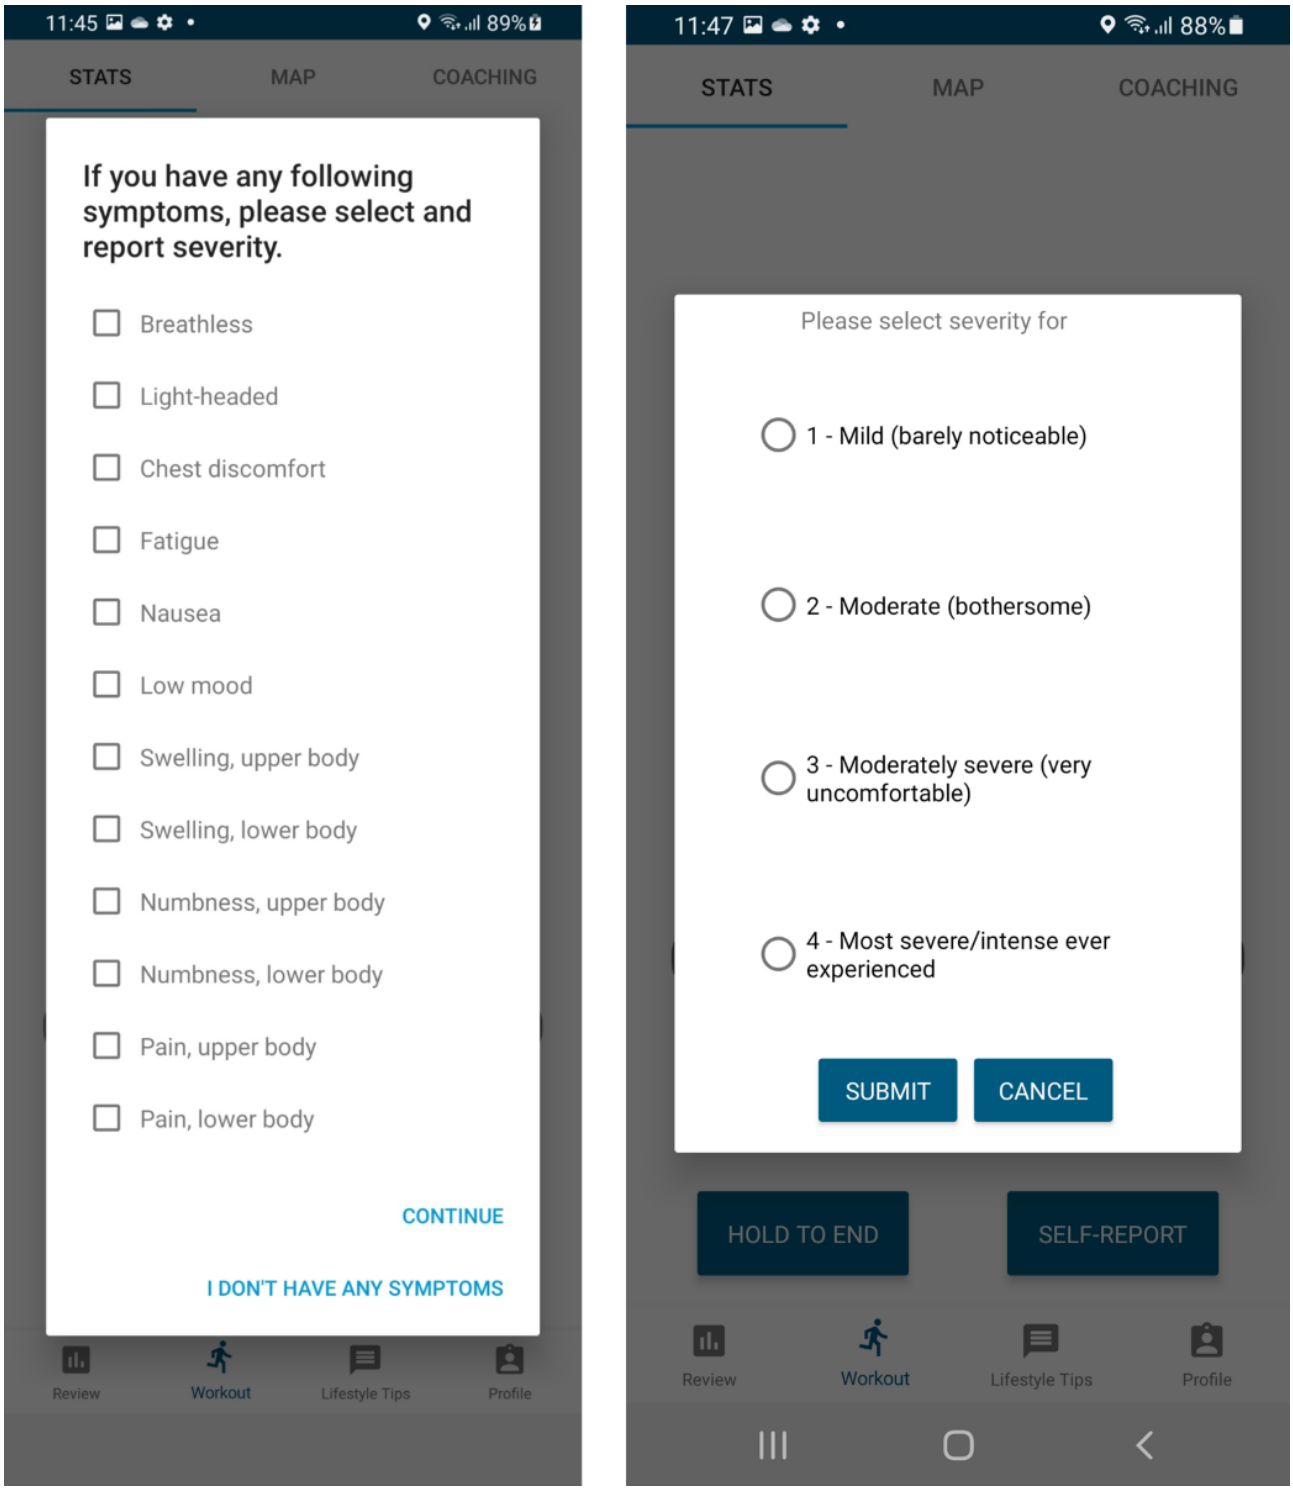
For this study, REMOTE-COR-B was adapted from the original REMOTE-CR platform, which is described in detail elsewhere [31]. In brief, the base platform comprises a smartphone and wearable sensor (currently compatible with BioHarness 3, Zephyr Technology, and H10, Polar Electro), as well as a custom-built smartphone app and web application. The platform facilitates remotely supervised exercise prescriptions that are delivered, monitored, and coached in real-time by an exercise professional. The participant's heart rate and geospatial data are displayed in the smartphone app for self-monitoring and streamed to a web server for review by an exercise professional (along with single-lead electrocardiogram [ECG] data, which are not visible to the participant in the smartphone app). The participant can also use the app to report "red flag" symptoms during exercise (chest pain, breathlessness, and dizziness), allowing the exercise professional to stop the session, make contact, and direct as needed. The exercise professional provides individualized audio coaching, feedback, and social support throughout the session, which is delivered to participants through earphones (text-to-audio feature) to optimize usability. At the end of an exercise session, participants are prompted to report their perceived exertion using the app. Outside of real-time interaction, participants can record exercise training for self-monitoring, receive behavior change education through direct messaging, review all recorded exercise performance data, and set or review goals to encourage behavior change.

Adaptations of REMOTE-CR for Breast Cancer

Following consultation with consumer representatives and the advisory committee, the following changes were made to the base platform for the REMOTE-COR-B trial: (1) expansion of the symptom reporting list to include common breast cancer treatment-related side effects and symptoms (Figure 1); (2) prompts for participants to report their symptoms at the start of each exercise session; (3) ability to report Rating of Perceived Exertion (RPE) both during and after exercise to enhance tailoring of prescription and coaching; (4) expansion of the heart rate data display to include beats per minute (BPM; the raw measurement unit) in addition to heart rate reserve, to allow use when a lack of maximal exercise testing precludes calculation of heart rate reserve; (5) revisions to the behavior change education to provide additional positive reinforcement, breast

cancer–specific content, and messages focused on planning, habit formation, and autonomous motivation; and (6) alternative options for wearing the heart rate monitor if chest irritation or pain is an issue (ie, delay enrollment post treatment, use an adhesive to place the sensor on an unaffected area or at a different location that yields sufficient signal quality, or monitor intensity exclusively through RPE).

Figure 1. Expanded symptom reporting list in REMOTE-COR-B: a single-arm feasibility trial for patients with breast cancer.



The Remote-COR-B Intervention

The REMOTE-COR-B intervention will be delivered over a period of 8 weeks and involves remotely delivered individualized exercise prescriptions, real-time supervision, and behavior change support (eg, goal setting and supportive messages). The aim of the intervention is for participants to attend 3 remotely monitored aerobic exercise sessions per week, with self-directed exercise encouraged (where appropriate) on ≥2 other days to align with current aerobic recommendations for patients with cancer (ie, 150 minutes of moderate to vigorous intensity activity per week) [13,14,28]. The REMOTE-COR-B trial will emphasize aerobic activity, given the focus of the intervention on improving cardiovascular fitness [14,28]. The

intervention is summarized below and described in detail according to the CERT requirements in Table S1 in Multimedia Appendix 2 [21,32,33].

Exercise Prescription

Each participant will be provided with an individualized and progressive exercise prescription based on their age, previous and recent exercise habits, motivation, personal goals, attitudes, values, treatment, and support. Exercise prescription components will include frequency (3 remotely monitored sessions per week), duration (20-60 minutes per session), and intensity (moderate: 40%-60% heart rate reserve [HRR] and RPE 3-5 [34]), with the aim of increasing peak oxygen consumption (VO_2peak). Intensity will be monitored through a combination of HRR and RPE if complete baseline cardiopulmonary exercise testing (CPET) is available (more details are provided in the "Secondary Outcomes" section), or BPM and RPE if baseline CPET is unavailable.

The progression of exercise prescription components will typically occur in the following order: duration, intensity, frequency (additional to remotely monitored sessions), and will be gradually increased as tolerated by the individual, with consideration to symptom status, fitness level, exercise response (based on heart rate data and RPE), and each participant's goals [35]. During the first half of the intervention (ie, weeks 1-4), exercise intensity targets will typically range from RPE 3 to 4 ("moderate" to "somewhat hard") and between 40% and 50% HRR [34]. In the second half of the intervention (ie, weeks 5-8), exercise intensity targets will typically range from RPE 4 to 5 ("somewhat hard" to "hard") and between 50% and 60% HRR [34]. The preferred mode of exercise is walking, though participants may choose other land-based aerobic activities (eg, cycling, jogging, and exercise videos).

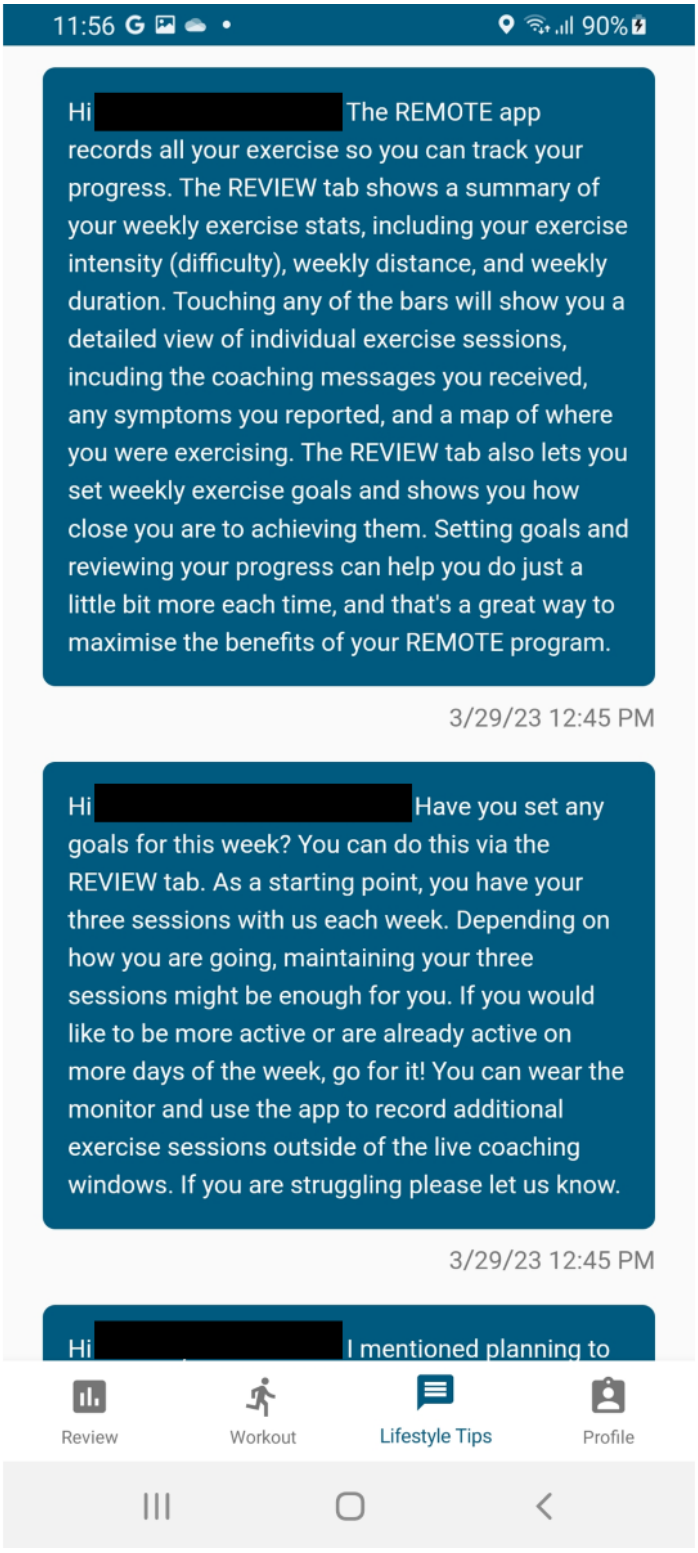
Remote Monitoring and Supervision

Participants will be able to attend remotely monitored exercise sessions during set operating hours each week, scheduled in both the morning (eg, between 6 AM and 10 AM) and evening (eg, between 5:30 PM and 7:30 PM). Participants can complete exercise in any location with an active broadband connection (mobile, Wi-Fi, or Bluetooth). The REMOTE-COR-B mobile app collects heart rate and single-lead ECG through a Polar H10 heart rate transmitter (loaned to participants throughout the study), location, distance, and speed through location services integration, as well as symptoms and RPE through self-report. These data are then transmitted to a cloud-based server and displayed on a companion web application in real-time. Exercise professionals remotely monitor all data in real-time through the web application, provide participants with real-time individualized coaching feedback and support through their smartphone app (through alerts, messages, or telephone calls), respond to adverse events if required, provide postexercise feedback, and modify exercise prescriptions as needed.

Behavior Change Support

Participants will receive behavior change education and support during the 8-week intervention period through push notifications (2-4 per week) delivered through the REMOTE-COR-B mobile app (Figure 2). The messages are based on social cognitive [36], self-determination [37], and habit theories [38] (Table S1 in Multimedia Appendix 2 outlines the specific strategies). Additionally, participants are encouraged to use the built-in data visualization features of the app to review their exercise performance data and set and review goals to encourage behavior change.

Figure 2. Example of behavior change support in REMOTE-COR-B: a single-arm feasibility trial for patients with breast cancer.



Outcomes and Assessment Timing

Data relating to intervention delivery outcomes (eg, adherence, feasibility, and safety) will be collected during the 8-week intervention (Table 1). Satisfaction and usability will be assessed post intervention. Objective and patient-reported efficacy outcomes will be assessed at baseline (within 24 months post completion of primary definition treatment), post intervention (2-month postbaseline assessment), and at follow-up (5-month postbaseline assessment). Demographic and medical data will be collected at baseline through self-reports and medical records. Criteria of success for core feasibility, usability, safety, and efficacy outcomes have been prespecified and are outlined below.

Table 1. Schedule of enrollment, intervention, and assessments for REMOTE-COR-B: a single-arm feasibility trial for patients with breast cancer (based on the SPIRIT [Standard Protocol Items: Recommendations for Interventional Trials] guidelines) [20].

Time point	Study period				
	Enrollment (prebaseline)	Intervention period			Follow-up

Self-reported exercise		✓		✓	✓
Psychological mechanisms		✓		✓	✓

[a]CPET: cardiopulmonary exercise testing.

[b]ISWT: incremental shuttle walk test.

Primary Outcome

Adherence will be assessed through the number of remotely monitored exercise sessions attended compared to the trial target (ie, 3 sessions per week). Previous research suggests ≥70% adherence is satisfactory to achieve fitness gains [8,12]. As such, participants will be considered adherent to the intervention if they complete ≥17 of 24 remotely monitored exercise sessions.

Secondary Outcomes

Trial Feasibility

Trial feasibility is assessed based on rates of screening, consent, device ownership, retention, and missing data across all assessment points. Prespecified cut points indicating feasibility include cardiac dysfunction risk level is accessible for ≥80% of cases identified; ≥60% of those invited to participate agree to complete eligibility screening [39]; the recruitment goal is reached within the allotted time (1 year); retention is ≥60%; and outcome data are collected for ≥80% of enrolled participants at both the postintervention and follow-up assessments (this is in line with retention observed by the chief investigator Maddison et al [19] in the REMOTE-CR trial).

Safety

Adverse events will be assessed through the frequency and severity of adverse events reported during remotely monitored exercise sessions, any unsupervised exercise sessions, and exercise testing sessions (as outlined in the "Cardiovascular Fitness: VO_2peak" section). Severity will be graded according to the Common Terminology Criteria for Adverse Events 5.0 and the National Health and Medical Research Council guidelines for safety monitoring and reporting [32,40]. Participants will be instructed to immediately report any adverse events that occur during the intervention period (during either supervised or unsupervised exercise sessions) to the study staff (ie, exercise professionals or study coordinators); these will be recorded. All adverse events reported to study staff will be communicated to the study coordinator and the coordinating principal investigator as soon as possible and recorded. The coordinating principal investigator will be responsible for ensuring serious adverse events are reported to the ethics committee and trial sponsor within the appropriate time frames. Participants can also retrospectively report adverse events during the postintervention and follow-up surveys. The trial will be deemed safe if no grade ≥3 adverse events attributed to

participating in the research project are reported. During the intervention period, participants can also self-report symptoms (new, ongoing, or worsening) through the smartphone app at the beginning and end of every exercise session (supervised and unsupervised). Any changes in symptomology will also be recorded.

Satisfaction and Usability

Satisfaction with the intervention and perceived intervention usability will be assessed using the validated 8-item Client Satisfaction Questionnaire (0-32) [41] and the 10-item System Usability Scale (0-100) [42]. The intervention will be deemed satisfactory and usable if mean scores are ≥24 and ≥68, respectively. Issues with wearing the heart rate monitor due to cancer treatment-related discomfort will also be discussed and recorded by the study coordinator in a study-specific form.

Cardiovascular Fitness: VO2peak

Cardiovascular fitness (VO_2peak) will be assessed through CPET and an incremental shuttle walk test (ISWT). The CPET will occur at the Peter MacCallum Cancer Centre (conducted by Peter MacCallum staff) and will involve participants exercising on an exercise bike against increasing resistance, during which time gas exchange analysis will be conducted to measure anaerobic threshold and VO_2peak. Blood pressure and 12-lead ECG will be monitored for signs of an adverse cardiac response. VO_2peak is a gold-standard measure for objectively assessing cardiorespiratory fitness and is an important clinical end point in this population because it is a strong predictor of adverse cardiovascular events and mortality [11]. A change in VO_2peak as small as 6% can be clinically meaningful in terms of cardiovascular outcomes among patients with chronic systolic heart failure [43]. We expect an average improvement in VO_2peak of ≥10%, as this is comparable to what has been achieved in posttreatment supervised exercise interventions among patients with breast cancer [44-46]. Additionally, this level of change is used clinically in a heart failure setting as indicating a clinically meaningful improvement in outcomes [47,48] and is associated with improved health-related quality of life in patients with breast cancer [46].

The ISWT is a valid and reliable field walking test to assess functional exercise capacity [49,50] and is shown to be moderately correlated with CPET-assessed VO_2peak (r=0.61) [51]. Due to possible COVID-19–related difficulties with performing CPETs on all participants, an ISWT will also be performed (conducted by trial staff), as the equipment is easily transportable and the test can be completed outdoors (potentially necessary if a home visit is required due to COVID-19 restrictions and a suitable indoor location is not available). Participants are required to walk around 2 cones placed 9 meters apart (a total of 10 meters of flat course) in time to a set of auditory beeps. Initially, the walking speed is very slow, but each minute, the required walking speed progressively increases. The test concludes when the participant cannot achieve the required speed, experiences clinical indications for test termination, or wishes to stop. The number of shuttles is recorded. Only standardized instructions will be used [50], the walking track will be kept the same for all tests for a participant, and no encouragement will be given throughout. An improvement of ≥48 meters from baseline to postintervention will be considered clinically significant [49]. The intervention will be deemed potentially efficacious for improving cardiovascular fitness if clinically significant changes in VO_2peak (≥10%) or meters walked in the ISWT are achieved.

Quality of Life

Quality of life will be assessed using the validated 38-item Functional Assessment of Cancer Therapy-Breast (FACT-B) questionnaire [52]. Total health-related quality of life (0-148) and subscale scores (physical, social, emotional, and functional well-being) will be calculated. A clinically important change in total quality of life has been defined as a 6% increase between baseline and postintervention [53].

Fatigue

Fatigue will be assessed using the validated 13-item Functional Assessment of Chronic Illness Therapy-Fatigue Scale (FACIT-Fatigue) questionnaire [54]. All items are summed to create a single fatigue score (0-52). A clinically important change in the FACIT-Fatigue has been defined as a 6% increase between baseline and postintervention [53,55].

Self-Reported Exercise

Self-reported exercise will be assessed using the validated 3-item Godin Leisure-Time Exercise Questionnaire (GLTEQ) [56]. Using the GLTEQ, participants self-report how often in the previous 7 days they completed ≥15 minutes of strenuous, moderate, and light physical activity. The number of bouts at each intensity is then multiplied by the corresponding MET value and summed to create a Leisure Score Index (LSI). The proportion of participants considered sufficiently active will also be reported, determined based on prespecified LSI scores (<14 units=insufficiently active or sedentary; between 14 and 23 units=moderately active; and ≥24 units=active or “meeting criteria for being physically active”) [56,57].

Psychological mechanisms

Potential mediators of intervention effects will be assessed, including self-efficacy (Multidimensional Self-Efficacy for Exercise Scale [58]), habit strength (self-reported habit index [59]), motivation type (Behavioural Regulation Questionnaire [60]), and autonomy-supportive exercise environment (The Perceived Environmental Supportiveness Scale [61]).

Data Analysis

Sample Size

We aim to recruit 40 participants over the course of 12 months. This sample size is considered sufficient to test the feasibility of delivering the intervention and other key trial parameters [62]. Notably, with this sample size, we will also have reasonable precision for estimating intervention adherence. For example, with a sample size of 40, if the average adherence rate observed in the study is 70%, we can be sure with 95% confidence that the true population proportion is between 56% and 85%; the 95% CI is ≥14.2. Given the potential reach of the intervention and the fact that adherence to current technology-based behavior change programs is 50% [39], this

finding would warrant further investigation. The target sample size is also equivalent to approximately 20%-30% of the sample size needed to adequately power (80%) a future definitive trial to demonstrate noninferiority in VO_2peak changes between groups (a *P* value of .05); based on differences observed in our formative work [19] and a systematic review [8].

Statistical Methods

The data will be presented descriptively where appropriate; this includes most feasibility outcomes (eg, recruitment rate, proportion of missing data, usability, and satisfaction), including the primary outcome (ie, adherence to the intervention), and safety outcomes (eg, number of adverse events, proportion of serious adverse events).

Changes in VO_2peak, patient-reported outcomes (quality of life and fatigue), and physical activity behavior will be examined in exploratory analyses at all assessment time points using mixed model repeated measures analyses. Unadjusted and age- and treatment pathway–adjusted models will be conducted with standardized coefficients reported with 95% CIs to aid interpretation of clinical significance rather than *P* values given a lack of statistical power. The choice of modeling link will be informed by residual diagnostics. The data for withdrawn participants collected before study withdrawal will be retained for use in intention-to-treat analyses, unless requested otherwise by the participant.

Further exploratory analyses may include (1) examining changes in the proposed psychological mechanisms (eg, self-efficacy) from baseline to postintervention; (2) examining associations between the proposed mechanisms and the study outcomes (eg, adherence to exercise sessions and cardiorespiratory fitness); and (3) examining associations between participant characteristics (potential moderators) and intervention adherence (sessions and intensity), as well as changes in VO_2peak. Given the small sample size and absence of a control group, a formal mediation analysis or moderation analysis will not be undertaken (as per Baron and Kenny [63]). However, the collection of these data will assist with determining the feasibility of mediator and moderator assessment in a larger trial, where a formal mediation analysis and moderator analysis may be undertaken.

Data Management

The data will be preferentially recorded in electronic case record forms (CRF) and through surveys using REDCap data management software, only accessible to trial staff. Hard copy forms will also be available if necessary (stored in a locked filing cabinet). Data collected through hard copy will be scanned and uploaded to REDCap and the secure study network drive as soon as possible. Hard copies will be shredded once the data are safely stored electronically (including a scan of the original). All data will be exported from REDCap at the end of the trial and stored on a password-protected network drive at the University of Melbourne for at least 5 years after the publication of the results. Deidentified data may be shared indefinitely through sites like Open Science or Figshare to ensure scientific transparency and to share knowledge with others.

Results

The recruitment for this trial began in March 2023, and 7 participants had been recruited as of the submission of the manuscript. Recruitment issues were encountered early, and changes to the prespecified protocol (ACTRN12621001557820) have been made to aid recruitment. The original eligibility criteria for the trial required participants to have completed primary, definitive anticancer therapy within 3-12 weeks. In addition, only anthracyclines and no other types of chemotherapy were considered in the cardiotoxic risk assessment. After screening potential participants, it became clear that recruitment would be slower than expected and that many patients at risk of poor heart health would not be eligible for the trial. Before enrolling the first participant, the eligibility criteria were amended so that participants could be up to 6 months post definitive treatment, and a wider range of evidence-based risk factors for cardiotoxicity and cardiovascular disease would be considered (Figure S1 in Multimedia Appendix 1 [3,6,23-27]). A second objective fitness test (the ISWT) was also added, which can be conducted outside of the hospital setting in case COVID-19 disruptions impact access to CPET assessments. Following these changes, the first participant was enrolled in March 2023.

Additional changes have since been made to the protocol to further aid recruitment. These include expanding screening opportunities to identify potentially eligible participants, streamlining the recruitment procedure through REDCap to reduce burden on hospital staff, and expanding eligibility criteria to include patients up to 24 months post definitive treatment. This amendment was recently approved, and the estimated completion date for the project is October 2024, with results expected to be published in mid-2025. Any future protocol amendments will be reported in the main outcomes publication and registered on the Australian New Zealand Clinical Trials Registry.

Discussion

The original intervention underpinning this trial has demonstrated efficacy and noninferiority compared to gold-standard in-clinic cardiac rehabilitation [19]. The adaptation of this intervention for patients with breast cancer who are at risk of cardiotoxicity is a novel and promising approach to providing accessible exercise therapy. This trial will address the extent to which this approach is satisfactory to patients with breast cancer, safe, and potentially effective, given the unique needs and risk profile of this group. The findings will be used to inform features of a future, adequately powered efficacy trial, including but not limited to eligibility and recruitment strategy, app features and functions, and delivery preferences (eg, session timing) [64]. Trial findings might also be used to inform the implementation of this approach in breast cancer services, given that remote strategies are needed now and the strong evidence-based basis behind the base software (REMOTE-CR). By publishing this protocol, we aim to ensure transparency around prespecified outcome criteria, inform

interested parties of the upcoming trial, and aid replication and critical review of study methodology.

Acknowledgments

This study is funded by a National Breast Cancer Foundation grant. TLJ is supported by a postdoctoral fellowship partly funded by the grant. CES is supported by a Victoria Cancer Agency Mid-Career Fellowship. LE is supported by a Victoria Cancer Agency Early Career Research fellowship. JCR received a National Heart Foundation of Australia Postdoctoral Fellowship (102585). ALS is supported by the National Heart Foundation of Australia Future Leader Fellowship (award ID 106025).

The University of Melbourne is the sponsor for the trial. The trial sponsor has responsibility for the quality and integrity of trial data, ensuring appropriate approvals are obtained before the commencement of the trial, and patient safety.

Data Availability

The data sets generated or analyzed during this study will be available from the corresponding author upon reasonable request.

Authors' Contributions

CES, JCR, SH, LD, and RM obtained study funding. CES led protocol development with support from all authors. CES led adaptation of the intervention software, with support from JCR, RB, and IH and feedback from SH, LE, RM, and LD. TLJ developed the exercise prescription protocol with input from LE, SH, and LD. CES, TLJ, JCR, and RM developed the behavior change content, which was reviewed and revised by RDB and IH. RDB and IH provided consumer input to the study. SN, RDB, FHJ, and ALS provided clinical expertise in developing cardiotoxicity eligibility criteria. HI oversees cardiopulmonary exercise testing at the Peter MacCallum Cancer Centre. SN and RDB oversee participant recruitment at the study sites. CES and TLJ wrote the original draft of the manuscript. All named authors reviewed, had input into revisions, and approved the final manuscript. Generative AI was not used in any portion of the manuscript writing.

Conflicts of Interest

JCR and RM are inventors of the telerehabilitation platform being examined in this study. They do not receive any related benefits over and above their normal salary.

Abstract

Background: Heart failure (HF) is a leading cause of morbidity and mortality globally, with a high disease burden. The prevalence of HF in Ghana is increasing rapidly, but epidemiological profiles, treatment patterns, and survival data are scarce. The national capacity to diagnose and manage HF appropriately is also limited. To address the growing epidemic of HF, it is crucial to recognize the epidemiological characteristics and medium-term outcomes of HF in Ghana and improve the capability to identify and manage HF promptly and effectively at all levels of care.

Objective: This study aims to determine the epidemiological characteristics and medium-term HF outcomes in Ghana.

Methods: We conducted a prospective, multicenter, multilevel cross-sectional observational study of patients with HF from January to December 2023. Approximately 5000 patients presenting with HF to 9 hospitals, including teaching, regional, and municipal hospitals, will be recruited and evaluated according to a standardized protocol, including the use of an echocardiogram and an N-terminal pro-brain natriuretic peptide (NT-proBNP) test. Guideline-directed medical treatment of HF will be initiated for 6 months, and the medium-term outcomes of interventions, including rehospitalization and mortality, will be assessed. Patient data will be collated into a HF registry for continuous assessment and monitoring.

Results: This intervention will generate the necessary information on the etiology of HF, clinical presentations, the diagnostic yield of various tools, and management outcomes. In addition, it will build the necessary capacity and support for HF management in Ghana. As of July 30, 2023, the training and onboarding of all 9 centers had been completed. Preliminary analyses will be conducted by the end of the second quarter of 2024, and results are expected to be publicly available by the middle of 2024.

Conclusions: This study will provide the necessary data on HF, which will inform decisions on the prevention and management of HF and form the basis for future research.

Introduction

Overview

Heart failure (HF) is a costly, multifaceted, and life-threatening syndrome characterized by significant morbidity and mortality. Globally, HF affects 64 million people, with a prevalence of 1%-2% of adults in the general population and an estimated incidence of 1-20 cases per 1000 person-years [1].

Sub-Saharan Africa (SSA) has no population-based data; however, in-hospital prevalence ranges from 9.4% to 42.5% [2,3]. HF in SSA mainly affects young people and middle-aged individuals, occurring in people aged between 36 and 62.4 years [4]. It poses a substantial disease burden, with high mortality, rehospitalization rates, and health care costs, primarily attributable to readmissions and prolonged hospitalization periods of 11-13 days [3,5,6].

HF contributes significantly to Ghana's cardiovascular disease burden, with a worse prognosis and a more malignant course [7,8]. It is a leading cause of death among Ghanaian adults; yet, there is a paucity of data on the epidemiological profiles, treatment patterns, and survival rates of patients with HF in Ghana [9-11]. Single-center studies indicate a high prevalence of HF in Ghana [7,8,12].

The diagnosis of HF in most patients is primarily based on clinical manifestations due to the limited availability of diagnostic equipment. Ghana has few cardiologists, who are mainly located in tertiary hospitals [13]. In addition, there is a lack of HF education and training for physicians and nonphysician health workers. While HF management teams or multidisciplinary teams for HF management are the gold standard model for the delivery of care, these teams are nonexistent in Ghana, and most health facilities lack resources for long-term patient follow-up, such as diagnostic equipment, dedicated HF clinics, and protocols [14-17].

A national network of heart failure management teams (NNHFMT) will be established as part of the Ghana Heart Initiative's efforts to improve cardiovascular disease care in Ghana to help mitigate the burden of HF. The NNHFMT is tasked with building the capacity of both secondary and tertiary levels of care to promptly and effectively identify and manage HF by creating heart failure management teams (HFMTs) and establishing a national registry for HF and HF clinics that will be integrated with routine clinical services to provide long-term follow-up and care. The establishment of HF clinics and a national registry will fill a significant gap in HF care and research by providing the most recent epidemiological, management patterns, and medium-term outcomes data on HF.

Objectives

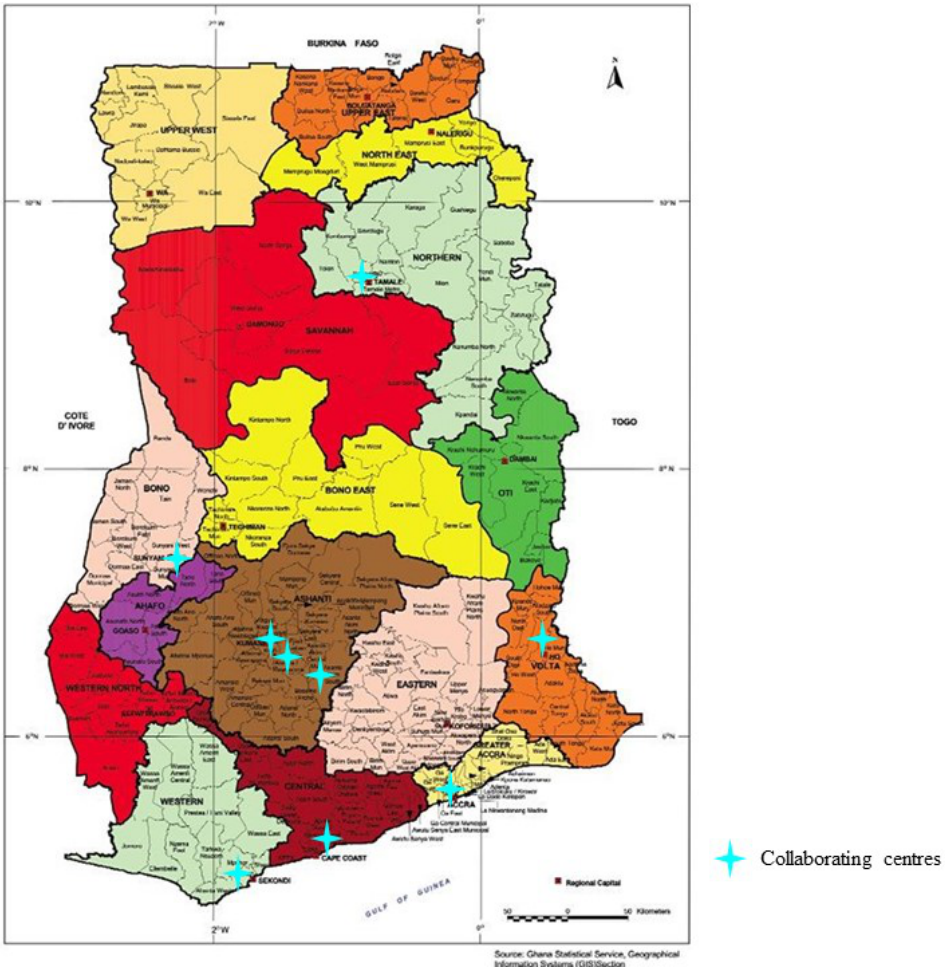
The primary objective of this study is to determine the epidemiological characteristics and medium-term outcomes of HF in Ghana by outlining the epidemiological and clinical characteristics of patients with HF in Ghana, identifying the underlying causes, evaluating the medium-term outcomes of HF in Ghana, and identifying the factors that predict hospitalization and mortality in patients with HF in Ghana. This study also aims to build capacity in the care of patients with HF and form the basis for a national registry for HF in Ghana.

Methods

Overview

An NNHFMT consisting of physicians, nurses, and researchers from 9 collaborating hospitals in Ghana was constituted to achieve the study objectives, with each institutional HFMT led by a cardiologist, 2 supporting cardiologists or physicians, and 2 nurses. The HFMTs will establish HF clinics and integrate them into the routine services of their hospitals; recruit patients with HF and manage them per guidelines and algorithm; and create awareness and train other personnel in the 9 centers on the diagnosis and management of HF. These institutions include 5 teaching hospitals, 3 regional hospitals, and 1 municipal hospital. They include the Korle-Bu Teaching Hospital (KBTH), Komfo Anokye Teaching Hospital (KATH), Tamale Teaching Hospital (TTH), Ho Teaching Hospital (HTH), Cape Coast Teaching Hospital (CCTH), Bono Regional Hospital, Presbyterian Hospital-Agogo, Kumasi South Hospital, and the Effia Nkwanta Regional Hospital (Figure 1) [18].

Figure 1. Map of Ghana showing the location of collaborating centers. Source: Ghana Statistical Service, 2020.

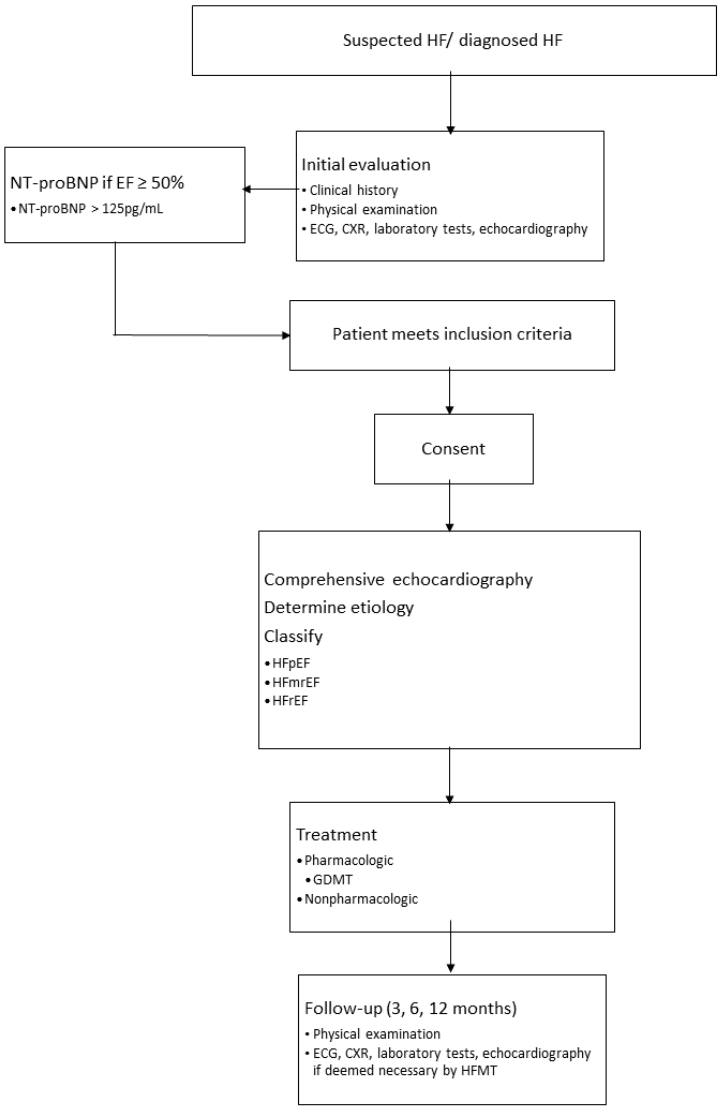


Study Design

This is a prospective, multicenter, and multilevel observational study of patients with HF. Patients presenting with HF will be recruited and evaluated according to a standardized protocol. Guideline-directed treatment for HF will then be prescribed after the diagnosis has been confirmed. The study will conduct a serum N-terminal pro-brain natriuretic peptide (NT-proBNP) and transthoracic echocardiogram for all participants for free, while the cost of treatment and other investigations will be borne by study participants as in routine care. Patients will be followed up prospectively for 6 months to determine the medium-term outcomes of interventions (Figure 2).

Patients will be recruited through the collaborating institutions' emergency rooms, admission wards, and established HF clinics from January to December 2023. The HFMTs of the 2 leading teaching hospitals in Ghana, KBTH and KATH, will be trained using a facilitators' training manual, which will be developed from current international HF guidelines. KBTH and KATH will then provide mentorship and training to the other collaborating hospitals. The HFMT of KBTH will train members of the HFMTs from the TTH, HTH, and Effia-Nkwanta Regional Hospital, while the HFMT of KATH will also train the HFMTs of CCTH, Bono Regional Hospital, Presbyterian Hospital-Agogo, and Kumasi South Hospital. The study will begin in the KBTH and KATH in January 2023, while the other 7 sites will begin recruitment in July 2023, and all areas will end enrollment in December 2023.

Figure 2. Chart outlining study design.



Study Population

Study participants will include patients aged 13 years or older who present with HF in the collaborating hospitals and consent to participate in the study. Patients with a life expectancy less than the expected duration of the registry due to non-HF comorbidities will be excluded.

Based on our estimation of a sample size of 5000 participants, we would be able to determine the mortality and hospitalization rate at 6 months with a 95% CI and a precision of ±1%. Each participating center will recruit 556 participants.

Recruitment of Study Participants

Participants will be recruited through the various departments or units of the collaborating institutions. All patients diagnosed with HF or suspected of having HF will be referred to the HFMTs for evaluation and enrollment. A total of 2 sensitization workshops will be organized at collaborating institutions during the study period: 1 before participants' enrollment and 1 midway through participant recruitment.

Data Collection

Data collection comprises administering questionnaires, reviewing medical records, physical examinations, imaging investigations, including chest x-rays and echocardiography, electrocardiography, and laboratory tests. The methods for data collection in this study are identical in all locations, following standardized operating manuals and tools.

Diagnosis of HF

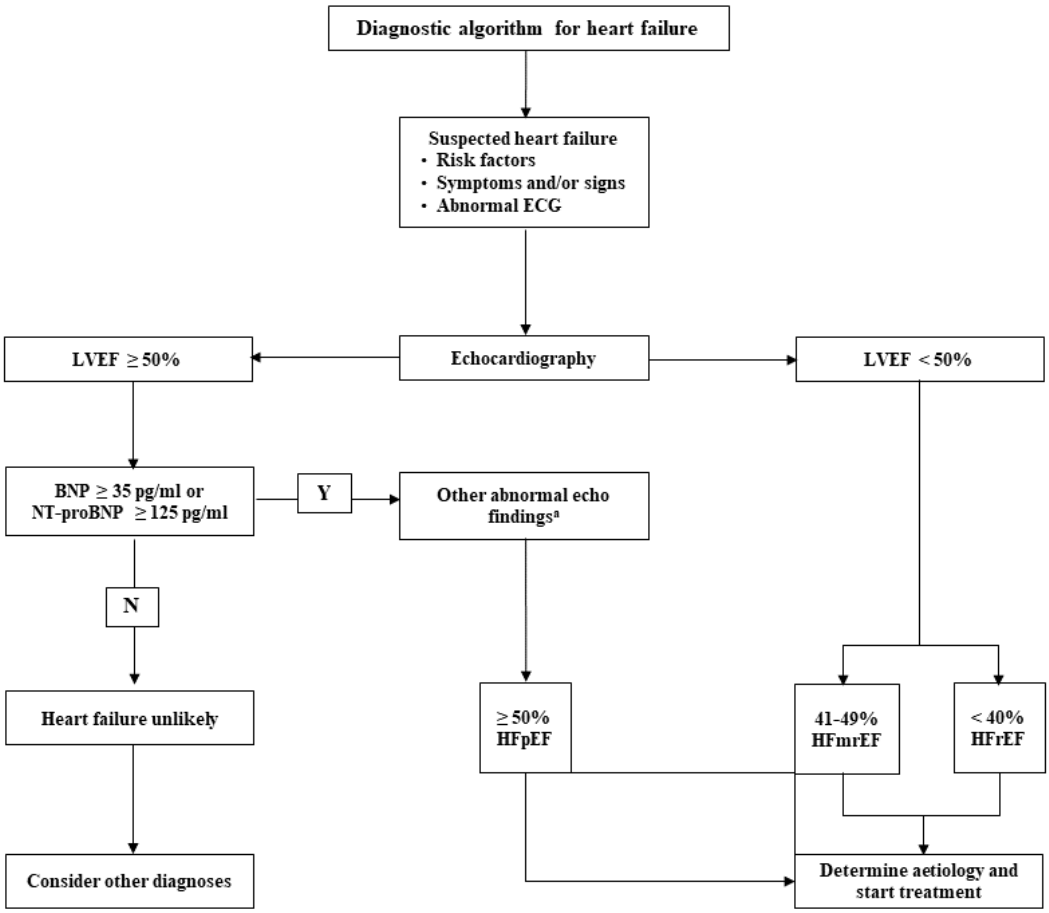
The diagnosis of HF will be made using a modified diagnostic algorithm adopted from the 2021 European Society of Cardiology Guidelines to diagnose and treat acute and chronic HF (Figure 3) [19]. The diagnosis of HF will be made based on the presence of typical symptoms of HF and objective evidence of cardiac dysfunction and categorized into three phenotypes: (1) heart failure with reduced ejection fraction (HFrEF), (2) heart failure with mildly reduced ejection fraction (HFmrEF), and (3) heart failure with preserved ejection fraction (HFpEF) based on the left ventricular ejection fraction (LVEF) [19].

All patients with typical symptoms and specific signs of HF and LVEF≤40% will be categorized as HFrEF, while patients with LVEF of 41%-49 % will be categorized as HFmrEF.

HFpEF will be diagnosed in patients presenting with typical symptoms and specific signs of HF and LVEF≥50%, the presence of elevated natriuretic peptides (NT-proBNP≥125 pg/mL), and objective evidence of cardiac structural and functional abnormalities consistent with the presence of left ventricular (LV) diastolic dysfunction or raised LV filling pressures. Objective evidence of structural or functional abnormalities includes the following:

- LV mass index ≥95 g/m^2 (female), ≥115 g/m^2 (male), and a relative wall thickness >0.42.
- Left atrial volume index >34 mL/m^2 in sinus rhythm (SR) and the presence of atrial fibrillation (AF) left atrial volume >40 mL/m^2.
- E/e' ratio at rest >9.
- NT-proBNP >125 (SR) or >365 (AF) pg/mL OR BNP >35 (SR) or >105 (AF) pg/mL.
- Pulmonary artery systolic pressure >35 mm Hg or tricuspid regurgitant velocity at rest >2.8 m/second.

Figure 3. Modified diagnostic algorithm for heart failure (HF). BNP: brain natriuretic peptide; ECG: electrocardiogram; HFmrEF: heart failure with mildly reduced ejection fraction; HFpEF: heart failure with preserved ejection fraction; HFrEF: heart failure with reduced ejection fraction; LVEF: left ventricular ejection fraction.



Etiology of HF

The etiology of HF will be determined based on the history, physical examination, laboratory, electrocardiographic, echocardiographic findings, and other imaging modalities (Table 1).

Table 1. Heart failure (HF) etiology and clinical characteristics.

Etiology of HF	Clinical characteristics	Specific investigations
Hypertension [20-22]	• Persistent elevated systolic BP[a] ≥140 mm Hg and diastolic BP ≥90 mm Hg • Presence of HMOD[b] • Current or previous use of antihypertensive medications	• 24-hour ambulatory BP • Plasma metanephrines and renal artery imaging • Serum renin and aldosterone • TTE[c]
Coronary artery disease [23]	• HF and ACS[d] • A pre-existing history of CCS[e] • Features suggestive of significant CAD[f] on coronary angiography or other imaging	• Invasive coronary angiography • CT[g] coronary angiography • Imaging stress tests (echo, nuclear, and CMR[h])
Valvular heart disease [24]	• Primary valve disease, for example, aortic stenosis • Secondary valve disease, for example, functional regurgitation • Congenital valve disease, for example, bicuspid aortic valve and mitral valve prolapse	• TTE/ TEE[i]/ stress echo • CT/ CMR
Rheumatic heart disease [25,26]	• Primary valve disease, for example, mitral stenosis and mitral regurgitation • Atrial fibrillation	• TTE/ TEE/ stress echo
Dilated cardiomyopathy [27,28]	• Unexplained dilated cardiac chambers with increased left ventricular mass index	• CMR, genetic testing • Trace elements, toxicology, LFTs[j]
Arrhythmia-induced cardiomyopathy [29]	• Mean heart rate above 100 beats per minute • Atrial fibrillation • Premature ventricular contractions burden equal to or greater than 10% • No other cause of LV dysfunction identified	• Ambulatory ECG recording • Electrophysiology study, if indicated
Congenital heart disease	• History of congenital heart disease • Incidental diagnosis of congenital heart disease during investigation for HF	• TTE/ TEE • CMR
Other etiologies of HF [19]	• Clinical features diagnostic of restrictive cardiomyopathy, arrhythmogenic cardiomyopathy, peripartum cardiomyopathy, endomyocardial fibrosis, cor pulmonale, infiltrative cardiomyopathy, pericardial disease, LV noncompaction cardiomyopathy, and toxin-induced cardiomyopathy.	• Serum electrophoresis and serum free light chains. • Echo, CMR, CT-PET[k], endomyocardial biopsy, Serum angiotensin-converting enzyme, fluorodeoxyglucose-PET, and chest CT • Right and left heart catheterization

[a]BP: blood pressure.

[b]HMOD: hypertension-mediated organ damage.

[c]TTE: transthoracic echocardiogram.

[d]ACS: acute coronary syndrome.

[e]CCS: chronic coronary syndrome.

[f]CAD: coronary artery disease.

[g]CT: computed tomography.

[h]CMR: cardiovascular magnetic resonance.

[i]TEE: transesophageal echocardiogram.

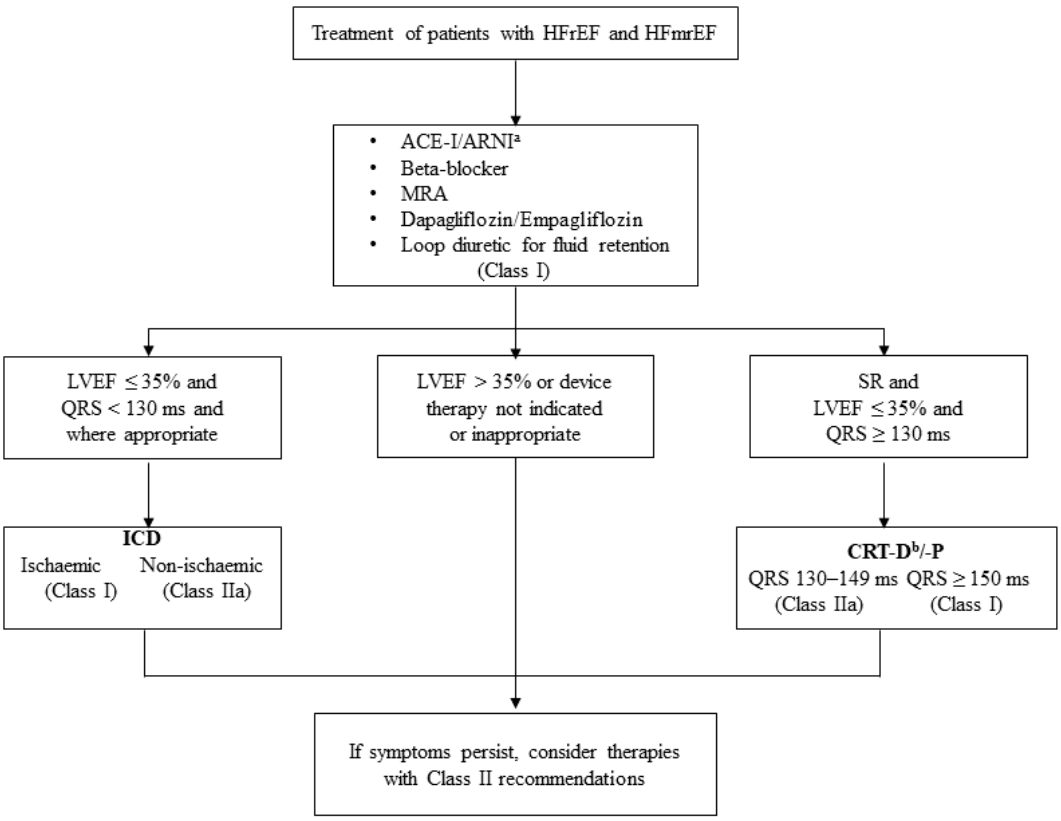
[j]LFT: liver function test.

[k]PET: positron emission tomography.

Treatment of HF

A modified treatment algorithm adopted from the 2021 European Society of Cardiology Guidelines for treating acute and chronic HF (Figure 4) will be used in the treatment of patients [19].

Figure 4. Modified treatment algorithm for treating HFrEF and HFmrEF. a: a replacement for ACE-I/ARB (angiotensin receptor blocker); ACE-I: angiotensin-converting enzyme inhibitor; ARNI: angiotensin receptor-neprilysin inhibitor; CRT-D: cardiac resynchronisation therapy with a defibrillator; CRT-P: cardiac resynchronisation therapy pacemaker; HFmrEF: heart failure with mildly reduced ejection fraction; HFrEF: heart failure with reduced ejection fraction; ICD: implantable cardioverter-defibrillator; MRA: mineralocorticoid receptor antagonist; ms: milliseconds; SR: sinus rhythm.



Data Handling and Analysis

The KoboCollect toolbox (v2022.4.4; [30]) will be used to capture data and upload it onto a cloud database that is only accessible to the principal investigator and the data manager. Collated data will be exported into SPSS (*package 2016*; SPSS Inc) for statistical analysis. Tables, bar charts, and pie charts will be used to present the data. For continuous variables, the central tendency and spread measures will be calculated using the mean (SD), and IQR. Categorical variables will be reported as numbers and percentages. Multivariable regression models will be used explore the relationships between variables and rehospitalization and death. We will perform a Kaplan-Meier analysis to estimate the survival and death rate of patients with HF. The Cox regression analysis will determine the relationship between the risk of death in an individual and selected variables and the significance of these variables. Missing values will be handled based on the type and frequency of missing values. A P value <.05 will be considered statistically significant.

Timelines

The table of timelines (Table 2) below summarizes the key activities of the study from the start to the end of the study.

Table 2. Table of timelines.

Ethical Considerations

Ethical approval has been obtained from the Ethical and Institutional Review Boards of Korle-Bu Teaching Hospital (STC/IRB/000150/2022), Cape Coast Teaching Hospital (CCTHERC/EC/2023/019), Tamale Teaching Hospital (TTH/R&D/SR/229), Ho Teaching Hospital (HTH-REC (30) FC_2023), and Komfo Anokye Teaching Hospital (KATH IRB/AP/166/22). All participants will be informed about the study, its objectives, and the data collection methods. Consent will be obtained from participants who agree to be part of the study and are assured of strict confidentiality and anonymity. Participants will also be informed that participation in the study is entirely voluntary, and all the services they receive at the clinic will continue as usual whether they decide to participate or not. A unique study number will be assigned to each participant, and the collected data will be deidentified. Only the assigned unique number will be used on study documents related to participants. Participants will also be informed that they can withdraw from the study at any time they choose without consequences.

Results

This intervention will generate the necessary information on the etiology of HF, clinical presentations, the diagnostic yield of various tools, and management outcomes. In addition, it will build the necessary capacity and support for HF management in Ghana. As of July 30, 2023, the training of the various health workers in all 9 hospitals has been completed. The KATH and the KBTH acted as supervisory sites and supported the training at 4 and 3 sites, respectively. Preliminary analyses will be conducted by the end of the second quarter of 2024, and results are expected to be publicly available by the middle of 2024.

The test-run of the research and registry instruments and modifications have been completed. Medical equipment (echocardiogram machines and NT-proBNP devices) has been calibrated and distributed to all sites.

Discussion

Overview

HF is one of the leading causes of hospital admissions in developing countries and is predicted to experience the most rapid growth worldwide [2,7,31,32]. This prospective study will answer many clinical questions about HF in Ghana. First, this study will address a notable data scarcity in HF care and research in Ghana by establishing a national HF registry, thus creating a vehicle for the accrual of large, comprehensive, and contemporary data encompassing the sociodemographic, clinical profiles, causes of HF, management of HF, and determinants of outcomes such as mortality and hospitalizations of patients with HF in Ghana. In addition, a national HF registry will also

provide a good opportunity to evaluate adherence to current guidelines and response to treatment among patients with HF in Ghana.

Clinical registries play a crucial role in gathering real-world data, essential for developing evidence for best clinical practice, measuring outcomes, providing feedback to clinicians, and enhancing the quality of care [1,33]. HF registries, like the Swedish Heart Failure Registry, have played a significant role in advancing knowledge and improving the management of HF. Established in 2000 and implemented nationwide in Sweden by 2003, this registry has yielded valuable research outcomes that have led to notable improvements in the understanding and care of patients with HF and under-treatment detection [1]. The NAtional TUnisian REgistry of Heart Failure (NATURE-HF) contributed valuable data that have the potential to enhance the treatment and overall prognosis of individuals with HF in North Africa [34]. Valuable data were also derived from the Abeokuta Heart Failure Clinical Registry of patients presenting with acute HF in Abeokuta, Nigeria, including acute HF presenting at a relatively younger age, commoner in men, and associated with severe symptoms [35].

While the acquisition of realistic data will address the data gap, this pragmatic study will provide capacity building for the management of HF by enhancing the skills and knowledge of health care providers in diagnosing and treating HF and making diagnostic equipment, including echocardiography, electrocardiograms, and point-of-care NT-proBNP devices, available to participating hospitals. Furthermore, participating institutions' HFMTs and HF clinics will broaden the prospect for specialist HF care and long-term follow-up in their regions.

Although numerous HF guidelines are available to aid in managing patients with HF, their generalizability presents variable challenges, as these guidelines may not be appropriate for managing HF in countries with limited health care resources [19]. Therefore, we anticipate that this study will serve as a significant milestone in establishing a standardized approach to managing HF in Ghana and the wider SSA region.

The study will address a notable void within Ghana's ever-evolving HF care and research domain. The study will generate novel and indispensable data that will improve HF care, serve as a foundation for teaching, develop locally tailored HF guidelines, and establish HF research programs.

Strengths and Limitations of This Study

This pragmatic, prospective, multicenter study will generate the most extensive contemporary data on HF in Ghana. The study will also enhance the knowledge and skills of health personnel in diagnosing and managing HF. The project is also designed to establish HF clinics and provide diagnostic services as part of routine health care services in participating hospitals. This study will describe associations rather than establish causality owing to its observational design.

Acknowledgments

The authors are grateful to the teams at all 9 centers for their dedication and sacrifice. This heart failure intervention is part of the Ghana Heart Initiative. The Ghana Heart Initiative is implemented through German International Cooperation (GIZ) and funded by Bayer.

Data Availability

The data sets generated and analyzed during this study will be available from the corresponding author on reasonable request following completion of the study and publication of the findings of the study.

Authors' Contributions

Conceptualization and development of study was done by AD and IKO. First draft by FRA. All authors reviewed and approved the final manuscript; FRA, EAA, CK, FA, AD, and IKO.

Conflicts of Interest

None declared.

Protocol

Investigating Rhythmicity in App Usage to Predict Depressive Symptoms: Protocol for Personalized Framework Development and Validation Through a Countrywide Study

Abstract

Background: Understanding a student's depressive symptoms could facilitate significantly more precise diagnosis and treatment. However, few studies have focused on depressive symptom prediction through unobtrusive systems, and these studies are limited by small sample sizes, low performance, and the requirement for higher resources. In addition, research has not explored whether statistically significant rhythms based on different app usage behavioral markers (eg, app usage sessions) exist that could be useful in finding subtle differences to predict with higher accuracy like the models based on rhythms of physiological data.

Objective: The main objective of this study is to explore whether there exist statistically significant rhythms in resource-insensitive app usage behavioral markers and predict depressive symptoms through these marker-based rhythmic features. Another objective of this study is to understand whether there is a potential link between rhythmic features and depressive symptoms.

Methods: Through a countrywide study, we collected 2952 students' raw app usage behavioral data and responses to the 9 depressive symptoms in the 9-item Patient Health Questionnaire (PHQ-9). The behavioral data were retrieved through our developed app, which was previously used in our pilot studies in Bangladesh on different research problems. To explore whether there is a rhythm based on app usage data, we will conduct a zero-amplitude test. In addition, we will develop a cosinor model for each participant to extract rhythmic parameters (eg, acrophase). In addition, to obtain a comprehensive picture of the rhythms, we will explore nonparametric rhythmic features (eg, interdaily stability). Furthermore, we will conduct regression analysis to understand the association of rhythmic features with depressive symptoms. Finally, we will develop a personalized multitask learning (MTL) framework to predict symptoms through rhythmic features.

Results: After applying inclusion criteria (eg, having app usage data of at least 2 days to explore rhythmicity), we kept the data of 2902 (98.31%) students for analysis, with 24.48 million app usage events, and 7 days' app usage of 2849 (98.17%) students. The students are from all 8 divisions of Bangladesh, both public and private universities (19 different universities and 52 different departments). We are analyzing the data and will publish the findings in a peer-reviewed publication.

Conclusions: Having an in-depth understanding of app usage rhythms and their connection with depressive symptoms through a countrywide study can significantly help health care professionals and researchers better understand depressed students and may create possibilities for using app usage–based rhythms for intervention. In addition, the MTL framework based on app usage rhythmic features may more accurately predict depressive symptoms due to the rhythms' capability to find subtle differences.

Background

Need for Identification of Depressive Symptoms

Every 40 seconds, a person commits suicide and there are more than 20 attempts worldwide [1]. Among suicide attempters, major depressive disorder (MDD) is common [2], and people having MDD are at greater risk of suicidality [3]. Despite these facts, there is a significant lack of interventions to mitigate depression, due to which the depression rate is increasing. In fact, it is estimated that depression will rank first as a global burden of disease by 2030 [4]. In addition, due to the COVID-19 pandemic, a significantly higher number of people have MDD [5], and such a negative impact may persist for a prolonged period. In Bangladesh, the depression prevalence is higher than the overall rate in South Asia [6]. Compared to Bangladeshi people of any other professions, the depression rate is higher among university students [7] (eg, 82.4% of students have at least mild depression [8]), which is alarming.

To significantly facilitate early interventions to mitigate depression, there is an urgent need for its early identification [9]. A person is identified as depressed if symptoms (eg, hopelessness) appear for a period, such as most days for a minimum of 14 days [10,11]. However, it is difficult to precisely assess depressive symptoms [12]. In fact, primary care providers fail to identify depression in more than 50% of cases [13,14]. Understanding the depressive symptoms, such as those in the 9-item Patient Health Questionnaire (PHQ-9) [15], of a person in real time can significantly facilitate mental health care professionals to understand the illness more precisely, to identify depression early, and to take steps accordingly for intervention.

Pervasive Health Research in Low- and Middle-Income Countries

Although over 80% of the burden of depression is found in low- and middle-income countries (LMICs) [16], there remains a severe scarcity of mental health care professionals in LMICs. In Bangladesh, there are only 565 psychologists [6], although the population is over 165 million [17], with 1.234 million university students [18]. In these cases, a pervasive technology, such as a smartphone-based monitoring system, which is available to a large number of people in LMICs, can play a significant role [19] In addition, to minimize the barriers to health care facilities in low-resource settings, artificial intelligence (AI)–based mobile apps can be useful [20]. However, almost all the studies that have demonstrated a pervasive technology–based automated system to identify depression have been conducted in the context of high-income countries. For instance, all the studies included in a recent systematic review were from countries other than LMICs [21], which indicates how little pervasive health research has been conducted in the context of LMICs. As a result, the models developed based on participants from high-income countries may not be applicable in LMICs, since the behavior (eg, app usage [22]) varies among countries and various factors, such as socioeconomic status [23] and culture [22], impact behavior.

App Usage Rhythm That May Resemble Biobehavioral Rhythm

Zeitgebers, social and environmental cues, help a person's rhythms synchronize well [24], which can impact their daily activities. Rhythms based on pervasive device–sensed physiological data change depending on external cues, such as light exposure, eating time, and physical activity [24]. Similarly, smartphone usage behavior is linked with factors such as eating behavior [25]. In addition, there is a relation of app usage with alertness, chronotype [26], and physiological data, such as sleep [26-28]. Like physiological data, app usage behavioral markers vary depending on the hour of the day [29-31] and exercise [28]. These facts show app usage behavior may also have a rhythmic pattern with reproducible waveforms similar to the rhythms based on physiological data.

Although a recent study extracted parametric rhythmic feature–dominant periods from smartphone usage data [32], the study was limited by not exploring rhythmic features, such as the acrophase, interdaily stability (IS), intradaily variability (IV), and relative amplitude (RA). In addition, the study explored mere screen usage, without any exploration of more informative features [33], such as entropy data–based features. In the case of other previous app usage data–based studies, researchers used descriptive statistical methods [29-31] to determine whether there is any variation over the day and inferential statistical methods [34,35] to find the difference in terms of aggregated data of the 4 time periods, namely morning, afternoon, evening, and night. These approaches have some limitations. First, there is a lack of statistical evidence to show whether there exists any rhythm that could be resolved with the zero-amplitude test [36,37], which is used to detect rhythm in the field of chronobiology. In addition, the mere analysis in presenting the difference between the aggregated data of morning and evening cannot show whether there is a cycle that can repeat over days. The average data may also miss the microscopic view of data [38]. However, an analysis fitting mathematical models (eg, cosinor model) to time series data can present a microscopic view of the data and inferential statistical estimates of the rhythmic properties [38]. In addition, many informative behavioral markers, such as the dominant period, stability in behavior, and the peak time of oscillations in the rhythm, cannot be extracted from just finding the differences between periods (eg, morning vs night).

Potential of App Usage–Based Rhythms in Identifying Depressive Symptoms in LMICs

In human life, physiological changes reappear in a cyclable waveform [38]. Rhythm features based on physiological data have been explored in both the chronobiology [39] and pervasive health [32] areas. Researchers have found a relation between physiological data–based rhythmic markers and health status [32]. These markers can find out subtle differences that enable marker-based features to predict hospital readmission [40] and to identify loneliness and the depression class [32]. This shows the possibility of improving the performance of the models upon the incorporation of app usage rhythmic features to predict the symptoms of depression. However, previous studies [32,40] have mostly relied on wearables to extract rhythmic features,

which are costly and may not be affordable [41] for people with a low income. In contrast, smartphones are economically attainable [42], and app usage data are resource insensitive [33]. As a result, app usage data–based systems may be feasible in LMICs.

Predicting Depression and Depressive Symptoms Through an Unobtrusive Method

Classification of the Depressed and Nondepressed

Most existing research based on AI for mental health has worked on classification problems [43]. Researchers have classified depressed and nondepressed individuals by developing personalized models [44] and using contextually filtered features where the rule mining technique was incorporated [45]. Some other studies (eg, [46,47]) have relied on sensing data (eg, GPS data), along with smartphone data call history, to predict depression. Researchers have also leveraged internet usage data [48], location data retrieved through the campus WiFi infrastructure [49,50], and the GPS [50-52]. Recently, some researchers focused on exploring rhythmic features to assess depression. For instance, Yan et al [32] leveraged rhythm-based features to classify depressed and nondepressed participants. However, the classification does not provide precise information about a participant's depressive status, since scores of all the symptoms are aggregated to keep the participant in a particular group (eg, depressed or moderate depression), resulting in a loss of the complexity of the psychological problem of depression.

Predicting Depression Scores

Compared to classification research problems, there is relatively less research on predicting the depression score (eg, PHQ-9 score=11). Studies in the pervasive health area can be broadly categorized into those that have developed models leveraging data based on both smartphones and wearables [53-56]; only smartphones [53,55]; various sensing devices, along with social media [57]; and subjective and smartphone data [58]. There remain mixed findings on whether the smartphone has superior performance than the wearable. Smartphone-sensed data showed higher performance in a previous study [55] when models were evaluated after splitting training and testing data based on time. However, in the same study [55], researchers found smartphones have inferior performance on another evaluation criterion. Regardless of superiority, both wearables and smartphones show promising performance in the automated assessment of depression [53], which can play a role in real-time remote monitoring of depressed individuals [59]. Wearable- and smartphone-sensed behavioral markers, such as call duration [58] and heart rate [60], as well as inferred markers, such as the circadian rhythm [60], have a significant correlation with the depression score, which may explain the fact of enabling the sensed data to predict depression. However, like the classification, in the prediction of depression scores also, there remains the inability to precisely understand depressive symptoms since a person's depression score (eg, 11) can be found in combination with different frequencies of the appearance of different symptoms.

Predicting Symptoms and Multitask Learning

Researchers have conducted a network analysis of depressive symptoms and presented a possible viable target for intervention [61] and central symptoms for possible focused treatments [62]. The relation of ecological momentary assessment of depressive symptoms with the PHQ-9 score [63] and the relation of depressive symptoms with behavioral data [64] have also been investigated in previous studies. Exploring pervasive device–sensed data, researchers have found a link of higher spending duration in students with higher fatigue, which is a depressive symptom [64]. Although there are studies predicting symptoms of other psychological problems, such as schizophrenia [65] and attention-deficit/hyperactivity disorder (ADHD) [66], few studies [67] have predicted the appearance of depressive symptoms. In a previous study [67], authors predicted depressive symptoms through the data of iPhone users and Android users. However, their study has several limitations. First, their models' performance is low in the case of the maximum depressive symptoms; particularly, the specificity score is around 60% or below 60% in many models developed by leveraging smartphone data. Second, they developed a separate model to predict each symptom, which makes the model resource sensitive. Third, they considered each symptom-predicting task as a separate one, which could be improved by leveraging the shareable information among symptoms through the multitask learning (MTL) framework as MTL has superior performance than the single-task learning (STL) technique [53,65]. However, researchers have grouped all the predicting tasks into a single model in previous studies [53,65], which may lower performance since all tasks do not help each other to improve performance [68].

Objective

To overcome the above-mentioned limitations, the main objective of this study is to explore app usage data–based rhythmicity detection and develop and validate an MTL framework leveraging app usage data–based parametric and nonparametric rhythmic parameters through a countrywide study in Bangladesh. Another objective of this study is to explore whether app usage rhythmic features are related to depressive symptoms.

Methods

Ethical Considerations

Our study was approved (reference: 2022/OR-NSU/IRB/0704) by the North South University Institutional Review Board/Ethics Review Committee. While collecting data, we presented the consent form in short in Bangla (native language) and English (Figure 1a), where we provided a summary of the data that we collected. In addition, we provided a consent form in detail (Figure 1b) about different matters, including data safety, privacy, and each data item that we collected. Furthermore, before data collection, we briefly described the research to the participants. All participants provided their consent. After collecting data, we provided an incentive of food tokens equivalent to around US $0.30 to almost all participants. For certain participants (<5%) where it was not feasible to give food

tokens, we provided an equivalent gift in other forms (e.g., by book diary).

All participants' data are stored in the Google Firebase database, which only 1 of the researchers can access with 2-factor authentication. We did not collect any personal information from the participants, such as name, email, and phone number. In addition, we did not collect the names of the participants' departments and universities so that they would feel more comfortable in providing data. We reported the number of departments and universities based on our aggregated notes.

Retrieval of App Usage Behavioral Markers

In this study, we will focus on developing our system in such a way that the users of the system and also health care professionals can be informed about depressive symptoms in real time. For instance, a health care professional, with the user's consent to access information, can be notified if our system's automatic prediction in a day shows that the depressive symptoms can worsen. For this research, we used our previously developed app [69], which can retrieve each participant's past 7 days' foreground and background app usage event data within 1 second once the participant provides consent. The average time required to retrieve app usage events is 307.94 milliseconds (SD 1.1 seconds) [33]. For each app usage event, there are data on the app name, package name, and timestamp of the event, which we will use to extract behavioral markers. The app (Figure 1) was used in our previous studies to explore different research problems, including students' academic results [70-72], depression [33-35,73], and loneliness [74,75], showing the app's reliability and validity.

Sample Size Determination and Data Collection

In Bangladesh, there are around 1.234 million university students [18], and an optimal sample that represents the behavior of this population with a 95% CI and a 5% margin of error is 385 university students, as we found with SurveyMonkey [76], which uses the formula for the finite sample size [77]. Using the same formula, we found that the required sample size to represent the 0.448 million female and 0.786 million male student groups each is 384 [18]. Since the depression rate differs between students of public and private universities in Bangladesh [78], we collected data from both types of universities. In the 0.329 million and 0.902 million students of public and private universities, respectively [18], we found that the required sample size in each case is 384. However, there is no fixed sample size that can ensure the generalizable performance of machine learning (ML) models. Therefore, to develop an impactful model, we tried to maximize the number of participants by conducting a countrywide study. In addition, we tried to maximize the number of students from public universities because the largest number of students study there [18].

We collected data from all 8 divisions of Bangladesh using the multistage convenient sampling method. From each division, we collected data from at least 1 university and multiple departments. We tried to maximize the diversity among the participants because the socioeconomic status and many other demographic characteristics vary by region of a country, which can have an impact on mental health [78] and smartphone usage behavior [79,80].

We collected data from a total of 2952 participants from September 2022 to March 2023. While collecting data, first, through our app [69], the participants responded to questions about demographic characteristics (eg, gender) after providing consent. Next, using the same app, they responded to the items of the PHQ-9 [15] based on their experiences of the past 14 days. After saving the responses to all psychological questions, the app automatically retrieved their app usage data, which may take less than 1 second in almost all cases, as shown in our

previous estimation [33]. After retrieval, the app saved the app usage data instantly.

Data Preprocessing and Data Set Description

Our app could not retrieve any app usage data from 14 (0.47%) participants' phones. One of the plausible reasons for this problem could be system problems in the phones, as shared by the participants. Several of these participants shared that they do not use the original version of the phones. In addition, for 2 (0.07%) participants, age values were missing, and we did not impute these values, as age information was not required for the primary purpose of the research. Furthermore, data on 82 (2.77%) participants' professions were missing. We imputed the missing professions based on 2 pieces of information: First, in our study, only 2 (0.07%) participants were not students, and we did not reach out to them for data collection; they provided data by installing the app from Google Play Store, which was based on their own interests, indicating a low probability of having a profession other than "student." Second, all 82 (2.77%) participants provided data when we reached the universities for data collection, as we found by matching the study dates and timestamps of when these participants provided data. Thus, we imputed these 82 participants' profession as "student."

Although the participants were required to provide data at least once, we encouraged them to provide data as many times as possible. After excluding the 14 (0.47%) participants for whom our app could not collect any app usage events and the 2 (0.07%) participants who were not students, 2936 (99.46%) participants remained. Of them, 71 (2.42%) provided data at least twice. However, since there were few participants who provided data twice, in this study, we kept only the first time–provided data for the next steps of the analysis.

Since in this study, we will estimate the circadian rhythm, we followed previous studies to find out the minimum number of days required to estimate the circadian rhythm. Studies have suggested to have data of at least 1 day for estimating the circadian rhythm [81]. However, sensed data of 2 days can estimate the circadian rhythm sufficiently [82]. Researchers have also found that rhythmic features extracted based on the data of 2 days can predict more accurately physiological and mental changes [65]. Therefore, inspired by these previous studies, we excluded 34 (1.15%) participants who had app usage data of less than 2 days.

Finally, after excluding 2 nonstudents, 14 students without any app usage data, and 34 students having app usage data of less than 2 days, we were left with 2902 (98.31%) students' app usage data (Figure 2), which will be analyzed in the next steps. In total, there are 24.48 million foreground and background app usage events of 24.84 million minutes. Of the 2902 participants, 2849 (98.17%) have app usage data of 7 days (Figure 3).

Figure 2. STROBE (Strengthening the Reporting of Observational studies in Epidemiology) flowchart.

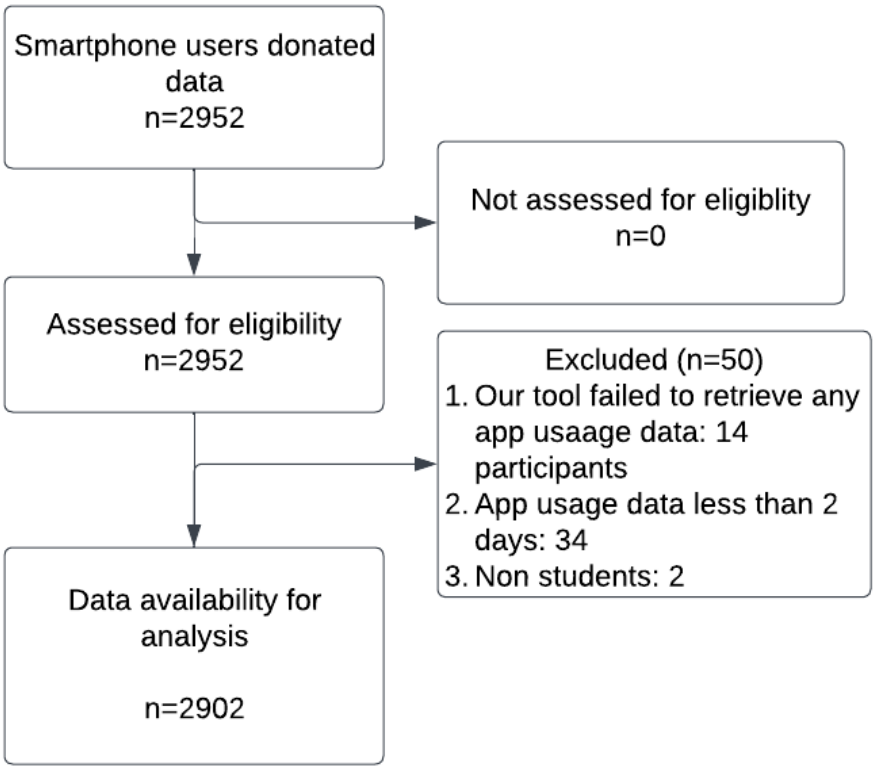

Figure 3. Number of days' data that each participant has for the final analysis. P: participant.

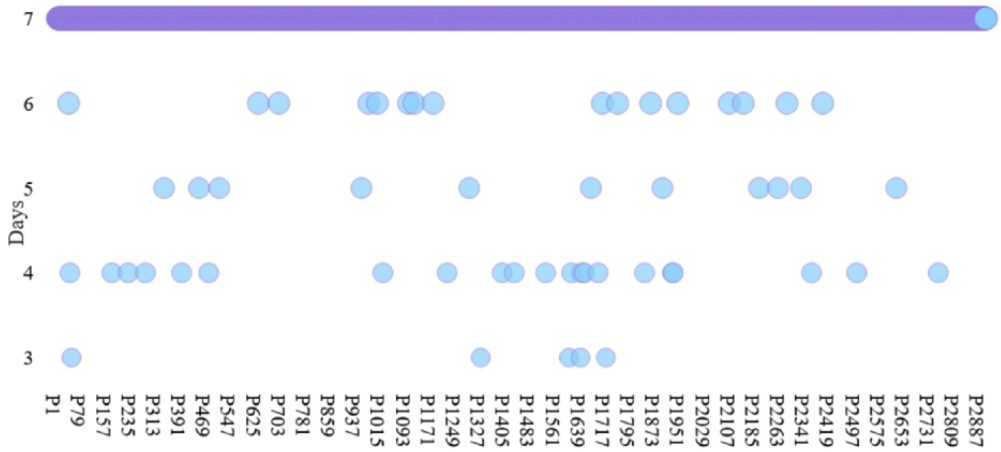

Ground Truth Data to Measure Depressive Symptoms

We used the PHQ-9 (Table 1) [15], which is one of the most commonly used scales to assess depression [21]. In our study, we used the PHQ-9 translated into Bengali [83], which has been validated and is largely used in Bangladesh (eg, [8,78]). The PHQ-9 score of 10 has a sensitivity and specificity of 88% in identifying MDD [15]. Based on this cutoff score, we will categorize the participants as depressed if the PHQ-9 score is at least 10.

In a previous study [67], a person was categorized as having a depressive symptom if that symptom appeared for several days or more. However, we will consider the threshold more than half of the days since the National Institute of Mental Health (NIMH) and the World Health Organization (WHO) define a person as depressed if symptoms appear for a specific time frame, such as most days for a minimum of 14 days [10,11]. In this study, if a participant reports being bothered by a depressive symptom (eg, hopelessness) in the PHQ-9 for more than half of the days or nearly every day of the past 14 days, we will categorize that participant as having that depressive symptom.

Table 1. Depressive symptom for each item of the PHQ-9[a].

Symptom number	Symptom in the PHQ-9
1	Little interest or pleasure in doing things
2	Feeling down, depressed, or hopeless
3	Trouble falling or staying asleep or sleeping too much
4	Feeling tired or having little energy
5	Poor appetite or overeating
6	Feeling bad about yourself or that you are a failure or have let yourself or your family down
7	Trouble concentrating on things, such as reading the newspaper or watching television
8	Moving or speaking so slowly that other people could have noticed or the opposite—being so fidgety or restless that you have been moving around a lot more than usual
9	Thoughts that you would be better off dead or of hurting yourself in some way

[a]PHQ-9: 9-item Patient Health Questionnaire.

Extraction of Behavioral Markers

As we will test the rhythmicity where the time series data are used [36] and explore the rhythmicity of the app usage behavioral markers instead of exploring raw foreground and background app usage events, we will set a time frame of 15 minutes based on which each app usage behavioral marker will be extracted. However, to check the robustness of the findings, we will follow the same process to explore rhythmicity using 2 other time frames as well: 10 minutes and 20 minutes.

In addition to calculating the usage duration, frequency of launching apps, entropy based on duration and entropy based on frequency of launching apps, and app usage sessions [33], we will calculate the following behavioral markers based on which we will extract parametric and nonparametric rhythmic features: relative importance of app categories, personalized top n apps, and cousage of apps.

Relative Importance of App Categories

In pervasive health research, aggregated app usage data (eg, [44-46]) are widely used, where the individual app categories remain unexplored. In our previous studies [33,74], we found that app category–based features are more important than aggregated smartphone usage regardless of category. However, in those studies, features of an app category were extracted independently regardless of the usage behavior of other categories. As a result, the individual category itself may not

provide higher information for the app categories that are less used but contain distinguishable markers. For instance, if a participant launches social media apps 100 times and health and fitness apps only 10 times, data from the health and fitness category may get lower importance. However, data from the health and fitness category can be more important since depressed students use apps that contain features for smoking prevention and body weight reduction, which may not be used more frequently but may contain enough information to be significantly different from those used by nondepressed students [34]. Hence, we will calculate the term frequency–inverse document frequency (TF-IDF), which is a widely used technique in natural language processing [84] where less frequent terms across documents can get more importance. To adapt TF-IDF in the context of app usage, we will use data from all time frames over all days. In each time frame f, the app usage sessions s will work as the set of documents, and in each session (ie, a document) j, the list of categories of the used apps will act as the words.

Let the set of documents of participant i in f be $\{D_{ij}, D_{ij+1}, \ldots D_{is}\}$, where , and n represents the number of participants. We will calculate TF-IDF_{icj} for each app category c based on the participant's data of sessions s.

$$\text{TF-IDF}_{icj} = \text{TF}_{icj} \times \text{IDF}_{icj},$$

where $\text{TF}_{icj} = \log[\text{freq}(c) + 1]$, $\text{IDF}_{icj} =$, freq(c) is the number of times app c was launched in session j, df is the number of sessions where c was used, and s represents the total number of sessions in f. After calculating TF-IDF_{icj} for each session, the mean TF-IDF value will be calculated for each category over the sessions of a time frame. Finally, using that mean value, we will extract the rhythmic features to understand how the relative importance of participant i in using a particular category c varied or remained constant over days and over the periods of a day and whether there was a rhythm in behavioral markers based on the TF-IDF.

To categorize the apps, we will follow relevant previous studies (eg, [30]) and the process in our previous studies [33-35,70,74], where we categorized the apps into more than 20 categories after exploring developers' referred categories in Google Play Store and other app stores and discussing with graduate students of the computer science and engineering (CSE) department.

Personalized Top n Apps

We will calculate entropy based on the usage duration and the frequency of launching the top n apps, which can vary by student. To find the value of n, we will use the probability distribution and plot the probability of using apps on the y axis and the number of apps on the x axis. The point where the curve falls will be considered the threshold (ie, the value of n) to find the top n apps. To find the cutoff value, we will follow a previous study [46] that found cutoff values to exclude the participants having missing values.

Cousage of Apps

A significant portion of app usage consists of switching from one app to another [29]. One plausible reason for such behavior can be changing moods during app usage [85], and the users may do it to seek support, overcome negative emotions, etc. To quantify how participants switch from one app to another, we will calculate the cousage of apps, where the usage of 2 apps will be considered coapp usage if they are used in a single app usage session and also used consecutively. However, in a smartphone, there are many system apps that open automatically to support the function of another app. Users do not need to use those apps intentionally, and as a result, the inclusion of those apps may misrepresent behavior. In addition, to switch from one app to another, the user returns to the home screen of the smartphone, where the launcher app opens automatically. Considering the aforementioned issues, we will exclude these system apps and launcher apps before quantifying the coapp usage.

To find subtle differences in the variation in app usage patterns, we will build a network based on cousage, where each edge will present the cousage of 2 different apps. The weight of the edge will be calculated using point mutual information (PMI).

where $p(A_1, A_2)$ represents the probability of A_1 and A_2 apps to consecutively appear in the same app usage session and $p(A_1)$ and $p(A_2)$ represent the probability of A_1 and A_2 apps, respectively, to appear in that session regardless of consecutiveness. Next, we will calculate the centrality and graph edit distance. The calculation of centrality will help us understand the most influential app in the network that is connected to the maximum number of nodes. The graph edit distance between 2 different sessions of the same time frame will inform whether the behavior differs. Finally, we will use the average data of each session of a time frame to explore the rhythmicity of the centrality and graph edit distance.

Rhythm Analysis and Extraction of Rhythmic Features

The parametric cosinor method is one of the most widely used approaches to find out rhythmic parameters. However, cosinor analysis cannot find out the fragmentation in the rest-activity rhythm [86], which can be detected by extracting nonparametric rhythmic parameters, such as the IS. Therefore, to obtain a comprehensive picture of rhythms, we will conduct both parametric and nonparametric tests and extract the respective rhythmic features, as described later. In this study, to extract rhythms, instead of focusing only on all students' data-based global models, we will also develop individual models and extract the rhythmic parameters for each participant. The main reason is that physiological data–based nonparametric rhythmic [87,88] and parametric rhythmic [89] parameters vary by the characteristics of people, and thus, there may also be a variation in parameters by the individual participant's rhythm that is solely based on app usage data.

Dominant Period

In cosinor analysis, a cosine curve is fitted on the given period (eg, 24 hours) using the least squares method, where the model reduces the difference between observed and estimated values. However, cosinor analysis itself cannot estimate the best-fitting period [90]. Thus, we will empirically investigate through

periodogram analysis and by setting the periods from 1 to 24. Later, the cosinor model will be developed for each given period (eg, 13 hours). The best-fitting period will be counted as the dominant period where the proportion of explained variance is the maximum.

Rhythm Detection

Cosinor analysis is a parametric method, and hence, we will first test normality [91]. Later, we will process the nonnormally distributed data through log transformation. Next, to find out whether a statistically significant rhythm of a participant exists, we will conduct a zero-amplitude test [36] by setting the significance level to .05. To find out whether an individual participant's rhythm differs from the rhythm based on all participants, we will perform population mean cosinor analysis based on all the participants. In addition, we will develop a cosinor model for each participant and then calculate the average of the cosinor rhythmic parameters [90].

MESOR, Amplitude, and Acrophase

After developing the cosinor model, we will extract the following parametric rhythmic parameters for each participant: midline estimating statistic of rhythm (MESOR), amplitude, and acrophase. MESOR is the rhythm-adjusted mean [36], the amplitude presents the difference between the equilibrium position and the peak point of the rhythm oscillation [92], and the acrophase presents the timing of the high values recurring in each cycle of the rhythm [36]. Since the amplitude can present the strength of the rhythm [93], while comparing the diurnal (12-hour period) and circadian (24-hour period) rhythms to determine which rhythm has more strength, we will compare the amplitude. Moreover, we will compare the coefficient of determination as it presents how well a model fits in a given period.

Interdaily Stability and Intradaily Variability

A person's mental state has a relation with the IS and the IV. For example, patients with bipolar disorder have less IS and higher IV [94]. Similar patterns may be found in the IS and the IV based on app usage data, and we will calculate the IS and the IV, based on a previous study [86] on actimetry.

Here, x_i is the behavioral marker's value at a specific time frame, x_m is the mean value of the same behavioral marker in all time frames, and N is the number of time frames.

Here, x_i is the behavioral marker's average value in that time frame over days and p is the number of time frames per day. The range of the IV value is 0-2 and that of the IS value is 0-1 [95]. The higher the IS, the greater the stability, as the name implies. However, the higher the IV, the higher the fragmentation in the rhythm. If a difference remains, for example, if someone sleeps during the daytime and keeps waking up at nighttime, their IV will be higher [86].

M10, L5, and Relative Amplitude

M10 presents the mean value of the most active consecutive 10 hours and provides information about the diurnal activity. Active persons have a higher M10 [86], and a lower M10 can be associated with exercise reduction [86] and also with a negative mental state [86,96]. L5 presents the mean value of the least active 5 consecutive hours of the day. It is a measure of nocturnal activity, and the higher L5 may represent activity during the rest cycle [86]. After calculating M10 and L5, we will calculate the RA = (M10 – L5)/(M10 + L5). As can be understood from the formula of RA, the RA is actually the normalized difference between M10 and L5. The larger the difference between L5 and M10, the larger the RA. People with psychological problems can have a lower RA [65,86].

Statistical Analysis

To explore whether there is any relation between depressive symptoms and app usage rhythmic features, we will perform binomial logistic regression. As having a variance inflation factor (VIF) of more than 5 can create a biased regression model [97], we will eliminate the variable if the VIF of any variable goes beyond 5.

ML Model Development

Participant Similarity and Development of Personalized Models

Most of the existing models (eg, [33,45,46,74]) to predict depression use training data to predict the outcome regardless of the characteristics of the participant whose class will be predicted. These models may have issues regarding generalizability since all individuals have unique characteristics that may not be captured in one-size-fits-all models (ie, 1 set of training data to predict the depression of all test participants). Indeed, through empirical investigation, it has been found that the personalized model performs better than the one-size-fits-all model [98,99]. The one-size-fits-all or global model is likely to capture the general or the "average" characteristics of the participants for the prediction due to which the model may perform well only on the "average" participants and may not work in the case of the participants whose behavior deviates from the "average" participants [100]. However, the personalized model is trained dynamically for each participant, which can facilitate finding the most relevant set of features to predict the outcome of the test participant [98]. Therefore, a personalized model may perform better in predicting depressive symptoms since each of the depressed students has a unique app usage signature [34] and depressed students have statistically significantly different smartphone usage behaviors than nondepressed students [35], as we found in our previous studies [34,35].

In our app to predict depressive symptoms, we will use each participant i's rhythmic parameters based on each of the app usage behavioral markers of m_i to calculate the cosine similarity with all other participants n – 1.

Here, B_i and B_j represent the vectors based on the rhythmic parameter sets m_i and m_j of participants i and j, respectively. The cosine similarity s_{ij} will be close to 1 when there is a higher similarity between participants i and j. After finding the similarities between participant i and all other participants, we will use the most similar N participants to train the MTL framework for participant i. The value of N will be decided empirically through a search on the values 200, 250, 300, and 350.

MTL Framework Development and Validation

Although some similar tasks remain, the development of the model through the MTL framework can facilitate improving the performance of the models through information sharing. In addition, if different models are developed for different tasks, then the system can be resource inefficient. In a previous study [65], researchers used MTL to develop systems for predicting the symptoms of schizophrenia. However, in that system, all symptom prediction tasks were considered the same. In reality, all the tasks included in a model do not help one another improve performance [68]. Therefore, we will find the similarities among the symptoms and use similar symptom prediction tasks in a model, while other similar symptom prediction tasks will be in another model. To group the tasks, we will calculate the correlation coefficients among the symptoms. Symptoms that are highly (coefficients>0.7), moderately (0.4≤coefficients≤0.7) [101], and less than moderately correlated or not correlated will be kept in 3 different groups.

While developing the MTL framework, we will use the hard parameter-sharing technique since in this approach, the model can find a common representation to capture all the tasks that can reduce the potential risk of overfitting [102]. Combining multiple loss functions leads to promising performances [103]. In our study, we will use a weighted loss of the hinge and cross-entropy. However, we will not use a fixed weight. Instead, we will tune the weight using the Bayesian search optimization technique, which selects the next parameter based on the performance of the previously selected one.

To validate the framework, we will use the nested cross-validation (CV) method since this approach is found to have a generalizable performance compared to K-fold CV [104]. In the outer loop, we will use the leave-one-out cross-validation (LOOCV) method, and in the inner loop, we will use a 10-fold CV, where in each interaction, 9 folds will be used for tuning the hyperparameters and the remaining 1 fold will be used for validation. We are aware of the fact using the LOOCV will increase the time complexity since there are 2902 participants and we will be developing a personalized model for each of them. However, we chose to use the LOOCV because it will work like the real-world scenario, where the model will predict a single participant's depressive symptoms at a time. In addition, this process will help in personalizing the model, where we will use only those participants in model training who are similar (in terms of app usage behavior without using any information about depressive symptoms) to the student for whom the model will predict the symptoms, as discussed in detail in the *Participant Similarity and Development of Personalized Models* section. During model development, we will maximize the balanced accuracy as it is based on sensitivity and specificity, and having a higher balanced accuracy can lead to higher precision and F_1-score values.

To understand the robustness of the proposed MTL framework, we will compare it with the performance in the following approaches:

- Comparison with STL-based models: We will compare the performance of the proposed personalized MTL framework with that of STL models. This will resemble the approach presented in a previous study [67], where each symptom was considered a single task. To develop the STL model, we will use ML algorithms, such as the random forest (RF), support vector machine (SVM), decision tree (DT) [105], and logistic regression [106], which are widely used in medical informatics, as shown in systematic reviews [105,106].
- Comparison with the nonpersonalized MTL framework: Since we expect that personalization may provide better performance, as discussed in the *MTL Framework Development and Validation* section, we will compare the performance of the personalized MTL framework with that of a nonpersonalized MTL framework, where we will use n – 1 participants' data for training instead of using a personalized subset of data.
- Comparison with the MTL framework without grouping tasks: To understand how grouping tasks based on similarity impact performance, we will compare the performance of the MTL framework with and without grouping tasks.

Results

As mentioned earlier, after applying inclusion criteria, we kept the data of 2902 (98.31%) of 2952 students for analysis, with the data of 24.48 million app usage events, and 7 days' app usage of 2849 (98.17%) students.

Figure 4 shows the findings regarding participants' demographic characteristics. The participants were from the 8 divisions of Bangladesh (Figure 4a). Most participants (n=887, 30.56%) were from the Dhaka division, which also reflects the fact that the majority of university students of Bangladesh reside in this division. The participants' age varied from 18 to 39 years, and 2309 (79.57%) participants were aged 20-23 years (Figure 4b). Of the 2902 participants, 1107 (38.15%) and 1783 (61.44%) were female and male participants, respectively (Figure 4c). There were 2430 (83.74%) and 472 (16.26%) students from public and private universities, respectively. The participants belonged to 19 universities (Figure 4d), including specialized universities, studying the following subjects: agriculture, engineering, and textiles. They also belonged to 52 different departments, including arts (eg, Department of Sculpture), business (eg, Department of Management Studies), engineering (eg, Department of Petroleum & Mining Engineering), science (eg, Department of Botany), textiles (eg, Department of Apparel Engineering), public health, and law faculties.

In the remaining part of the study, we will work on rhythm detection, rhythmic feature extraction, and MTL framework development. We expect to publish our findings by June 2024.

Discussion

Significance

By using the data set constructed through a countrywide study on 2902 students having over 24 million app usage events, we will explore whether there is a statistically significant rhythm based on the different app usage behavioral markers. We hypothesize that app usage behavioral markers, such as the relative importance of an app category, have rhythmic patterns with reproducible waveforms because, like physiological data, the markers vary depending on factors such as the time of day [29-31]. In addition, since rhythmic features based on physiological [39,107] and activity [108] data have potential applications in problems such as determining which participants have a higher risk of disease [107], determining sedentary behavior [39], and finding subtle changes in detecting COVID-19 [107], an in-depth exploration of app usage marker–based rhythms may show an alternative source of data to understand the rhythms in human life. App usage marker–based rhythms have the possibility to be used for different purposes. For example, a statistically significant relation between the rhythmicity of app usage and depressive symptoms can create the possibility of using these rhythmic features for an intervention to mitigate depression.
